Dysthyroidism and Chronic Heart Failure: Pathophysiological Mechanisms and Therapeutic Approaches

Caterina Rizzo, Margherita Ilaria Gioia, Giuseppe Parisi, Vincenzo Triggiani, and Massimo Iacoviello

Abstract

Among comorbidity in chronic heart failure (CHF), dysthyroidism represents a relevant problem especially in the ageing CHF patients worldwide. Thyroid greatly affects many cardiovascular activities and its dysfunction may worsen a CHF condition. In particular, hypothyroidism has a relative high prevalence in patients with heart failure and it plays a key role in influencing CHF onset, progression and prognosis. Hyperthyroidism, is less frequent in this clinical context but it necessitates of immediate treatment because of its negative effects on cardiovascular balance. Also, it must be considered that dysthyroism may also be iatrogenic and the main responsible drug is Amiodarone.

Based on the best available evidence and our cumulative clinical experience, this manuscript analyzes the prevalence, the pathophysiology and the prognostic impact of thyroid disorders in chronic heart failure.

Keywords

Chronic heart failure · hypothyroidism · hyperthyroidism · Amiodarone

1 Introduction

Comorbidity and multimorbidity in chronic heart failure (CHF) represent an emerging problem especially in the ageing CHF patients worldwide. In particular the well-known adaptive or maladaptive modifications of the neuroendocrine and the immune system are heavily involved in the pathogenesis as well as in the worsening of CHF, leading to functional and structural modifications of the cardiovascular system (Fiore et al. 2013). In addition, several hormone deficits and comorbid endocrine and metabolic conditions have been described, with a strong

impact on the prognosis of these patients (Arcopinto et al. 2015a). Specifically, thyroid dysfunction (Triggiani and Iacoviello 2013; Triggiani et al. 2016), hypogonadism (Giagulli et al. 2013a, b) GH/IGF1 axis impairment (Arcopinto et al. 2017), diabetes (Dei Cas et al. 2015), especially when associated with depression (Fiore et al. 2015) and obesity (De Pergola et al. 2013) can influence either the development and the progression and prognosis of CFH itself. The therapy of endocrine and metabolic conditions, moreover, can be very challenging in patients with CHF (Triggiani and Iacoviello 2013; Triggiani et al. 2016; Giagulli et al. 2013; Arcopinto et al. 2017; Dei Cas et al. 2015; Fiore et al. 2015; De Pergola et al. 2013; Arcopinto et al. 2015b; Butler et al. 2008).

Thyroid function greatly affects cardiovascular balance, particularly heart rate, systemic vascular resistance, arterial pressure, and cardiac excitability as well as lusitropic properties. Thyroid dysfunction, therefore, may have a negative impact on the symptoms of patients with CHF and it can be associated with a poor prognosis. An early diagnosis and treatment of thyroid disorders, therefore, should be considered of importance to better treat CHF patients and to prevent worsening of the heart failure (Butler and Kalogeropoulos 2008; Jessup et al. 2009; Dalström 2005; Manowitz et al. 1996).

2 Hypothyroidism and Heart Failure

Subclinical hypothyroidism is characterized by a TSH above the normal range with thyroid hormones free fractions still normal, and it can be mild when TSH is between 4.5 and 9.9 mU/L or severe when TSH is $\geq$10 mU/L. It is frequently "asymptomatic", even though many patients actually can develop mild symptoms of thyroid hormone deficiency. Furthermore, these patients can develop an overt hypothyroidism, characterized by a reduction of thyroid hormones, over the time, at a rate of about 2–5% per year (Cooper and Biondi 2012; Cooper 2001; Huber et al. 2002; Turnbridge et al. 1977).

The prevalence of overt hypothyroidism has been estimated to be between 14 and 19/1000 for women and less than 1/1000 for men whereas the prevalence of subclinical hypothyroidism shows higher figures: 75/1000 for women and 28/1000 for men. This percentage increases with age, up to 15–20% more in the ninth decade of life (Vanderpump et al. 1995; Hollowell et al. 2002; Canaris et al. 2000; Ruggeri et al. 2017).

When dealing with elderly people, however, it should be take into account that there is a large body of evidence that TSH distribution curves shift to higher concentrations with increasing age and such a rise in TSH serum concentrations does not reflect a real increase in the prevalence of hypothyroidism with age, but rather a change in age-specific population distribution of TSH. This may be due to an age-associated alteration in TSH set point caused by a diminished sensitivity of the pituitary gland to the negative feedback by thyroid hormones, a decrease in TSH biological activity or in thyroid gland sensitivity to TSH. For these reasons, the use of an age-specific reference range for TSH has been recommended, especially in patients over 70 years, to avoid subjects being misclassified with subclinical hypothyroidism and even inappropriately treated with thyroid hormone with possible consequent negative effects (Klein and Ojamaa 2001).

2.1 Hypothyroidism and Heart Failure: Pathophysiologic Aspects

The reduced production of thyroid hormones results in adverse cardiac effects, represented by reduced contractility with impaired left ventricular systolic function on exercise and impaired ventricular filling (diastolic dysfunction) associated with increased systemic vascular resistance and diastolic hypertension (Klein and Danzi 2007; Biondi and Cooper 2008). In subclinical hypothyroidism, the abnormalities in cardiac function observed are the same but less severe than those showed in the overt form (Dillmann 2002).

Reduction in cardiac contractility and diastolic dysfunction are partly due to changes in heart gene expression. Thyroid hormones, in fact, affect the expression of genes involved in contractile properties and intracellular calcium handling through interaction with Thyroid-Responsive Elements (TREs), thus regulating cardiomyocytes contractility (Dillman 1990; Van Tuyl et al. 2004; Chen et al. 2000). Moreover, chronic hypothyroidism is also characterized by the stimulation of the activity of fibroblasts resulting in myocardial fibrosis (Van Bilsen and Chien 1993), and can lead to loss of small coronary arteries, impaired blood flow, and cardiomyocytes' shape alterations.

The pattern of cardiac gene expression observed in hypothyroid subjects is very similar to that developed in response to hypertension, ischemia, myocardial infarction and valvulopaty, conditions that can cause pathological hypertrophy and CHF (Nakao et al. 1997; Lowes et al. 1997; Feldman et al. 1986).

As a consequence, in HF, the cardiac gene expression is similar to that of subjects affected by hypothyroidism. This genetic pattern of expression is called "fetal gene program recapitulation". This is a typical condition of intrauterine life when placental type 3 deodinase (D3) converts T4 into inactive reverse T3, resulting in a low T3 concentration in fetal blood, a condition that promotes cell proliferation more than cell differentiation. After birth, there is a replacement with a new gene expression program (Gerdes 2015). However, it can be reversed in case of chronic hypothyroidism, in low T3 syndrome, in myocardial hypertrophy and HF, raising the question whether CHF itself may be in part due to a deficit of cardiomyocytes' thyroid hormone receptor stimulation and response, due to the expression of different thyroid receptors isoforms and an increased expression of D3, with impaired genomic and non-genomic signaling (Pantos et al. 2008) and whether hormone replacement therapy could be an effective therapy to improve cardiac function in CHF patients (Brenta et al. 2007; Cappola et al. 2006).

Non-treated hypothyroidism also increases coronary heart disease's risk factors such as LDL and Apolipoprotein B (Christ-Crain et al. 2003; Squizzato et al. 2007). This condition leads to a lower expression of liver receptors for LDL, with a reduction of their clearance. HDL (high density lipoproteins) are normal or often increased due to a lesser CEPT (Cholesteryl ester transfer protein) and liver lipase activity. This causes a reduced transport of cholesterol esters from HDL to VLDL (very low density lipoprotein) and IDL (intermediate low density lipoproteins). In addition, hypothyroidism increases plasma cholesterol oxidation primarily because its capture pattern is altered. In this setting, particular attention should be paid to the subclinical forms, which are often left untreated for a long period (Monzani et al. 2004). A significant increase in mortality for cardiovascular causes, particularly ischemic disease, in patients with subclinical hypothyroidism compared to euthyroid subjects is reported by Iervasi et al. (2007). In fact thyroid hormones play an important role in regulating myocardial morphology, metabolism and cell response to stress, increasing heart tolerance to ischemia, and improving, by inotropic and anti-apoptotic actions, hemodynamics in setting of ischemia-reperfusion.

2.2 Hypothyroidism and Heart Failure: Prognostic Implications

Different studies have evaluated the prognostic impact of thyroid hormone deficiency in patients with CHF. Hamilton et al. demonstrated the role as a marker of the fT3 / reverse T3 ratio in predicting a worse prognosis in terms of death or need for cardiac transplantation, in patients hospitalized for advanced cardiac heart failure (Hamilton et al. 1990).

Pingitore et al. (2005) evaluated the role of low T3 levels in predicting mortality in 281 CHF patients. A multivariate model has highlighted the only two independent predictors of mortality for any cause: the ejection fraction and the total T3 level. In this study a high percentage of patients

showed a low total T3 value (43%). This was probably due to severe systolic insufficiency (20% of patients showed an ejection fraction <20%) associated with a functional status that may have affected T3 levels. Finally, in this study population, the presence of a low percentage of patients receiving ACE inhibitors and beta-blockers may have affected hemodynamics and thyroid function.

The relationship between serum FT3 levels, hemodynamic parameters and prognosis was also evaluated in a small population of patients with dilated cardiomyopathy (Kozdag et al. 2005). In this study, 21% of the subjects had abnormalities in thyroid function tests. The results also showed that the free triiodothyronine (fT3) / free thyroxine (fT4) ratio was significantly correlated with echocardiographic parameters that reflect cardiac remodeling and systolic-diastolic function. In addition, the fT3 / fT4 ratio, considered as a continuous variable and fT3 / fT4 < 1.7, were both associated with an increased risk of mortality, regardless of other prognostic markers. Once again only a small percentage of patients were treated with ACE inhibitors and beta-blockers at the time of enrollment. Low fT3 level was also associated with adverse outcomes in patients hospitalized for Acute Decompensated HF (Okayama et al. 2015).

In an Italian study based on a population of CHF outpatients (93% treated with ACE inhibitors or angiotensin receptor blockers, 88% beta-blockers), in a 15-month of follow-up, it has been proven that in a univariate analysis model, TSH, thyroid hormones and the ratio fT3/fT4 were all associated with the events (cardiac failure exacerbations); however, a multivariate analysis, after correcting for other variables associated with events, showed that only TSH was independently associated with the occurrence of the events (Iacoviello et al. 2008).

Another study by the same authors, involving a larger sample of patients, has confirmed the role of hypothyroidism in CHF outpatients (Triggiani et al. 2012). Patients with pre-diagnosed hypothyroidism, new diagnosis of hypothyroidism at the enrollment and hypothyroidism developed during follow-up showed a higher risk of progression of HF compared to the euthyroid patients. These evidence suggests that in patients with stable CHF, hypothyroidism plays a role in determining worsening of heart failure.

In a pooled analysis of individual participant data performed on 25,390 subjects from six prospective cohorts in the USA and Europe, the risk for acute HF events, hospitalization or death for HF events was higher in the subjects with higher TSH concentration. In particular, the HR was 1.01 for TSH 4.5–6.9 mU/L, 1.65 for TSH 7.0–9.9 mU/L, and 1.86 for TSH 10.0–19.9 mU/L (Gencer et al. 2012).

In a prospective follow up study of a large cohort of 5,599 patients with HF by Chen et al. (2014) a high TSH concentration and a low concentration were both associated with an increased mortality rate in CHF patients, and the mortality in the highest quartile of TSH was 36% higher than that in the second quartile. Moreover, a TSH between 4.5 mU/L and 10.0 mU/L was associated with a 40% higher mortality, whereas a TSH >10.0 mU/L was associated with a more than twofold increase in mortality. In a meta-analysis of 13 studies by Ning et al. (2015) both overt hypothyroidism and subclinical hypothyroidism were associated with increased risk of all-cause mortality, cardiac death and/or hospitalization in patients with HF. In a paper by Hayashi et al., the role of TSH as a marker of worse prognosis and the negative impact of subclinical hypothyroidism were confirmed also in patients admitted for acute decompensated HF: higher TSH, but not free T3 and free T4, was independently associated with composite cardiovascular events, including cardiac death and re-hospitalization for heart failure in these patients. Therefore, subclinical hypothyroidism was an independent predictor, whereas low-T3 syndrome as well as subclinical hyperthyroidism were not (Hayashi et al. 2016).

Figure 1 summarizes the pathophysiological mechanisms through which hypothyroidism can alter the progression of HF.

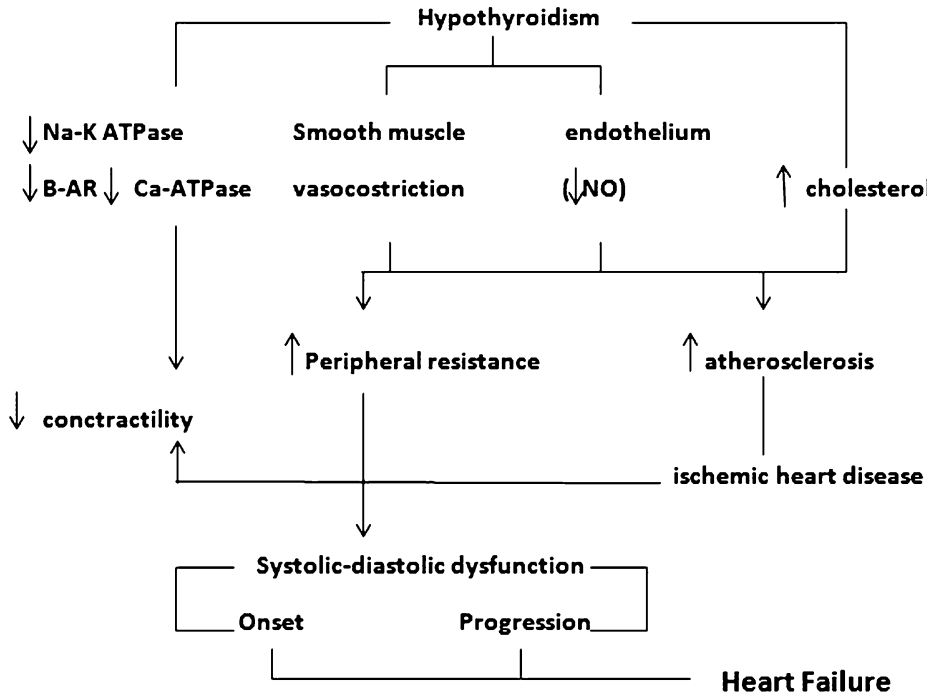

Fig. 1 Hypothyroidism and heart failure: pathophysiological mechanisms
Na-K ATPase: Sodium-potassium pump, Ca2 + −ATPase: calcium pump, β-AR: Beta adrenergic receptor, NO: Nitric oxide
Hypothyroidism causes cardiovascular and metabolic alterations. On the one hand it reduces contractility, due to a decreased activity of the Sodium Potassium ATPase and CA2 + −ATP-ase pump. On the other hand, it increases peripheral resistances by acting on the endothelial and smooth muscle cells causing vasoconstriction. It also determines an increase in serum cholesterol levels, causing possible ischemic disease. All these result in a systolic-diastolic dysfunction that may favor the onset or progression of heart failure

2.3 Hypothyroidism and Heart Failure: Therapeutic Aspects

The treatment of hypothyroidism is based on Levothyroxine (L-T4). The replacement treatment with thyroid hormones allows the control of cardiovascular manifestations of hypothyroidism. Levothyroxine treatment, although increasing myocardial oxygen consumption, because of the inotropic and cronotropic effect, in fact, is also responsible for the reduction of ventricular volume and diastolic pressure, with benefits for patients with HF. The initial dose of levothyroxine is generally 12.5–25 mcg/day, with TSH control at 6–8 weeks and with gradual titration over time, avoiding both too low and too high doses, with a target represented by the normal TSH reference range for the age of the patient, which is: 21–54 years: 0.4–4.2 mIU / L and 55—87 years: 0.58.9 mIU/L (Triggiani and Iacoviello 2013).

While there is no doubt about the need for replacement therapy for overt hypothyroidism, the treatment of subclinical hypothyroidism, especially for TSH values under 10.0 mUI/L still remains controversial, in particular in the elderly (Ruggeri et al. 2017). We are waiting for the full results of the cardiovascular outcomes of the TRUST Study (Thyroid Hormone Therapy for Older Adults with Subclinical Hypothyroidism), (Stott et al. 2017a) in which, preliminary reports, do not find any beneficial effect of Levothyroxine therapy versus placebo in improving symptoms of hypothyroidism, tiredness as well as health-related quality of life,

cognitive and physical performance (Stott et al. 2017b). Moreover, considering the apparent beneficial influence of subclinical hypothyroidism reported by the Leiden 85+ Study in the "oldest old"(Gussekloo et al. 2004) the IEMO 80+ Thyroid Trial (The Institute for Evidence-based Medicine in Old age) will probably shed light on the real utility to treat those patients by means of Levothyroxine (Mooijaart and IEMO 80-Plus Thyroid Trial Collaboration 2014).

3 Low T3 Syndrome ("Euthyroid Sick Syndrome")

"Euthyroid sick syndrome" or "low T3 syndrome" is a condition characterized by an alteration in thyroid profile with typically low circulating T3 levels in the presence of normal TSH, and normal or reduced T4 levels, in patients with cardiac disease and more generally in patients with non-thyroid disease (for example malnutrition, diabetic ketoacidosis, chronic renal failure). The pathophysiologic mechanisms involved have not been fully clarified, but the most acclaimed hypothesis is a reduction in the enzymatic activity of 5′-monodeiodinase, which is responsible for the peripheral conversion of T4 to T3 (Chopra 1997). This syndrome is viewed as an adaptation in the presence of severe systemic pathology, reducing the production of active thyroid hormone T3 and, consequently, lowering energy consumption. It is not therefore a pathological condition. Several cross-sectional case control studies have shown that about 30% of patients with CHF have low T3 levels and T3 in serum decreases proportionately to the severity of heart disease (Pingitore et al. 2005) (Fig. 2).

However, the reduction in serum T3 concentrations levels could alter the cardiovascular system and enhance the progression of heart failure. In fact, cardiac myocytes lack an appreciable deiodinase activity, depending therefore on the plasma T3. Low T3 syndrome, therefore, can be considered at the beginning as a response aiming at reducing proteins and energy loss. This adaptive response, however, when persistent, becomes a maladaptive response, contributing to an unfavorable prognosis in these patients (Triggiani and Iacoviello 2013). In a study of 281 patients hospitalized for CHF, the presence of low T3 values was associated with an increased risk of mortality. In multivariate analysis, the concentration of T3 was the most important independent predictor of mortality, after correction for the conventional prognostic markers (Kozdag et al. 2005). Pingitore et al. (2008) studied the acute effects of substitution therapy with T3 in CHF patients with low T3 syndrome. Twenty clinically stable patients were randomly assigned to synthetic L-T3 or placebo for 3 days. In the first group an increase in serum fT3 concentration was observed reaching a plateau after 24–48 h. No side effects were observed, but a significant improvement in neuro-hormonal status, due to a significant reduction in plasma noradrenaline, NT-proBNP and serum aldosterone levels. Furthermore, a significant increase in systolic output has been observed. Conversely, no significant variations in neuro-hormonal profile and heart rate were observed in placebo-treated patients. The main problem in administering T3 is the need for intravenous administration and its short half-life which is a pharmacokinetic parameter indicating the time required to reduce the bioavailability of a drug by 50%, i.e. the amount of a drug or protein in plasma or serum. Better results could be achieved with the development of new long-term oral formulations to improve the therapeutic profile of this drug.

4 Hyperthyroidism and Heart Failure

The overt form of hyperthyroidism has a prevalence of 0.5–2% in women, ten times greater than that in men (Levey and Klein 1994). The subclinical form seems to be a more frequent condition (Surks et al. 2004). It has a prevalence of 0.5–6.3% in the general population, with the highest figures in the elderly.

The excess of thyroid hormone has important effects on the cardiovascular system (Klein and Danzi 2007). The relative reduction of peripheral

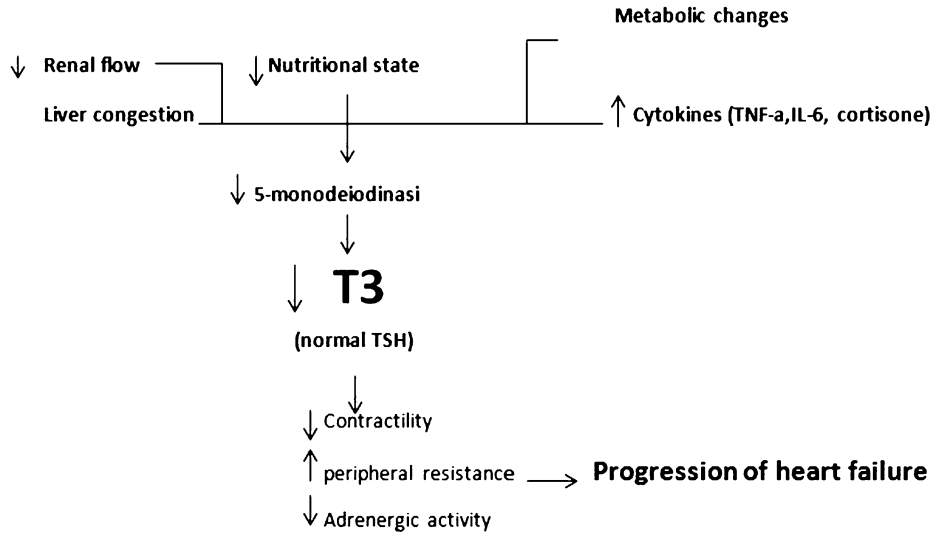

Fig. 2 Low T3 syndrome and progression of heart failure TNF-α: tumor necrosis factor α; IL-6: interleukin-6; T3: triiodothyronine; TSH: thyrotropin
Any condition that reduces the activity of 5′-monodeiodinase leads to a reduction of T4 to T3 conversion, in presence of normal TSH values. This could alter the function of the cardiovascular system (reduced contractility and adrenergic activity, increased peripheral resistance) and enhance the progression of heart failure

resistance and the increase in circulating blood volume and heart rate cause a hyper-dynamic circulatory state (Vanderpump 2005; Biondi et al. 2005). This condition can often lead to symptoms of heart failure. An impairment of left ventricular ejection fraction, however, is rarely observed in hyperthyroidism (Shirani et al. 1993; Umpierrez et al. 1995; Watanabe et al. 1995).

Thyrotoxicosis is characterized by an increase in heart rate, with possible onset of arrhythmias, a selective increase in blood flow to the muscles, skin and heart, vasodilatation with decreased diastolic blood pressure, decreased renal perfusion and subsequent activation of the Renin-angiotensin-aldosterone (RAAS) system, with increased blood volume (Klein and Danzi 2007; Biondi and Cooper 2008). The combination of increased diastolic relaxation and augmented blood volume leads to an increase in preload. Conversely, the increase in myocardial contractility associated with reduced systemic vascular resistance leads to a after-load reduction. This explains the increase in systolic output which, combined with increased heart rate, leads to an increase in cardiac output up to three times the standard (Biondi and Cooper 2008; Watanabe et al. 1995; Kasper et al. 1994; Siu et al. 2007; Kahaly and Dillmann 2005).

The demand for oxygen and energy consumption are both increased at rest with impossibility to increase further and adequately during physical activity (Fazio et al. 2004). These hemodynamic changes are the consequence of thyroid hormone excess that acts both at vascular and cardiac level, increasing the production of Nitric Oxide and directly acting on vascular smooth muscle cells, and increasing the expression of sarcoplasmic reticulum Ca2 + −ATPase and alpha-myosin heavy chain as well as the number of beta1 adrenergic receptor, while reducing the activity and/or expression of phospholamban, sodium/calcium exchanger and beta-myosin heavy chain (Biondi and Cooper 2008; Kasper et al. 1994).

Over time, hyperthyroidism may lead to a myocardial hypertrophy similar to that seen during pregnancy, with an increase in both length and cross section of cardiomyocytes, (Fazio et al.

2004; Biondi et al. 2002) with adverse effects on morphology and cardiac function, increasing the ventricular mass and the left atrial size with impairment of systolic and diastolic function. The most well-known form of heart failure caused by hyperthyroidism is the high output, essentially caused by a high peripheral demand rather than by a pump deficit. However, the onset of CHF may also be related to other factors (Biondi and Cooper 2008). Coronary vasodilatation, already present in resting conditions to increase blood flow to hyperkinetic cardiac muscle, results in reduced capacity for further dilation during stress, resulting in myocardial ischemia. In the presence of hyperthyroidism, in patients already affected by coronary artery disease, the onset of myocardial ischemia is further favored by the increased oxygen consumption by myocardium and tachycardia (Klein and Danzi 2007). Heart failure may also be favored by the variations in the duration of the action potential and refractory period and the consequent onset of atrial fibrillation (Frost et al. 2004). Regarding this point, an experimental study, conducted on hypothyroid rats because they were thyroidectomized and on hyperthyroid rats because they were treated with Levothyroxine, demonstrated that the duration of the repolarization phase of the action potential was highly prolonged in the atria from the first group and shortened in the atria of the second group. Thyroid hormone may abbreviate the duration of the action potential by accelerating sodium extrusion as a consequence of increased metabolic turnover. These changes could account for a reduced probability of arrhythmias such as atrial fibrillation and atrial flutter in hypothyroidism, and the opposite in hyperthyroidism (Freedberg et al. 1970).

Signs and symptoms generally attributed to heart failure in hyperthyroid subjects, such as exercise intolerance, fatigue, peripheral edema are caused by hyper-dynamic circulatory state due to the inability of cardiac output to cope with the exercise. In some cases, symptoms such as resting dyspnea, liver congestion, and pleural effusion may also appear. Generally, these tend to improve with the restoration of euthyroidism and the use of diuretics and beta-blockers (Cruz et al. 1990). This condition, however, if untreated, can worsen over time and lead to a "pathological" type of hypertrophy, ventricular dilatation and a "true" chronic heart failure. Low-cardiac output heart failure is rare in hyperthyroidism. It is described in about 6% of patients, especially elderly and with a long history of untreated or not well-controlled hyperthyroidism, often with pre-existing cardiomyopathy, atrial fibrillation or tachycardia (Umpierrez et al. 1995). In these cases myocardial contractility is reduced, while systemic vascular resistance and circulating blood volume are both increased (Hak et al. 2000). Some longitudinal studies and the analysis of the pooled data from six cohort studies showed, that HF events are increased in overt but also in patients affected by subclinical hyperthyroidism (Gencer et al. 2012).

Figure 3 summarizes the pathophysiological mechanisms through which hyperthyroidism can enhance the progression of heart failure.

4.1 Hyperthyroidism and Heart Failure: Therapeutic Aspects

In hyperthyroid patients with CHF the aim of the therapy is to rapidly restore the euthyroidism using thionamides, surgery and/or radioiodine.

In Italy, Metimazole is the preferred drug for the treatment of hyperthyroidism. It induces blockade of thyroid hormone synthesis by inhibiting the oxidation of iodide to organic iodine. Secondly, it determines the inhibition of the production of TSH antibodies. In fact, Metimazole accumulates in the thyroid where it inhibits the activity of thyroid lymphocytes, the main source of antibody synthesis against thyroid hormone receptors. The initial dose is ranged between 15 and 60 mg per day (divided into three doses); the maintenance dose is 5–15 mg per day. Metimazole cannot be taken for more than two consecutive years, then it should be suspended and 1 year should be expected for a new intake. Carbimazole is the drug for the treatment of hyperthyroidism in British territory. It should be taken for 1–2 years, given the high risk of post-suspension hyperthyroidism. It may

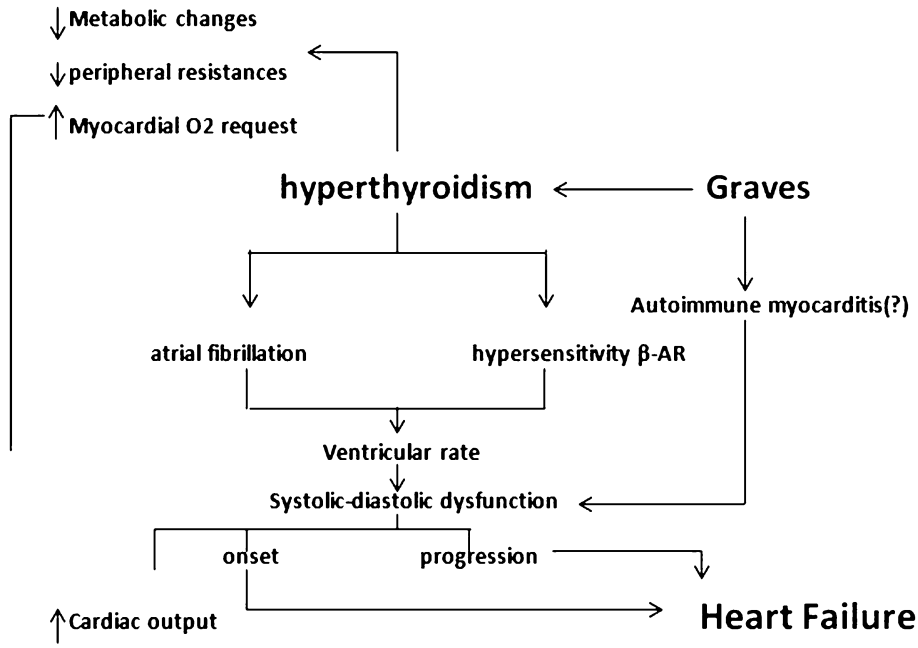

Fig. 3 Hyperthyroidism and heart failure. Pathophysiological mechanisms
O_2: oxygen, β-AR: Beta adrenergic receptor
Hyperthyroidism acts both at vascular and cardiac levels, resulting in a reduction in peripheral resistances and metabolic changes and an increase in myocardial O_2 demand by an rise in heart rate and possible onset of arrhythmias such as atrial fibrillation. This causes, moreover, an increase in ventricular rate and, in time, a systolic-diastolic dysfunction. This leads to hyper-dynamic circulatory state that can favor the onset or progression of the heart failure

cause itching and skin rashes. These side effects can be kept under control by the administration of antihistamines. Propylthiouracil should be used if the patient is allergic to carbimazole. It belongs to the class of thionamides and has its therapeutic action as an immunosuppressor. Potassium perchlorate is also used to treat hyperthyroidism. It represents a second-choice drug after Metimazole and Propylthiouracil. It is a ion sterically similar to iodine. It is able to compete for binding to specific channels, capable of transporting this ion, in the form of iodides, from the vascular lumen to the thyrocytes. The reduced absorption of iodides prevents thyroide synthesis of thyroid hormones re-balancing the blood profile of these hormones. It is available in the form of 200 mg tablets to take 3–4 times daily (600–800 mg) in three doses. Iodine 131 is the drug of radiometabolic therapy, widely used to treat hyperthyroidism in surgically inoperable patients. The medication is usually taken by mouth. The therapeutic effects of the drug are only observed after 4–-5 weeks of treatment. In CHF patients, pharmacological therapy should be preferred. Radiometabolic therapy is considered a second choice because of a slow control of hyperthyroidism and the possibility of re-emergence of illness. However, it is preferable to surgery in the cardiopath.

Beta blockers can improve cardiac function reducing heart rate (Bahn et al. 2011). One of the most used drugs for this purpose is Propanolol, at an indicative dose of 120–240 mg/day. Other least known drugs of the category are Atenolol and Metoprolol.

Surgical therapy is used in patients where hyperthyroidism recurs after medical therapy.

Longitudinal studies are required to asses wether the treatment is effective also in the subclinical form of hyperthyroidism.

5 Amiodarone-Induced Thyroid Diseases and CHF

Amiodarone is a class III antiarrhythmic drug. It is a benzofuranic derivative containing two iodine atoms. It contains 37.2 mg iodine per 100 mg of active substance. With standard daily dosage (200 mg/day), therefore, a significant amount of iodine is administered, with an increase of more than 40 times of its plasma and urinary levels. The drug is stored in the fat tissue; therefore, iodine levels can remain elevated for more than 6 months from its suspension (Vassallo and Trohman 2007).

The incidence of amiodarone-induced hyperthyroidism varies from 1 to 23% and may occur at any time of treatment, even months after its suspension. Two main mechanisms are involved: metabolic and inflammatory-toxic, responsible respectively for type I and type II Amiodarone-induced hyperthyroidism (Martino et al. 2001; Bogazzi et al. 2003).

Type I occurs in subjects with pre-existing thyroid pathologies and is caused by the increased synthesis of thyroid hormones induced by iodine in subjects with nodular goiters or latent Graves' disease; it is linked to an alteration of the mechanisms leading to the blockade of iodine uptake and hormone synthesis when the intrathyroidal concentration of inorganic iodine exceeds a certain threshold.

It is characterized by low TSH concentration, high levels of fT4 or fT3 and low radioiodine uptake. The eco-color Doppler of the thyroid shows a hypervascularization, as in Graves's disease.

Type II occurs in a normal gland. It is probably secondary to a destructive thyroid process caused by iodine or the same amiodarone. In the latter case, amiodarone can induce antibodies against the thyrotropin receptor causing hyperthyroidism. The cytotoxic mechanism leads to an excessive release of preformed T3 and T4 by the follicles, resulting in a destructive process. The main mechanism responsible for this seems to be the mono-N-desethyl amidarone (MDEA), an active metabolite of the amiodarone. The eco-color Doppler of the thyroid shows a hypovascularization and there is an increase of serum interleukin-6 level.

At the onset of hyperthyroidism, amiodarone treatment should be stopped (Loh 2000). It should, however, be considered that the half-life of the drug, about 50 days, implies that it continues to affect thyroid function even after its effective withdrawal. In addition, discontinuation of therapy may be associated with adverse effects, such as potentially fatal arrhythmias.

A different therapeutic approach was proposed for the two forms of thyrotoxicosis (Martino et al. 2001). For type I, treatment should be a combination of a thionamide (metimazole or propylthiouracil) to inhibit hormone biosynthesis, and potassium perchlorate to block the thyroid transporter of iodine. As the usual therapeutic dosage becomes ineffective for high iodine intracellular concentration, a higher thionamide dose than normal (metimazole 40–60 mg/day; propylthiouracil 600–800 mg/day) should be used. Potassium perchlorate should be used for a period not exceeding 1 month (30–40 days maximum). The treatment should not be prolonged because of the risk of severe side effects such as agranulocytosis, aplastic anemia and nephrotic syndrome, but it should not be reduced to a shorter period because this seems to favor the onset of recurrences of thyrotoxicosis. For Type II, considering the presence of a destructive thyroiditis, the use of corticosteroids alone or in combination with thionamides has been considered an effective therapy (Loh 2000). The dosage and therapeutic pattern changes depending on the type of steroid used (15–80 mg/day of prednisone or 3–6 mg/day of dexamethasone). The most common scheme is the use of prednisone starting at 80 mg/day, reducing the dose every 2 weeks for about 3 months. Premature suspension of cortisone therapy may result in recurrence of thyrotoxicosis; in these patients, steroid treatment must be restarted (Martino et al. 2001).

It is also necessary to observe in Type II for a transition to hypothyroidism after amiodarone withdrawal. In this case it is desirable to resume therapy with hormone replacement therapy for the restoration of euthyroidism. In mixed forms it would be helpful to use an initial combination of propylthiouracil or metimazole and potassium perchlorate, at the dosages already mentioned, with the addition of steroids for 2 weeks in the absence of improvement (Triggiani et al. 2012). Surgical thyroidectomy should be considered in those cases refractory to medical treatment.

In a study by our group, (Kannan et al. 1984) a high prevalence and incidence of hypothyroidism has been demonstrated among CHF patients and the key role played by amiodarone therapy in its genesis has been clearly shown.

The mechanisms through which amiodarone can induce hypothyroidism are at least three: (1) modification of the natural course of a pre-existing autoimmune thyroiditis; (2) the lack of adaptation to the overload of iodine induced by amiodarone and (3) the direct cytotoxic damage (Forfar et al. 1982).

Besides the possible development of hypo and hyperthyroidism, the most important metabolic effect of the amiodarone is definitely the inhibition of the 5′-monodeiodase type I enzyme, which results in a moderate and persistent increase in T4 and fT4 and a mild but persistent reduction of the total T3 and fT3, sometimes associated with a slight transient increase in TSH (Butler and Kalogeropoulos 2008; Baker et al. 1994). Such changes in the hormonal pattern begin to manifest after about 3–4 months of treatment. The action is exerted through the binding of its main metabolite to thyroid hormone receptors alpha 1(Bogazzi et al. 2001) and beta 1 (Franklyn et al. 1989), inhibiting T3 binding and causing a condition of "local hypothyroidism" which would explain its therapeutic efficacy as antiarrhythmic and antianginal, but also its adverse effects on cardiac function.

Amiodarone can directly induce the so-called "fetal gene program recapitulation"(Franklyn et al. 1989), further compromising myocyte function. These additional effects, not mediated by thyroid hormone deficiency, may explain why restoration of euthyroidism by substitution therapy can not completely counter the adverse effects of amiodarone therapy in the progression of heart failure.

6 Conclusions

Thyroid hormones are involved in cardiovascular balance. They affect the heart rate, systemic vascular resistances, arterial pressure and cardiac contractility. Dysthyroidisms, therefore, have a negative impact on the symptoms on the prognosis of patients with heart failure.

In particular, hypothyroidism, which can be *subclinical* (TSH above the normal range with thyroid hormones free fractions still normal) or *overt* (reduction of thyroid hormones), leads to progression of HF trough the reduction of myocardial contractility and the increased peripheral resistances and serum cholesterol, causing possible ischemic disease. On the other hand, the excess of thyroid hormones (hyperthyroidism), through the relative reduction of peripheral resistance, the increase in circulating blood volume and the increase in myocardial O_2 demand, by a rise in heart rate and possible onset of arrhythmias, leads to hyperdynamic circulatory state that can favor the onset or progression of the heart failure. Moreover, about 30% of patients with CHF have low T3 level, in the presence of normal TSH and normal or reduced T4 levels, and T3 in serum decreases proportionately to the severity of heart disease, causing the progression of heart failure. This condition is known as "low T3 syndrome" and is caused by a reduction in the activity of 5′-monodeiodinase, the enzyme which peripherally converts T4 to T3. This is initially viewed as an adaptation to reduce energy consumption in the presence of severe systemic pathologies, but when persistent, it becomes "maladaptive".

Finally, dysthyroism may also be iatrogenic. One of the most commonly used antiarrhythmic drug in patients with CHF is Amiodarone, which may induce hyperthyroidism trough two main mechanisms: metabolic in type I and inflammatory-toxic in type II.

Whatever is the underlying mechanism, an early diagnosis and treatment of thyroid disorders is important to better treat CHF patients and to prevent worsening of the heart failure: Levothyroxine in patients with overt hypothyroidism; Thionamides, Potassium perchlorate, surgery and/or radioiodine in hyperthyroidism and in amiodarone-induced hyperthyroidism; substitution therapy with T3 in CHF patients with low T3 syndrome, while considering the problems associated with the existence of an exclusive intravenous formulation; corticosteroids in type II amiodarone-induced hyperthyroidism.

Management of Bradyarrhythmias in Heart Failure: A Tailored Approach

Daniele Masarone, Ernesto Ammendola, Anna Rago, Rita Gravino, Gemma Salerno, Marta Rubino, Tommaso Marrazzo, Antonio Molino, Paolo Calabrò, Giuseppe Pacileo, and Giuseppe Limongelli

Abstract

Patients with heart failure (HF) may develop a range of bradyarrhythmias including sinus node dysfunction, various degrees of atrioventricular block, and ventricular conduction delay. Device implantation has been recommended in these patients, but the specific etiology should be sought as it may influence the choice of the type of device required (pacemaker vs. implantable cardiac defibrillator). Also, pacing mode must be carefully set in patients with heart failure (HF) and left ventricular systolic dysfunction.

In this chapter, we summarize the knowledge required for a tailored approach to bradyarrhythmias in patients with heart failure.

Keywords

Heart failure reduced ejection fraction · Heart failure preserved ejection fraction · Bradyarrhytmias · Implantable cardioverted defibrillator · Pacemaker · Cardiomyopathies

1 Introduction

Rhythm disturbances in patients with heart failure (HF) are not confined to tachyarrhythmias (Stevenson et al. 2002). While the ever-increasing percentage of HF patients implanted with devices capable of pacing interfere quantification of bradyarrhythmias at the current time, earlier registries illustrated that bradyarrhythmias with electromechanical dissociation are the mechanism of sudden cardiac

death in a significant number of selected HF patients (Luu et al. 1989).

Also in the Euro Heart Failure survey, 6% of patients with a HF-related admission also had bradycardia, and a bradyarrhythmia complicated their clinical course in about one in six patients (Cleland et al. 2000). HF is an umbrella term comprising a wide range of different patients, those with preserved (>50%) left ventricular ejection fraction (LVEF), those with reduced LVEF (LVEF <40%) and those with mid-range ejection fraction (LVEF >40 <50%) (Ponikowski et al. 2016).

Differentiation of patients with HF based on LVEF is important due to different demographics, etiology, co-morbidities and indication/response to therapies; the last is particularly true for the bradyarrhythmias in which the management is closely dependent on underlying etiologies. In this chapter, we briefly discuss the etiology and the pathophysiology of the conduction system disorders and then focus on the specific knowledge and skills that cardiologists must achieve for a "*personalized*" management of bradyarrhythmias in patients with Heart Failure with reduced EF (HFrEF). Heart Failure with mid-range Ejection Fraction (HFmrEF) and Heart Failure with preserved Ejection Fraction (HFpEF).

2 Etiology and Pathophysiology of Bradyarrhythmias

Bradyarrhythmias are most commonly caused by the failure of impulse formation (sinus node dysfunction) or by the failure of impulse conduction over the atrioventricular (AV) node/His-Purkinje system (Rubart and Zipes 2014). Bradyarrhythmias may be caused by a disease that directly alters the structural and functional integrity of the sinus node, atria, AV node and His-Purkinje system or by extrinsic factors (e.g., autonomic disturbances, drugs) without causing structural abnormalities (Table 1) (Bayés de Luna 2011).

2.1 Sinus Node Dysfunction

Sinus node dysfunction (SND) can result from various conditions, which cause depression of the automaticity and electrical conduction from the sinus node, perinodal and atrial tissue (Sneddon and Camm 1992). These conditions may be intrinsic (diseases that directly alter the sinus node or sinoatrial structure) or extrinsic (most often cardiovascular drugs or systemic illness). In most of cases, SND is caused by both structural and molecular remodeling of sinus node caused by aging (idiopathic SND) (Dobrzynski

Table 1 The potential etiologies of bradyarrhytmias include both intrinsic and extrinsic causes, however in half of more of the cases, no specific causes are identified, and the block is felt to be related to idiopathic progressive cardiac conduction disease with myocardial fibrosis and/or sclerosis that affects the conduction system

Intrinsic	Extrinsic
Idiopathic degenerative disorder	Antiarrhythmic agents
	Class IA quinidine, procainamide
	Class IC propafenone, flecainide
	Class II blockers
	Class III sotalol, amiodarone, dronedarone
	Class IV diltiazem, verapamil
Ischemic heart disease	Increased vagal tone
Hypertensive heart disease	Carotid sinus hypersensitivity
Infiltrative cardiomyopathy	Hypothyroidism
Trauma	Intracranial hypertension
Inflammation	Hypothermia
Collagen vascular disease	Hyperkalemia
Infection	Hypoxia
Neuromuscular disorder	Sleep apnea

et al. 2007). Also, any process that results in damage of the sinoatrial node (e.g., collagen vascular diseases, ischemia, infiltrative diseases or surgical trauma) can be a causative/contributing factor (Bharati et al. 2012). At least 50% of patients with sick sinus syndrome develop alternating bradycardia and tachycardia, also known as tachy-brady syndrome (Mangrum and DiMarco 2000; Brignole 2002).

In patients with HF, the most common etiologies of SND are brady-tachy syndrome and ischemia; the remaining are called idiopathic forms. In patients with tachy–brady syndrome, atrial fibrillation or flutter with rapid ventricular response are particularly frequent in older patients with advanced sinoatrial nodal disease in whom sinoatrial node fibrosis may favor re-entrant beats or tachycardia (Choudhury et al. 2015). However recently it has been demonstrated that atrial arrhythmias can be the cause of SND. Indeed, in patients undergoing electrical cardioversion for persistent atrial fibrillation, an increase of sinus node recovery time and a reduction in both maximal and intrinsic heart rate it has been documented (Manios et al. 2001). Acute or chronic ischemia, due to disease of the right coronary artery or sinus node artery, are often quoted as a cause of SND. The pathogenesis of this is still unknown, however some evidence showed that stenosis of sinus node artery leads to longer sinus node recovery time and prolonged sinoatrial conduction time (Morris and Kalman 2014). Finally, idiopathic SND is not only caused by fibrosis of the sinoatrial node but also related to "electrical remodeling" of the atria and the sinoatrial node (i.e., reduced expression of ion channels and some gap junction) (Tellez et al. 2011).

2.2 Atrioventricular Node Dysfunction

Acquired atrioventricular (AV) block is caused by several extrinsic and intrinsic conditions already discussed with sinus node dysfunction. First degree AV block is commonly associated with idiopathic progressive degeneration of the cardiac conduction system, but it can also be due to drug effect (e.g., beta-blockers) (Waller et al. 1993; McVay 1984).

Type I 2nd-degree AV block almost always results from impaired conduction in the AV node (rather than more distally in the conduction system). It is usually benign and may be seen in children, trained athletes, and people with high vagal tone, particularly during sleep. It may also occur during an acute myocardial infarction because of increased vagal tone or ischemia of the AV node, but the block is usually temporary.

Finally type II 2nd-degree or 3rd-degree AV block are often associated with ischemia or myocardial disease (Barold and Hayes 2001).

In patients with HFrEF ischemia accounts for about 40% of cases of high-grade AV block (Zoob and Smith 1963). Conduction can be disturbed with either chronic ischemia or during an acute myocardial infarction (Mullins and Atkins 1976). In case of ischemia of the right coronary artery, the AV nodal artery may be involved with subsequent necrotic changes in the AV node while the His-Purkinje system is usually spared.

In case of ischemia of left coronary artery and circumflex branch, necrotic changes are seen most often in the distal His bundle and in the bundle branches.

Less frequent causes are represented by neuromuscular disorders (muscular dystrophy, Kearns-Sayre syndrome) (Limongelli et al. 2013), systemic disease (cardiac sarcoidosis) (Hamzeh et al. 2015) and Lyme myocarditis (Lo et al. 2003).

In patients with HFpEF apparently, idiopathic progressive cardiac conduction defects are the most common cause of AV block (Schwartzmann 2014) while hypertensive heart disease (Masarone et al. 2017), diabetes and infiltrative cardiomyopathies (amyloidoses, Fabry disease) represent less frequent causes (Falk 2005; O'Mahony and Elliot 2010).

3 Diagnosis of Bradyarrhythmias

Patients presenting with bradyarrhythmias complain of dizziness, vertigo and syncope (Vogler et al. 2012). To establish the diagnosis of SND, it

is crucial to find a causal relationship between the patients' symptoms and the electrocardiogram (ECG) abnormalities. Apart from a thorough medical history, a 12-lead surface ECG, Holter ECG recording, and exercise testing are usually adequate.

Whenever surface ECG and repetitive Holter recordings are incapable of documenting the cause of a patient 's symptoms, an external event recorder or an implantable loop recorder should be considered (Solbiati et al. 2016).

Diagnosis of AV block can be achieved in most of these cases, non-invasively, in fact, the surface ECG (if the recording is sufficiently long) usually provides the information to characterize the type of the AV block (Haines et al. 2014). In patients with intermittent AV block, Holter ECG and exercise testing are important to establish a correlation between symptoms and cardiac rhythm.

With rare exceptions, such as persistent 2:1 AV block or failure to establish a symptom-rhythm correlation, the invasive electrophysiologic study does not make a significant contribution to the management of patients with bradyarrhythmias (Adan and Crown 2003).

The diagnosis of bradyarrhythmias represents a starting point and not the end of the diagnostic process. In fact, it is crucial to recognize the presence of red flags (Tables 2 and 3) (Rapezzi et al. 2013) suggesting the presence of a cardiomyopathy whose recognition is essential for proper treatment.

4 Therapy of Bradyarrhythmias

Treatment for bradyarrhythmias is divided into acute and chronic phases (Link et al. 2015). Acute therapy depends on the presence of bradycardia-related symptoms and is aimed at the prevention of acute HF and asystole. Intravenous drug therapy (atropine, isoprenaline, or epinephrine) and transcutaneous or transvenous temporary pacing can be used during this phase (Wung 2016). The decision to proceed from temporary to permanent pacing (chronic therapy) and which device must be used (pacemaker vs. implantable cardioverter defibrillator) is determined by the type of HF and by the etiology of the bradyarrhythmias (i.e., tailored treatment).

5 Tailored Treatment of Bradyarrhythmias in Patients with HFrEF/HFmrEF

Patients with HFrEF/HFmrEF can manifest SND, various degrees of AV block and interventricular conduction delay. In older adults, the main cause of bradyarrhythmias is ischemic heart disease. The onset of AV conduction defects in middle age or earlier should prompt an evaluation for non-ischemic etiology (e.g., inflammatory or genetic cardiomyopathy) (Barra et al. 2012).

According to the tailored approach, we proposed a different management based on specific etiology (Fig. 1).

5.1 Ischemic HFrEF/HFmrEF

Bradyarrhythmias can be caused by both acute or chronic ischemia.

In acute coronary syndromes with right coronary artery as culprit's vessel, high-grade AV block has been described in up to 17% of cases (Tans et al. 1980). Most of these cases are transient and resolve either spontaneously or with revascularization, about 9% will ultimately require a permanent pacemaker (Nicod et al. 1988).

Management of patients with HFrEF/HFmrEF of ischemic etiology must be conducted according to 2012 ACCF/AHA/HRS Guidelines for Device-Based Therapy (Tracy et al. 2012) that indicates permanent pacing in:

- Permanent 3rd-degree AV block complicating acute coronary syndrome in whom the block does not resolve with revascularization,
- Transient advanced 2nd or 3rd-degree infranodal AV block and associated bundle branch block.

In both cases, careful evaluation of the device must be considered, in fact, according to the

Table 2 In patients with cardiomyopathies and bradyarrhythmias the red flags must be sought to reach an etiologic diagnosis

Family and personal history
First degree relative with cardiomyopathies
Unexplained sudden death in the first-degree relative
Unexplained pacemaker implantation in the first-degree relative
Age of onset of bradyarrhythmias <55 y/o
Symptom and clinical examination
Learning difficult/mental retardation
Sensorineural deafness
Visual impairment
Muscle weakness
Paraesthesiae/sensory abnormalities/neuropathic pain
Bilateral carpal tunnel
Angiokeratomata
Laboratory finding
↑ Serum creatine phosphokinase
↑ Transaminase
Leukocytopenia
Proteinuria with/without reduction of glomerular filtration rate
Myoglobinuria
Lactic acidosis
Electrocardiography
Low QRS voltage (or normal voltages despite LVH)
Short PR interval
Echocardiography
Concentric LVH with MWT ≥ 15 mm
Concentric LVH with MWT ≥13 mm in patients with family history for HCM
Symmetric LVH
Increased interatrial septum thickness
Increased atrioventricular valve thickness
Increased right ventricle free wall thickness
Ground glasses appearance of ventricular myocardium
Mild/moderate pericardial effusion
LV non-compaction
Postero-lateral akinesia/dyskinesia
Cardiac magnetic resonance imaging
Postero-lateral LGE + concentric and symmetric LVH
Diffuse subendocardial LGE
Intense myocardial "avidity" for gadolinium
Patchy mid-wall LGE

2015 ESC Guidelines for the management of patients with ventricular arrhythmias and the prevention of sudden cardiac death (Priori et al. 2015) and 2016 ESC Guidelines for the diagnosis and treatment of acute and chronic heart failure (Ponikowski et al. 2016):

- In patients with HFmrEF, a pacemaker (PM) is reccomended.
- In patients with HFrEF with severe reduction of LVEF (<35%) and no bundle branch block an implantable cardioverter defibrillator (ICD) is reccomended after 40 days of myocardial infarction,
- In patients with HFrEF with severe reduction of LVEF (<35%) despite 3 months of optimal medical therapy and bundle branch block

Table 3 In patients with cardiomyopathy, the identification of the clinical-echocardiographic phenotype (hypertrophic, dilatative, restrictive) is only the first diagnostic step. The next step is to search red flags to reach an etiologic diagnosis of cardiomiopathies

Laminopathies
Autosomal dominant inheritance pattern
Muscle weakness
Dilated cardiomyopathy
AV block
↑ Serum creatine phosphokinase
Sarcoidosis
AV block
Postero-lateral pseudo infarction pattern on ECG
↑ Serum angiotensin converting enzyme level
Hypokinetic non-dilated cardiomyopathy
LGE at the anterobasal septum or papillary muscles
Muscular dystrophies
Autosomal dominant inheritance pattern (rarely X linked)
Muscle weakness
AV block
Postero-lateral pseudo infarction pattern on ECG
↑ Serum creatine phosphokinase
Dilated cardiomyopathy with postero-lateral akinesia/dyskinesia
LGE at the anterobasal septum or papillary muscles
Anderson-Fabry disease
X liked inheritance pattern
Visual impairment (cataracts, corneal opacities)
Angiokeratomata
Short P-R /preexcitation
AV block
Proteinuria with/without reduction of glomerular filtration rate
Concentric LVH
RV free wall thickness
Posterolateral LGE
Amyloidosis
Autosomal dominant inheritance pattern (familial TTR amyloidosis)
Bilateral carpal tunnel syndrome (TTR amyloidosis)
AV block
Low QRS voltage (or normal voltages despite LVH)
Proteinuria with/without reduction of glomerular filtration rate
Concentric LVH
Global hypokinesia (late stage)
Increased RV free wall thickness
Mild pericardial effusion
Diffuse subendocardial LGE
Mitochondrial disease
Matrilinear inheritance pattern
Sensorineural deafness
Learning difficult
Muscle weakness
Short P-R /preexcitation
AV block
↑ Serum creatine phosphokinase
↑ Transaminase
Leukocytopenia (TAZ gene/Barth syndrome)
Concentric LVH
Global hypokinesia (late stage)

(QRS > 150 msec) a cardiac resynchronization therapy device with a defibrillator backup (CRT-D) is reccomended,

- In patients with HFrEF with severe reduction of LVEF (<35%) despite 3 months of optimal medical therapy and left bundle branch block (QRS > 130 msec <150 msec) a CRT-D is reccomended,
- In patients with HFrEF with severe reduction of LVEF (<35%) and in patients with HFmrEF and expected high percentage of ventricular pacing CRT-D may be considered

In patients with chronic ischemic heart disease the indications for pacing are the same as for the general population:

- PM implantation is indicated in symptomatic bradycardia,
- PM implantation is indicated in patients with 3rd or 2nd-degree type 2 AV block irrespective of symptoms,
- PM implantation should be considered in patients with 2nd-degree type 1 AV block which causes symptoms or is found to be located at intra- or infra-His levels at the electrophysiological study,
- When PM is planned an ICD is recommended in patients with HFrEF and severe reduction of LVEF (EF < 35%).

5.2 Non-ischemic HFrEF/HFmrEF

Non-ischemic dilated cardiomyopathy is an umbrella term comprising a variety of different etiologies with a different approach to bradyarrhythmias. In patients with non-ischemic HFrEF/HFmrEF management of bradyarrhythmias is the same as for patients with ischemic etiology; however, recently the indication to ICD implantation has been questioned. Generally, in these patients according to results of large randomized clinical trials including Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) (Bardy et al. 2005) and Multicenter Automatic Defibrillator Implantation Trial (MADIT-II) (Moss et al. 2002) ICD implantation carries a class I recommendation for patients with symptomatic HFrEF and LVEF $\leq$35%.

The benefit of ICD implantation is considered to be similar in patients with non-ischemic vs. ischemic HFrEF even though the majority of patients in SCD-HeFT and all of the patients in MADIT-II had HFrEF of ischemic origin. However, the recent Defibrillator Implantation in Patients with Non ischemic Systolic Heart Failure (DANISH) showed at 68 months of follow-up that all-cause of mortality was not significantly lower in the ICD group compared to the control group (Køber et al. 2016). Nevertheless, a relatively high rate of non cardiovascular mortality in the study (31%), may have masked out any potential benefit from ICD therapy, as ICD placement do not have effects on non cardiovascular death. Furthermore, an age-by-therapy analysis was observed whereby patients $<$59 years old derived a mortality benefit from ICD therapy whereas older patients did not. Likewise, patients with more severe HFrEF as determined by NT-proBNP level and functional class also appeared to benefit from ICD. Ultimately, the DANISH trial suggests that routine ICD therapy for all patients with non-ischemic HFrEF with LVEF $\leq$35% may not result in the strong mortality benefit previously extrapolated from data in patients with ischemic cardiomyopathy. For this reason, the decision to place an ICD in these patients should likely be considered on an

individual basis considering the severity of underlying disease and concomitant arrhythmia risk versus age/life expectancy and comorbidities. For some etiology (discussed below) specific considerations are required.

5.3 Laminopathies

Lamin A/C gene mutations can be associated with myocardial diseases, usually characterized by dilated cardiomyopathy and arrhythmic disorders (cardiolaminopathies) (Cattin et al. 2013). Patients with cardiolaminopathies may present a wide range of arrhythmic disturbances, which include either bradyarrhythmias (AV blocks, sinus node dysfunction, atrial standstill) (Sylvius and Tesson 2006) or tachyarrhythmias (atrial fibrillation, ventricular tachycardia, and ventricular fibrillation) (Finsterer et al. 2016), in varying combinations, and with frequent association with HFrEF.

In cardiolaminopathies the incidence of sudden cardiac death in patients with pacemakers is very high (Rankin and Ellard 2006) for this reason we recommend ICD implantation in pacemaker candidates with "specific" risk factors for sudden cardiac death (male sex, LVEF $< 45\%$, non-sustained ventricular tachycardia, non-missense mutation) (Van Rijsingen et al. 2012).

5.4 Myocarditis

Myocarditis is a common cause of transient cardiac rhythm disturbances; supraventricular and ventricular arrhythmias are the main findings. However, symptomatic bradycardia/AV blocks can occur in about 30% of cases, particularly in children and in some etiologies (Chagas disease, Lyme disease, diphtheria) (O'Rourke 1972; Sinagra et al. 2016). In myocarditis associated AV block recovery occurs in most of the cases, and rarely permanent PM implantation is required (Batra et al. 2003). For this reason, in patients with "de novo" HFrEF/HFmrEF and bradyarrhythmias, the diagnosis of myocarditis should be excluded (also through cardiac magnetic resonance and cardiac biopsy) to avoid improper PM/ICD implants.

5.5 Sarcoidosis

Sarcoidosis is a systemic inflammatory disease of unknown cause, characterized by the formation of non-caseating granulomas and resultant scarring of affected organs (Newman et al. 1997). Myocardial involvement occurs in 20–30% of cases, though only roughly one-quarter of these patients are diagnosed ante mortem (Kim et al. 2009). AV block is a common presentation of clinically manifest cardiac sarcoidosis because of the involvement of the basal septum by scar tissue, granulomas, or the involvement of the nodal artery (Kandolin et al. 2011). However, although conduction abnormalities are the most common cardiac presentation, the risk of sudden death from ventricular arrhythmias is high in the presence of significant cardiac involvement (Kumar et al. 2015). Recent Heart Rhythm Society expert consensus statement on the diagnosis and management of arrhythmias associated with cardiac sarcoidosis recommend (Birnie et al. 2014):

- PM implantation can be useful in patients with cardiac sarcoidosis with an indication for pacing even if the AV block reverses transiently.
- Immunosuppression can be useful in patients with cardiac sarcoidosis presenting with type II 2nd-degree and 3rd-degree AV block.
- ICD implantation can be useful in patients with cardiac sarcoidosis and an indication for PM implantation.

5.6 Muscular Dystrophies

Muscular dystrophies are a group of inherited diseases affecting skeletal muscle that also affect cardiac muscle (Hermans et al. 2010). Cardiac involvement is characterized from a

pathophysiologic point of view by a degenerative process with fibrosis and fatty replacement of the myocardium and of conduction system (Yilmaz and Secthem 2012) and from a clinical point of view by HF, conduction disease, atrial and ventricular arrhythmias, and sudden cardiac death (Groh 2012).

Since the incidence of sudden cardiac death is high in this group of disorders, and because conduction system disease tends to be unpredictable, the development of 2nd or 3rd-degree AV block, even in the absence of symptoms, is considered an absolute indication for permanent pacing implantation (Table 4) (Finsterer et al. 2012).

The benefit of an ICD implantation compared with pacemaker implantation in patients with muscular dystrophies remain under evaluation.

6 Mode of Pacing in Patients with HFrEF

Careful individual decision-making is required in selecting the optimum pacing mode in patients with HF and reduced LVEF (Fig. 2). In patients with SND, but intact atrioventricular conduction atrial pacing alone might be considered; on the other hand, patients with AV block (present or expected) will require ventricular pacing. Dual chamber pacing with AV delay optimization has beneficial functional and clinical effects when applied to the appropriate patients, namely, symptomatic patients in sinus rhythm with a long PR interval, functional mitral regurgitation and a ventricular filling time of less than 200 msec at rest (Auricchio and Salo 1997).

Pacing the right ventricle can be deleterious, resulting in a relative delay in left ventricular activation and may induce ventricular asynchrony, possibly due to a site of activation being distant from the left ventricle (Sweeney and Prinzen 2006). For similar reasons pacing the right side of the heart in patients with dilated cardiomyopathy and grossly uncoordinated ventricular contraction due to left sided conduction abnormalities, can do little to improve coordination (Dresing and Natale 2001). In the Dual Chamber and VVI Implantable Defibrillator (DAVID) trial it was documented that the dual chamber (right atrial and right ventricular) pacing was detrimental in patients with HFrEF/HFmrEF, with increased HF admissions and mortality compared to sinus rhythm (Wilkoff et al. 2002). Also, support for the deleterious effect of right ventricular pacing was provided by a posthoc analysis of data from "The mode selection" (MOST) trial in sinus node dysfunction (Sweeney et al. 2003). Of the 2010 patients enrolled in the MOST trial, this analysis was restricted to the 1339 participants who had a baseline QRS duration <120 msec. Among these patients, 707 were assigned to dual-chamber rate-modulated and 632 to the single-chamber sensor-based, rate-modulating pacemakers pacing. Regardless of pacing mode, patients with a higher cumulative percentage of ventricular paced beats had significantly higher rates of subsequent hospitalization and atrial fibrillation.

For this reason, in selected patients with HFrEF/HFmrEF with PM indication and expected high percentage of ventricular pacing bi-ventricular pacing appears the best choice.

7 Tailored Treatment of Bradyarrhythmias in Patients with HFpEF

SND and AV block are common in elderly patients with HFpEF, because idiopathic fibrosis of sinus node is age related and for the presence of comorbidities such as hypertension diabetes and chronic ischemia that favors the sinus node fibrosis (Josephson 2008). The onset of bradyarrhythmias in the middle age or the association between bradyarrhythmias and moderate/severe left ventricular hypertrophy should raise the suspicion of genetic disease (Fig. 3).

7.1 Anderson-Fabry Disease

Anderson-Fabry disease is an X linked multisystemic disorder caused by the deficiency of α-galactosidase A, which leads to abnormal

Table 4 Cardiac conduction defects are common and progressive in neuromuscular Disorders and often requiring permanent pacemaker implantation

Type of dystrophy	Conduction system involvement	Indication to permanent pacing
Duchenne's muscular dystrophy	Frequent	2nd or 3rd -degree AV block, especially in the setting of a widened QRS complex
Becker muscular dystrophy	Possible	2nd or 3rd -degree AV block, especially in the setting of a widened QRS complex
Myotonic muscular dystrophy	Frequent	HV interval > 70 msec (perform EPS in all patients even in the absence of high-degree AV block)
Emery-Dreyfuss muscular dystrophy	Possible	2nd or 3rd -degree AV block, especially in the setting of a widened QRS complex
Limb girdle muscular dystrophy	Frequent	Family history of heart block or sudden death (familial form)
		2nd or 3rd -degree AV block, especially in the setting of a widened QRS complex (sporadic form)

lysosomal accumulation of glycolipids (Garman and Garboczi 2004).

Even though left ventricular hypertrophy and ventricular arrhythmias are the most prominent cardiac manifestation, bradyarrhythmias, and progressive AV conduction disease have been reported and these may cause sudden cardiac death (Linhart et al. 2007).

Considering that the enzyme replacement therapy does not affect the bradyarrhythmias once they are established (but early therapy may prevent them) symptomatic bradycardia or asymptomatic patients with progressive conduction system abnormalities, intermittent AV block, and/or significant bradycardia should be treated with permanent pacing (Kim et al. 2016).

In the absence of specific guidelines and indications for device therapy for Anderson-Fabry disease, it is our experience to discuss an ICD implantation in patients with an indication for pacing and/or in patients with ventricular arrhythmias and a severe cardiac phenotype (hypertrophy, fibrosis). Recently O′ Mahony and coll. Showed, in a retrospective cohort study including 208 patients with Anderson-

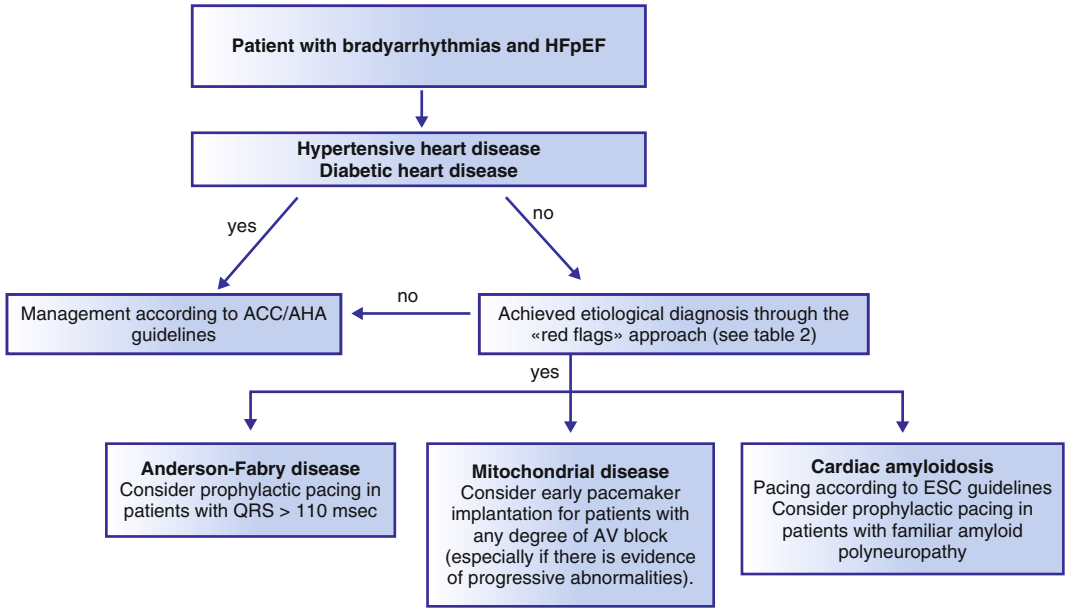

Fig. 3 In patients with HFpEF, the search for specific etiologies is essential for a tailored approach to pacing therapy. *HFpEF* Heart Failure Preserved Ejection Fraction, *ACC/AHA* American College of Cardiology/American Heart Association, *ESC* European Society of Cardiology, *AV* Atrio-Ventricular

Fabry disease, that 6% of patients need a pacemaker implantation for anti bradycardia therapy. At multivariate analysis, the most accurate predictor of future anti-bradycardia pacing is a wide QRS (O'Mahony et al. 2011). For this reason, in all patients with Anderson-Fabry disease and a QRS duration >110 msec a "prophylactic" ICD implantation should be considered.

7.2 Mitochondrial Disease

Mitochondrial diseases include a wide range of clinical entities involving tissues that have high energy requirements (Limongelli et al. 2012). Abnormalities in the mitochondrial function cause cardiomyopathies, arrhythmias, and abnormalities of the conduction system disorders (Bindoff 2003). Of note, in patients with mitochondrial disease progression to high-grade AV block is often unpredictable; for this reason, early pacemaker implantation for patients with any degree of AV block (including first-degree AV block with PR interval >300 ms), or any fascicular block with or without symptoms, especially if there is evidence of progressive abnormalities should be considered (Limongelli et al. 2016).

7.3 Amyloidosis

Amyloidosis comprises a unique group of diseases that share the extracellular deposition of insoluble fibrillar proteins in organs and tissues (Weatherall et al. 2010). Cardiovascular amyloidosis can be primary, a part of systemic amyloidosis, or a result of chronic systemic diseases elsewhere in the body. The most common presentation is congestive HF, mainly with normal left ventricular ejection fraction, high pulmonary capillary wedge pressure (Fig. 4) and conduction system disturbances (García Ropero et al. 2015). There are no specific indications for device therapy in cardiac amyloidosis, however, for patients with familial amyloid polyneuropathy with conduction disorder,

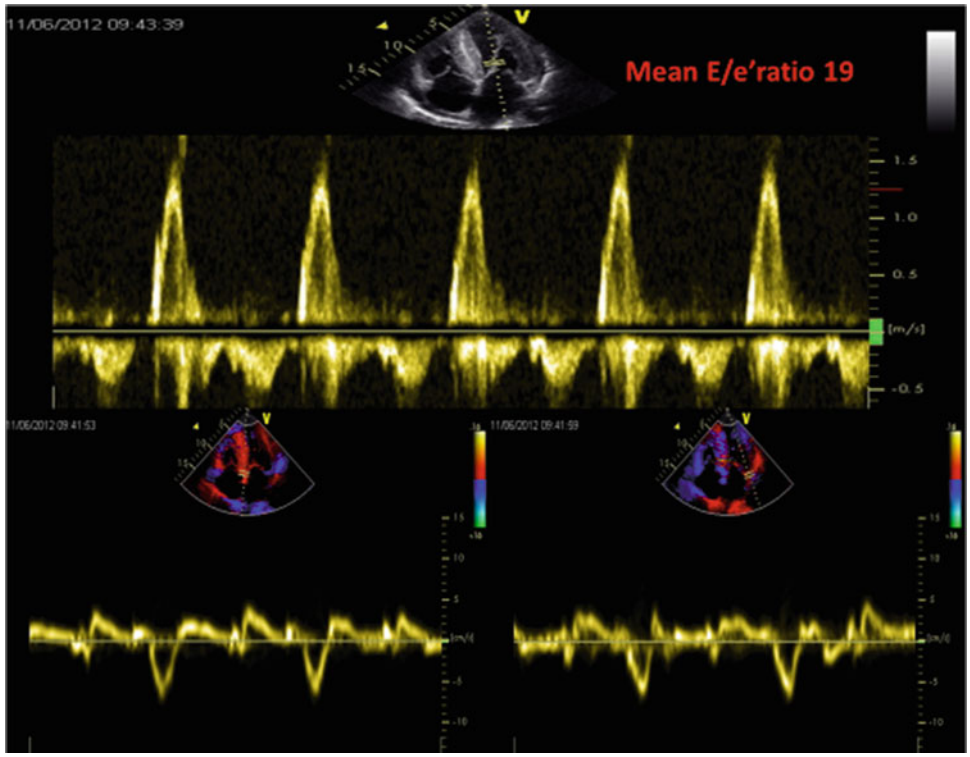

Fig. 4 Echocardiographic evidence of diastolic dysfunction in patients with AL Amyloidosis. Note the high E/e′ ratio suggestive of high pulmonary capillary wedge pressure

early "prophylactic" pacing should be considered (Rapezzi et al. 2010; Algalarrondo et al. 2012).

8 Mode of Pacing in Patients with HFpEF

Compared to patients with HFrEF/HFmrEF less evidence is present regarding the choice of pacing mode in patients with HFpEF. In patients with HFpEF due to hypertension, diabetes or ischemia, we proposed to select a pacing mode according to current ESC guidelines on cardiac pacing and cardiac resynchronization therapy (Brignole et al. 2013). In patients with Anderson-Fabry cardiomyopathy and mitochondrial disease, the pacing mode is selected according to the presence of left ventricular tract obstruction (Fig. 5). In fact in patients with left ventricular tract obstruction, we propose to set PM/ICD in DDD mode, regardless of the presence of AV blocks, to reduce left ventricular outflow gradient (Lucon et al. 2013; Montaigne and Pentiah 2015), while in patients without left ventricular outflow gradient we set PM/ICD mode according to international guidelines.

Finally, in our view, biventricular pacing should be the mode of choice in patients with cardiac amyloidosis, as conventional right ventricular pacing may lead to LV dyssynchrony and thus further decrease the stroke volume (Mathew et al. 1997).

9 Conclusion

The overall burden of a conduction disease is high in patients with HF and its management is complex and multifaceted. The current guidelines propose a general, evidence based approach relying on the type of bradyarrhythmias in patients with HF. A future personalized

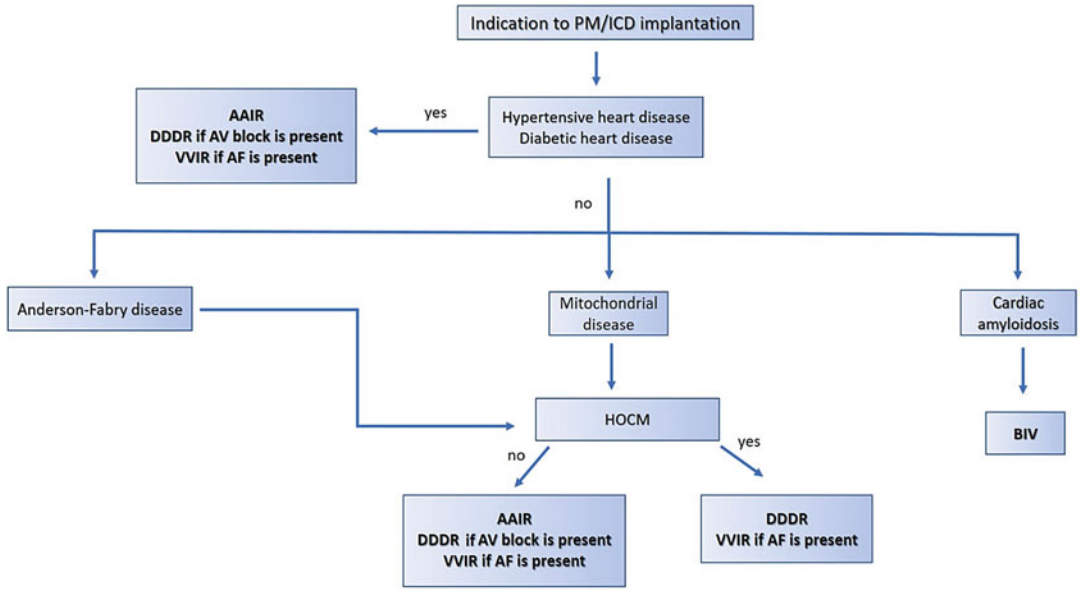

Fig. 5 Optimal pacing mode in HFpEF *PM* Pacemaker, *ICD* Implantable cardioverter defibrillator, *AAIR* Atrial pacing with rate responsive, *DDDR* Dual chamber pacing with rate responsive, *VVIR* Ventricular pacing with rate responsive, *BIV* Biventricular pacing

approach is warranted in this wide and heterogeneous cohort of patients. On this ground, HF specialist and electrophysiologist should broaden the horizon of the "ischemic vs non-ischemic HF" to provide a much tailored and personalized therapeutic approach in these patients.

Percutaneous Mitral Valve Interventions and Heart Failure

Abhishek Sharma, Sunny Goel, and Sahil Agrawal

Abstract

Mitral regurgitation (MR) is the most frequent Valvular Heart Disease (VHD) and is an important cause of heart failure. MR can be caused by primary valve abnormality (Degenerative MR/Primary MR) or it can be secondary to cardiomyopathy (Functional MR/Secondary MR). Medical management alleviates symptoms but does not alter the progression of the disease. Current guidelines recommend surgery for moderate-to-severe (Grade $>$ 3) MR in patients with symptoms or evidence of left ventricular dysfunction. Despite current practice guidelines, the majority of patients with severe MR do not undergo surgery. The reasons include high surgical risk from advanced age or multiple comorbidities, and a lack of clear data supporting valve surgery for secondary MR with LV dysfunction. The recent emergence of percutaneous interventional approaches in treating MR has expanded therapeutic options for patients who are at high risk for conventional Mitral Valve (MV) surgery. In this chapter, we will review the novel advancements in the field of percutaneous MV interventions that could potentially become the standard of care for patients with MR and heart failure.

Keywords

Mitral regurgitation · Heart failure · Percutaneous mitral valve intervention · Leaflet repair · MitraClip · Chordae repair · Direct annuloplasty · Left ventricle remodeling · Transcatheter mitral valve replacement

1 Introduction

Mitral regurgitation (MR) is the most prevalent VHD and is an important cause of congestive heart failure (CHF). MR affects up to 2% of the general population, with an incidence increasing with age. Approximately 10% of population older than 70 years of age is affected by MR

The original version of this chapter has been revised. An erratum to this chapter can be found at https://doi.org/10.1007/5584_2018_204

(Jones et al. 2001). MR can be caused by primary abnormality of the valve apparatus (degenerative/primary) or it can be secondary to cardiomyopathy (functional/secondary). Degenerative MR is relatively uncommon, found mostly in younger patients and is potentially curable with repair of the damaged valve. Functional MR in comparison is caused by left ventricular (LV) dysfunction leading to mitral annular dilatation, tethering of the valve and inadequate leaflet coaptation (Nishimura et al. 2014; Hammerstingl et al. 2013; Kaul et al. 1991). Because valve abnormality is not the primary pathology in functional MR, valve surgery by itself is not curative but can help ameliorate symptoms.

Severe MR leads to progressive LV dysfunction and CHF (Trichon et al. 2003). Without intervention, symptomatic patients have an annual mortality of ≥5% (Carabello 2008; Carabello 2009). Medical management may alleviate symptoms but does not alter progression of the disease (Carabello 2008). Current practice guidelines recommend valve surgery for severe MR in patients with symptoms or evidence of LV dysfunction (American College of Cardiology/American Heart Association 1998; Bonow et al. 2006; Bonow et al. 2008). A substantial proportion of patients with severe symptomatic MR are not offered valve surgery despite clear indications (Bach et al. 2009; Mirabel et al. 2007; Vahanian et al. 2012). The reasons for this lack of surgical referral include high surgical risk from advanced age or multiple comorbidities, and lack of clear data supporting valve surgery for secondary MR with LV dysfunction (Bach et al. 2009; Mirabel et al. 2007; Vahanian et al. 2012). The advent of percutaneous approaches to treating MR has expanded therapeutic options for patients who are at high risk for conventional MV surgery. In this chapter, we will discusses the novel advancements and the future developments in the rapidly expanding field of percutaneous MV interventions that could potentially become the standard of care for patients with MR who are unable to undergo traditional surgery.

2 Mitral Regurgitation and Heart Failure

Normal MV function depends on a balance between closing forces of LV contraction and tethering forces of the papillary muscles (Levine and Hung 2003). MR results when this balance is perturbed by abnormalities of the valve itself or those resulting from cardiomyopathy- annular dilation, leaflet tethering, and loss of force and/or synchrony of LV contraction [Ref]. In the early stages of chronic MR, the resulting volume overload is tolerated until the left atrium reaches its maximum compliance, beyond which symptoms start to develop. A vicious cycle develops, as the regurgitant volume in the left atrium returns to the LV during diastole, resulting in LV volume overload and progressive LV dilatation with subsequent fall in LV ejection fraction. Progressively, chamber dilatation results in annular dilation, lateral and apical displacement of the papillary muscles, and malcoaptation of the mitral leaflets (Gaasch and Meyer 2008).

Papillary muscle displacement may occur because of global LV enlargement or focal myocardial scarring, and can affect one or both papillary muscles (Ray 2010). With chronic MR, the mitral leaflet area may increase up to 35% over time, an adaptive response that minimizes the degree of regurgitation; insufficient leaflet remodeling may contribute to severe MR (Chaput et al. 2008; Saito et al. 2012). However, even in patients with increased mitral leaflet area, papillary muscle displacement with subsequent decreased coaptation length may still result in significant MR (Saito et al. 2012). The normal saddle-shape of the annulus is also important for maintaining normal leaflet stress (Dal-Bianco and Levine 2013). Loss of this shape and annular flattening with LV remodeling result in increased

leaflet stress with secondary MR. In addition, LV systolic dysfunction reduces the strength of MV closing, which opposes the leaflet tethering forces created by papillary muscle displacement. These pathological changes culminate in failure of leaflet coaptation and decreased valvular closing forces due to LV dysfunction, resulting in MR and propagating the vicious cycle of heart failure and MR.

3 Treatment Options

The goals of therapy for patients with MR and heart failure are aimed at reducing symptoms, increasing exercise capability, improving quality of life (QoL) and decreasing MR-associated complications. There is considerable debate regarding the optimal approach, timing of intervention, indications, and efficacy of interventions. Treatment options include medical therapy and valvular interventions, which include surgery and percutaneous MV repair/replacement. Patients with functional MR caused by ischemic cardiomyopathy undoubtedly benefit from revascularization while cardiac resynchronization therapy (CRT is recommended for suitable patients with CHF who meet guideline criteria.

4 Medical Therapy

The most recent American College of Cardiology/American Heart Association/ (AHA/ACC) guidelines on valve disease recommend guideline-directed medical therapy (GDMT) as the first-line treatment for patients with MR and CHF, although the morbidity and mortality for patients with LV dysfunction and secondary MR remain high (Nishimura et al. 2014). Angiotensin-converting enzyme inhibitors or angiotensin receptor blockers, beta blockers, aldosterone antagonists, and diuretic agents should be considered for all patients with CHF. In the absence of LV dysfunction or CHF symptoms, there is little evidence that vasodilators are useful for treatment of the MR (Nishimura et al. 2014; Seneviratne et al. 1994)

5 Cardiac Resynchronization Therapy

CRT is a well-established treatment in select CHF patients with LV dyssynchrony (Cleland et al. 2005). In addition to improving CHF outcomes, it is shown to improve secondary MR from resynchronization of LV contraction (Madaric et al. 2007). Improved myocardial contractility increases closing forces of the MV while reverse LV remodeling reduces leaflet tethering by improving LV geometry (Breithardt et al. 2003; Abraham et al. 2002). Unfortunately, severe secondary MR improves in only one-half of patients after CRT, but such improvement identifies a cohort with improved prognosis (Cleland et al. 2005). CRT is a reasonable front-line therapy for secondary MR in CHF patients (along with GDMT), and should be considered prior to surgery or percutaneous valvular intervention.

6 Surgical Intervention

Surgical correction is the gold standard for patients with degenerative MR (Carabello 2008). Valve surgery may be attempted for secondary MR but has never been clearly demonstrated to alter the natural history of the primary cardiomyopathy or improve survival (Wu et al. 2005; Silberman et al. 2006; Calafiore et al. 2013; O'Gara 2012). Although practice guidelines currently recommend MV repair or chordal sparing replacement for functional MR, they do not specify the choice of operation. The 2014 ACC/AHA VHD guidelines contain three recommendations for valve surgery in secondary MR (Nishimura et al. 2014) (Table 1).

Table 1 ACC/AHA valvular heart disease guidelines for surgical management of functional MR

1. MV surgery is reasonable for patients with chronic severe secondary MR (stages C and D) who are undergoing CABG or AVR **[COR- IIa, LOE- C]**
2. MV surgery may be considered for severely symptomatic patients (NYHA class III/IV) with chronic severe secondary MR (stage D) who have persistent symptoms despite optimal GDMT for heart failure **[COR- IIb, LOE- B]**
3. MV repair may be considered for patients with chronic moderate secondary MR (stage B) who are undergoing other cardiac surgery **[COR- IIb, LOE- C]**

AVR aortic valve replacement, *CABG* coronary artery bypass graft, *COR* class of recommendation, *LOE* level of evidence, *MR* mitral regurgitation, *MV* mitral valve

7 Percutaneous Intervention for MV

Several transcatheter technologies mimicking surgical techniques of MV repair have emerged for treating high surgical risk MR patients. Whereas transcatheter aortic valve replacement has now become standard of care for high and prohibitive surgical risk patients with aortic stenosis, transcatheter MV replacement has been lagging. The primary deterrent is the unique challenge posed by the non-symmetrical shape of the mitral annulus; which is noncircular, relatively large, dynamic in shape, and subject to cyclical, high LV systolic pressures. In addition, the subvalvular apparatus is complex, is variable in anatomy, and lies in close proximity to the LV outflow tract (LVOT) making it difficult to successfully deploy and anchor a percutaneous prosthesis (Goel et al. 2014). Need for trans-septal puncture and the pathologic heterogeneity of MR further add to these challenges (Table 2).

7.1 Leaflet Repair

The common goal of the various transcatheter mitral leaflet repair techniques is to increase the coaptation surface between the anterior and posterior mitral leaflets. The first and the foremost device in this category is the MitraClip®(Abbott Vascular, Santa Clara, California). This device, CE marked since 2008, has since been used to treated more than 35,000 patients (Ladich et al. 2011; Feldman et al. 2011). The MitraClip is a polyester-covered cobalt-chromium clip inserted via the femoral vein and advanced under transesophageal echocardiographic guidance into the LA following trans-septal puncture. The clip is opened, positioned above the regurgitant jet, and advanced into the LV. It is then retracted to grasp the free edges of the mitral leaflets, the grippers are dropped, and the clip is closed and released, emulating the Alfieri surgical edge-to-edge repair**.** Multiple clips may be safely placed, if necessary. MitraClip is effective to treat both degenerative MR and functional MR. Currently, the MitraClip® is approved by the Food and Drug Administration for transcatheter repair in selected high-risk patients with symptomatic primary and degenerative MR (Goel et al. 2014).

The MitraClip system was initially evaluated in the EVEREST (Endovascular Valve Edge-to-Edge Repair Study) trials (Ladich et al. 2011; Feldman et al. 2011). The EVEREST-II trial randomized treatment of 279 patients in a 2:1 ratio to either MitraClip® or surgery (Feldman et al. 2011). 73% of patients had primary MR, and 27% had secondary MR. At 5 years, the rate of the composite endpoint of freedom from death, surgery, or 3+ or 4+ MR in the as-treated population was lower in the percutaneous repair than the surgical group (44.2% versus 64.3%, respectively; $p = 0.01$) (Mauri et al. 2013). The difference was driven by higher rates of 3+ to 4+ MR (12.3% vs. 1.8%; $p = 0.02$) and more need for surgery (27.9% vs. 8.9%; $p = 0.003$) with percutaneous repair. Patients treated with percutaneous repair more commonly required surgery for residual MR during the first year after treatment, but between 1- and 5-year follow-up, rates of surgery with either therapy were similarly low. Five-year mortality was similar for either treatment strategy. Both MitraClip and surgery

Table 2 Summary of percutaneous interventions for MV in current clinical use or under investigation

Therapeutic target	Device and Manufacturer	Device mechanism of action	MR etiology treated
Leaflet	Mitraclip [Abbott vascular] (Ladich et al. 2011)	Edge-to-edge leaflet plication using a clip, resulting in a double orifice valve	Primary and secondary MR
	PercuPro (MitraSpacer) [cardio-solutions]	Provides a coaptation surface for the leaflets by placing a space occupier across the MV orifice	Primary and secondary MR
	Thermocool SmartTouch [Biosense Webster] (Williams et al. 2008)	Leaflet ablation resulting in reduced motion or structural alteration	Primary MR
	Middle peak [middle peak medical]	Implantation of a posterior neoleaflet	Primary and secondary MR
Chords	NeoChord DS (NeoChord) (Sack et al. 2009; Pedersen et al. 2008)	Artificial chordae implantation anchored to the prolapsed leaflet and the LV apex	Primary MR
	V-chordal [Valtech] (Kim et al. 2009)	Artificial chordae implantation anchored to the prolapsed leaflet and the papillary muscle tip	Primary MR
	Babic [Edward Lifesciences] (Harnek et al. 2011)	Artificial chord implantation anchored to the prolapsed leaflet and the LV	Primary MR
	MitraFlex [Transcardiac therapeutics]	Combination of artificial chord implantation anchored to the prolapsed leaflet and the LV, and edge-to edge leaflet plication using a clip creating a double orifice valve	Primary and secondary MR
Annulus [direct annuloplasty]	Mitralign Bident(Mitralign)	Reducing mitral annulus (MA) circumference by plication of pledgets placed on the posterior MA and connected by a suture	Primary and secondary MR
	AccuCinch GDS (guided delivery systems [GDS])	Reducing MA circumference by implanting a ring of anchors at the posterior annulus interlinked with a cable that can be restrained	Primary and secondary MR
	Cardioband (Valtech)	Reducing MA circumference by anchoring an adjustable partial ring at the posterior MA	Primary and secondary MR
	QuantomCor (QuantomCor) (Rahman et al. 2010; Heuser et al. 2008)	Reducing MA circumference by using radiofrequency energy to cause scarring and constriction of the MA	Primary and secondary MR
	Milipede (Milipede)	Reducing MA circumference by self-expanding ring annuloplasty	Primary and secondary MR
	ReCor [ReCor medical] (Jilaihawi et al. 2010)	Reducing MA circumference by using heat to induce collagen, and thus MA, shortening	Primary and secondary MR

(continued)

Table 2 (continued)

Therapeutic target	Device and Manufacturer	Device mechanism of action	MR etiology treated
Annulus [indirect annuloplasty]/ coronary sinoplasty	CARILLON (cardiac dimensions) (Schofer et al. 2009)	Reducing MA antero-posterior diameter by indirect anterior displacement of the posterior MA following plication of the posterior periannular tissue	Secondary MR
	MONARC (Edwards) (Webb et al. 2006)	Reducing MA antero-posterior diameter by coronary sinus reshaping	Secondary MR
	Mitral cerclage (NIH) (Kim et al. 2009)	Reducing MA circumference by creating a loop around the MA and LVOT anchored to the CS	Secondary MR
	Valcare (Valcare medical) (Sack et al. 2009)	Rigid "D"-shaped annuloplasty using percutaneous annuloplasty ring	Primary and secondary MR
Left ventricle remodeling	Mardil BACE [Mardil medical Inc]	Reducing MA and LV circumference by implantation of a pouch around the heart with a saline inflatable bladder to externally compress the LV	Secondary MR
	PARACHUTE (CardioKinetix)	Ventricular partition of damaged ischemic muscle, isolating the non-functional muscle segment from the functional segment, thereby decreasing the overall volume and restoring a more normal geometry and function in the left ventricle.	Secondary MR
	Coapsys (Myocor) (Grossi et al. 2010)	Transventricular reshaping with 2 extracardiac epicardial pads that are connected by a flexible tether running through transventricular subvalvular space and anchored on the other side of epicardial surface. The chord can be shortened to reduce MR during the operation	Secondary MR
Valve replacement	Caisson TMVR (caisson interventional)	Transfemoral trans-septal MV replacement	Primary and secondary MR
	CardiAQ (CardiAQ) (Swaans and van der Heyden 2013)	Transfemoral trans-septal, self-anchoring MV replacement	Primary and secondary MR
	Cardia AQ 2nd generation (cardia AQ) (Ussia et al. 2016)	Transapical MV replacement. Anchored through leaflet engagement, chordal preservation and annular attachment	Primary and secondary MR
	Tiara (Neovasc Inc) (Cheung et al. 2014)	Transapical device with three bovine pericardial tissue leaflets mounted on self-expanding D-shaped metal alloy frame	Primary and secondary MR
	Tendyne (Tendyne holding) (Lutter et al. 2014)	Transapical self-expanding bovine pericardial valve in-stent with atrial and ventricular fixation	Primary and secondary MR
	High life (HighLife SAS) (Lange and Piazza 2015)	Transatrial MV replacement	Primary and secondary MR

Table 2 (continued)

Therapeutic target	Device and Manufacturer	Device mechanism of action	MR etiology treated
	Medtronic TMVR (Medtronic) (Piazza et al. 2014)	Self-expanding nitinol ring and a cylindrical, tri-leaflet pericardial valve	Primary and secondary MR
	Fortis (Edwards) (Abdul-Jawad Altisent et al. 2015)	Transapical MV replacement using bovine pericardial tissue and cloth-covered self-expanding frame	Primary and secondary MR
	MitrAssist (MitraAssist)	Transventricular or transapical prosthesis positioned within native valve	Primary and secondary MR
	CardioValve (Valtech)	Transfemoral, trans-septal two-step MV replacement system	Primary and secondary MR
	Navigate TMVR (NCSI)	Self-expandable MV replacement device featuring a nitinol stent and dehydrated tissue	Secondary MR

demonstrated sustained reductions in mitral regurgitation and improvements in functional class and LV dimensions compared with baseline.

Although currently approved for only degenerative MR in the US, data from registries have demonstrated high rates of procedural success and favorable short-term outcomes in high or prohibitive risk patients with functional MR in large patient cohorts. The REALISM (Real World Expanded Multi-center Study of the MitraClip System Continued Access) study was a prospective, multicenter, continued access registry to collect data on the real-world use of the MitraClip device with high-risk (estimated STS PROM $\geq$12%) and non-high risk arms. Recently, aggregate data from the REALISM and EVEREST-II High Risk registries on 351 patients with symptomatic $\geq$3+ MR (functional MR = 70%) was published (Glower et al. 2014). 327 of 351 patients completed 12 month follow-up. MitraClip reduced MR to less than 2+ in 86% of patients at discharge ($P < 0.0001$). Major adverse events at 30 days included death in 4.8%, myocardial infarction in 1.1%, and stroke in 2.6%. At 12 months, 84% of patients had less than 2+ MR and rate of surgery was 2.2%. Significant improvements were seen in NYHA functional class and QoL scores (Glower et al. 2014). Among the 127 patients with degenerative MR, initial success rate was 95% and 30-day mortality was 6.3%. Although the 1-year mortality rate of 23.6% was high, it reflects the patients' baseline comorbidities. Importantly, 57.5% demonstrated New York Heart Assosication (NYHA) functional status of I or II at 1 year compared with only 12.6% with NYHA I or II at baseline.

The TRAMI (Transcatheter Mitral Valve Interventions) study is the largest published registry evaluating transcatheter MV repair conducted at 20 centers in Germany enrolling 1064 patients (Schillinger et al. 2013). The median age was 75 years; 87% had NYHA functional class III/IV CHF symptoms; 69% had LVEF <50%; secondary MR was present in 71% of patients; and the median STS score was 10%. Procedural success was achieved in 95% of patients, with no procedural deaths. At 3-month follow-up, although 12% of patients had died and 12% had been hospitalized for CHF; 66% remained in NYHA functional class I/II (Schillinger et al. 2013). At 1 year follow up, out of 749 (90.5%) patients that were available for

follow-up, the mortality rate was recorded to be 20.3%. and 63.3% of patients pertained to NYHA functional classes I or II (compared with 11.0% at baseline). Importantly, a significant proportion of patients regained the complete independence in self-care after MitraClip implantation (independence in 74.0 vs. 58.6% at baseline) (Puls et al. 2016)

In the ACCESS-EU (MitraClip Therapy Economic and Clinical Outcomes Study Europe) registry, the MitraClip was implanted in 567 patients at 14 sites across Europe (Puls et al. 2016). The mean logistic EuroSCORE was 23, and 77% of patients had secondary MR. The clip implant rate was 99.6%, with multiple clips used in 40% of patients. MR was reduced to $\leq$2+ in 91% of patients, and there were no procedural deaths. NYHA functional class and 6-min walk distance (6MWD) substantially improved at 1-year follow-up (Maisano et al. 2013).

The efficacy of the MitraClip device in inoperable patients with secondary MR is currently being evaluated in randomized controlled trials. The COAPT (Clinical Outcomes Assessment of the MitraClip Percutaneous Therapy) trial, RESHAPE-HF (MitraClip Device in Heart Failure Patients with Clinically Significant Functional Mitral Regurgitation) and MITRA-FR (Multicenter Study of Percutaneous Mitral Valve Repair MitraClip Device in Patients With Severe Secondary Mitral Regurgitation) studies will compare MitraClip device to standard GDMT in CHF patients with functional MR.

Other leaflet repair techniques are currently under clinical development. These include leaflet ablation for primary MR that aims to structurally alter leaflet anatomy and reduce leaflet motion (Thermocool irrigation ablation electrode), the implantation of a posterior neoleaflet to restore leaflet coaptation in either functional or degenerative MR (Middle Peak Medical) as well as an indirect approach to improve leaflet coaptation by filling of the coaptation gap between the anterior and posterior leaflet using a space occupier device across the mitral annulus (Percu-Pro MitraSpacer).

7.2 Chordae Repair

Transcatheter implantation of adjustable synthetic chordae tendinae to restore leaflet coaptation in patients with MR due to flail leaflets is currently under development. By adjusting the length of the chord, the MR can be reduced or abolished. The NeoChord uses a mini-thoracotomy transapical approach to capture the leaflet, and the chords are then exteriorized, adjusted, and tightened to the LV myocardium. This technology is mainly designed for degenerative MR with posterior leaflet prolapse. The V-Chordal system (Valtech Cardio Ltd., Or Yehuda, Israel) uses a slow rotation of a helical element to attach the chordae to the papillary muscle. The chordae are then sutured to the through a minithoracotomy left atriotomy approach. A clip attaching mechanism is under development, to allow for transfemoral access.

The Babic device creates two continuous guiding tracks from the LV puncture site through the target leaflet. The device is then exteriorized via the transseptal catheter and femoral vein. A polymer loop is apposed onto the venously exteriorized guiding tracks via docking adapters and is anchored onto the atrial leaflet surface by retracting the guiding tracks from the epicardial end. An elastic polymer tube is interposed between the leaflet and the free myocardial wall and secured to the epicardial surface by an adjustable knot. The MitraFlex device places an anchor in the inner LV myocardium and another on the leaflet via a transapical approach and connects the two with a synthetic chord; it can also perform an edge-to-edge repair at the same time.

7.3 Direct Annuloplasty

Transcatheter MV annuloplasty techniques attempt to abolish MR by reducing MV annulus circumference in an effort to increase leaflet coaptation. In the direct annuloplasty techniques; the posterior mitral annulus is targeted and the

mitral annulus is approached either from the left atrium (LA) through a transseptal approach or transapically via the LV. An attempt is made to reduce the mitral annulus circumference by implanting adjustable rings or purse-string sutures that cinch the mitral annulus or by delivering radiofrequency energy that shrinks the mitral annulus by creating a scar. Presence of annular calcification or causing potential damage to circumflex artery or valve leaflet poses challenge to successful direct annuloplasty.

The Mitralign device uses a retrograde transfemoral approach via the aortic valve into the LV to deliver pairs of pledgets which anchor through the posterior annulus. Each pledget pair can be cinched to achieve selective plications of the annulus and more than two pairs of pledgets can be implanted along the posterior annulus. Mitralign Percutaneous Annuloplasty first in man study was reported in 71 patients with moderate to severe Functional MR. Device success rate was 70.4% (n = 50 of 71). 30 day (n = 45) and 6-month (n = 41) rates for all-cause mortality, stroke, and myocardial infarction were 4.4%, 4.4%, and 0.0% and 12.2%, 4.9%, and 0%, respectively. At 6 months, non-urgent mitral surgery was performed in 1 patient (2.4%) and non-urgent percutaneous repair in 7 patients (17.1%). Core lab echocardiographic analysis showed MR reduction in 50% of treated patients by a mean of 1.3 grades after 6 months. There was significant reduction of anterior-posterior (–0.31±0.4 cm) and septal-lateral dimensions (–0.21±0.3 cm), a decrease in MV-tenting area (–0.57±1.1 cm^2) and increase in MV coaptation length (0.13±0.2 cm). Reverse LV remodeling with reduction of LV end-diastolic diameter (–0.20±0.4 mm) and volume (–22±39 ml) was also seen. Treatment was associated with significant improvement in 6 MWD (56.5±92.0 m) and improvements in NYHA functional class at 6 months (Nickenig et al. 2016).

The Accucinch (Guided Delivery Systems, Santa Clara, California) annuloplasty system which is also delivered via a retrograde transfemoral route, is designed to implant a series of anchor elements circumferentially under the posterior mitral annulus, from trigone to trigone. All anchors are connected by a cable that is used to cinch the annulus and the basal portion of the LV to reduce annulus circumference and MR. The feasibility and the safety of the device was shown in 10 patients, with no conversion to surgery and no 30- day major events; however, mitral regurgitation reduction was inconsistent (Kleber 2012).

The Cardioband system (Valtech Cardio, OrYehuda, Israel) is a transcatheter-implantable surgical-like ring which utilizes placement of a series of small corkscrew anchors on the atrial side of the left atrium. The anchors are connected by a Dacron sleeve that can be subsequently tensioned to reduce the mitral annular circumference. It is delivered anterograde via the right femoral vein through a transseptal puncture. Results in 15 swine using a transatrial access have been promising (Maisano et al. 2012) and recently early (1 month) outcomes of the first-in-man pre-CE-mark feasibility and safety trial were reported (Maisano et al. 2016). .The study enrolled 31 high-risk adult individuals with symptomatic functional mitral regurgitation (MR) despite optimal medical therapy, and who received the full implant of a Cardioband. Adjustment of the Cardioband resulted in significant reduction in the septolateral dimension in all but two patients (septolateral dimension from 36.8+4.8 to 29+5.5 mm after the procedure, $P < 0.01$). Following Cardioband adjustment (29 of 31 patients) MR was none or trace in 6 (21%), mild in 21 (72%), and moderate in 2 (7%) patients. No patient had severe MR after adjustment. Procedural mortality was zero and in-hospital mortality was 6.5% (2 of 31 patients, neither procedure nor device related). At 30 days, 22 of the 25 patients (88%) had MR $\leq$2+ (Maisano et al. 2016).

Another device in this category, the Millipede (Millipede, LLC, Ann Arbor, Michigan) is a repositionable and retrievable ring fixing the entire mitral annulus placed via a percutaneous or minimally invasive approach.

Several radiofrequency energy based annuloplasty techniques are in various stages of development. The QuantumCor (QuantumCor, Lake Forest, California), placed by the transseptal route, consists of a 40-mm loop with

7 electrodes and 14 thermocouples. RF energy is delivered to the circumference of the mitral annulus leading to tissue scarring and reduction of the mitral annulus dimensions, thereby improveming leaflet coaptation and reducing MR (Rahman et al. 2010; Heuser et al. 2008).

7.4 Indirect Annuloplasty/Coronary Sinoplasty

Percutaneous indirect mitral annuloplasty systems use implantable wires or systems placed through the coronary sinus to indirectly shrink the posterior mitral annulus and reduce MR. Although less invasive, this approach has some important limitations – (1) The CS is at a variable distance from the mitral annulus which is frequently increased in case of severe MR with annular dilation thereby reducing chances of successful abolition of MR (Maselli et al. 2006) (2) Left circumflex coronary artery compression has been frequently observed with this procedure (Sponga et al. 2012).

The Carillon Mitral Contour System, the most popular device in this category, consists of a nitinol device with two anchors connected by a bridge. After cannulation of the coronary sinus, the distal anchor is positioned at the end of the great cardiac vein in close vicinity with the anterolateral commissure of the MV and the bridge is retracted to plicate the posterior mitral annulus under fluoroscopy and TEE guidance. The device is placed percutaneously via the right internal jugular vein approach and can be easily retrieved if MR reduction is not favorable or coronary artery compromise develops. The device has undergone several design modifications to prevent slippage during implantation and now has reinforcement at its ends to prevent late fracture. Once significant MR reduction is achieved, the proximal anchor is deployed in the selected position. Due to the associated risk of impingement of the circumflex coronary artery, coronary angiography is performed throughout the deployment.

The CARILLON Mitral Annuloplasty Device European Union Study (AMADEUS) was the first to assess the safety and efficacy of the Carillon device (Schofer et al. 2009). Forty eight patients with dilated cardiomyopathy, moderate to severe FMR, an EF $<$ 40%, and a 6MWD between 150 and 450 m were enrolled in the study. Eighteen patients did not receive a device because of access issues, insufficient acute FMR reduction, or coronary artery compromise. Major adverse event rate was 13% at 30 days. At 6 months, the degree of FMR reduction ranged from 22% to 32%. 6MWD improved from 307+/−87 m at baseline to 403+/−137 m at 6 months ($P < 0.001$). Quality of life, measured by the Kansas City Cardiomyopathy Questionnaire, improved from 47+/−16 points at baseline to 69+/−15 points at 6 months ($P < 0.001$) (Siminiak et al. 2012). The Transcatheter Implantation of Carillon Mitral Annuloplasty Device (TITAN) trial was a prospective nonrandomized trial in which 53 patients with symptomatic FMR were enrolled for CARILLON device therapy (Siminiak et al. 2012). Thirty-six patients received a permanent implant; 17 had the device recaptured. Patients in whom the device was placed then acutely recaptured for clinical reasons served as a comparator group. Safety and key functional data were assessed in the implanted cohort up to 24 months. The 30-day major adverse event rate was 1.9%. In contrast to the comparison group, the implanted cohort demonstrated significant reductions in FMR as represented by regurgitant volume [baseline 34.5 ±11.5 mL to 17.4 ±12.4 mL at 12 months ($P < 0.001$)]. There was a corresponding reduction in LV diastolic volume [baseline 208.5 ±62.0 mL to 178.9 ±48.0 mL at 12 months ($P = 0.015$)] and systolic volume [baseline 151.8 ±57.1 mL to 120.7 ±43.2 mL at 12 months ($P = 0.015$)], compared with progressive LV dilation in the comparator group. The 6MWD markedly improved for the implanted patients by 102.5 ±164 m at 12 months ($P = 0.014$) and 131.9 ±80 m at 24 months ($P < 0.001$) (Siminiak et al. 2012).

The Cerclage System creates a loop around the mitral annulus and the LV outflow tract (LVOT), entering through the CS ostium, passing through the anterior interventricular vein and returning near the CS ostium, perforating the myocardium either coming out in the right

ventricle and passing through the anterior tricuspid commissure, or directly coming out through the septum in the right atrium; the loop is then tightened and secured near the CS ostium (Kim et al. 2009). Different from the other coronary sinus devices, the Cerclage system allows for circumferential remodeling of the mitral annulus. The development of other indirect percutaneous mitral annuloplasty devices such as the Edwards Monarc and the Viacor was halted due to the relatively high rate of device-related adverse events including circumflex artery occlusion and fatal CS perforation (Noble et al. 2011; Machaalany et al. 2013).

7.5 Left Ventricle Remodeling

LV remodeling devices improve mitral leaflet coaptation and reduce functional MR by restoring LV shape and reducing mitral annulus dimensions. These technologies force reduction of the septo-lateral annular dimension through approximation of two devices connected by a bridge. The Mardil-BACE (Mardil, Inc., Morrisville, North Carolina) is a silicone band with an inflatable chamber that is slipped externally around the atrio-ventricular groove of the beating heart without cardiopulmonary bypass through a mini thoracotomy. The chamber can be inflated by saline through subcutaneous ports, and their volume can be adjusted intra- and postoperatively, thus remodeling the MV annulus and the sub-valvular apparatus. The surgical device seems effective in reducing functional MR and a percutaneous development is ongoing (Raman et al. 2011).

The Myocor i-Coapsys device consists of two epicardial pads (anterior and posterior) connected by a load-bearing transventricular chord, all deliverable through a port inserted in the pericardium via a percutaneous sub-xiphoid approach [Fig. 7]. Under TEE guidance the flexible cord is shortened to reduce the LV and mitral annulus anteroposterior dimension, improving leaflet coaptation and MR. In the Randomized Evaluation of a Surgical Treatment for Off-Pump Repair of the Mitral Valve (RESTORE-MV) trial, 165 patients were randomly assigned to undergo CABG with or without Coapsys ventricular reshaping. Patients treated with the device had greater reductions in LV end-diastolic diameter, and lower mortality at 2 years, compared with the conventional annuloplasty control arm. A percutaneous approach was developed but despite the positive results of the trial, this device is no longer manufactured as the sponsor failed to secure funding (Grossi et al. 2010).

7.6 Percutaneous MV replacement

Transcatheter mitral valve replacement (TMVR) systems that can replace or be implanted into the native valve may be a feasible solution to treat MR independently of the underlying mechanism and have the potential to become an alternative to treat severe MR in high surgical risk patients. One of the many key obstacles in designing successful TMVR is anchorage of the bioprosthesis to the mitral annulus because of difficulty anatomy of mitral valve. Although these procedures were technically successful, the clinical outcomes have been mixed. Several of these devices are under clinical development.

The CardiAQ-Edwards transcatheter MV implantation system consists of a self-expanding trileaflet bovine bioprosthesis mounted on a nitinol frame. The foreshortening frame that allows for controlled deployment and self-positioning within the native mitral annulus preserving mitral leaflets and chordae, LV contractility. The valve can be implanted through a transseptal or transapical route and no rotational alignment is required. Supra-annular implantation avoids LVOT obstruction and a polyester skirt reduces risk of paravalvular leak. The first human implantation was in 2012 and the RELIEF prospective registry is currently ongoing and plans to recruit 200 patients to assess the safety of this device [Ref]. The FORTIS which consisted of a bovine pericardial valve within a cloth-covered self-expandable frame and a unique anchoring system to minimize

paravalvular leakage. The trial was terminated after a high incidence of valve thrombosis was noted and the valve is not currently available.

The Neovasc Tiara device consists of a trileaflet bovine pericardial valve on a self-expanding nitinol frame. The D-shaped orifice conforms to the saddle shape of the mitral annulus. The flat part of the frame is positioned anteriorly avoiding impingement of the LV outflow tract. The ventricular part of the valve has a covered skirt structure that prevents paravalvular leakage and 3 anchors (2 anteriorly to the trigone and 1 behind the posterior mitral leaflet) that stabilize the position of the valve within the mitral annulus along with the atrial flange. The valve is implanted through a transapical approach, and the valve is retrievable and repositionable. Initial clinical experience has been encouraging and a feasibility study will enroll 30 patients (Banai et al. 2012).

The Tendyne is a transcatheter transapical self-expanding nitinol prosthesis supporting a trileaflet porcine pericardial valve (effective orifice area of >3.2 cm^2, 34 Fr delivery sheath). Novel aspects of the Tendyne device include an outer D-shape with an asymmetric sealing cuff and a braided polyethylene tether that helps to anchor the prosthesis to an apical epicardial pad [Fig. 8]. Recently, the authors published the global feasibility data for the device in 30 patients with symptomatic MR and high surgical risk (Banai et al. 2012). Patients (mean age 76 years, 83% male) had a mean Society of Thoracic Surgery predicted risk of mortality of 7.3%. The majority (77%) had secondary MR and nearly one-half had LV EF of $<50\%$. The device was successfully implanted in 28 patients (93%) and was retrieved without complications in the other 2 patients. Grade 0 MR was reported in all but 1 patient. There were no device embolizations, no strokes, and no LV outflow tract obstruction. At 30 days, there was 1 death due to pneumonia and only 1 patient had mild MR. Overall freedom from major adverse events was 83%, and there was significant improvement in NYHA functional class, walk time, and QoL (Muller et al. 2017).

The Intrepid TMVR is a tri-leaflet bovine pericardial valve within in a self-expanding nitinol frame delivered transapically using a 33 Fr sheath The frame consists of a circular inner stent housing a 27-mm valve, and a conformable outer fixation ring (available in 3 sizes) which engages the mitral annulus. The outer fixation ring is designed to accommodate the variability of the native mitral annulus and facilitates anchoring through a 'champagne cork' like effect. The native leaflets and chordae are preserved and leveraged to seal around the device.

8 Conclusion

Transcatheter techniques for mitral regurgitation are still largely in their infancy but hold great promise for the management of select high-risk patients with severe MR who otherwise have a grave prognosis. MitraClip has emerged as a durable alternative to surgery in selected high-risk population groups and is currently approved in the US for patients with symptomatic primary MR. Encouraging progress has also been made in transcatheter MV replacement despite the technical challenges posed by the complex anatomy of the MV and the subvalvular apparatus. Progression from conventional surgery through minimally invasive surgery to transcatheter therapies can be viewed as a natural and inevitable procedural evolution. Further research involving a wider spectrum of patients and devices would shape the future of this exciting field of cardiology.

Conflict of Interest None.

Left Ventricular Assist Devices – A State of the Art Review

Christina Feldmann, Anamika Chatterjee, Axel Haverich, and Jan D. Schmitto

Abstract

Cardiovascular diseases are the leading cause of mortality rates throughout the world. Next to an insufficient number of healthy donors, this has led to increasing numbers of patients on heart transplant waiting lists with prolonged waiting times. Innovative technological advancements have led to the production of ventricular assist devices that play an increasingly important role in end stage heart failure therapy. This review is intended to provide an overview of current implantable left ventricular assist devices, different design concepts and implantation techniques. Challenges such as infections and thromboembolic events that may occur during LVAD implantations have also been discussed.

Keywords

End-stage heart failure · Mechanical circulatory support · Ventricular assist device · VAD

Keywords and Abbreviations

VAD	Ventricular assist device
LVAD	Left ventricular assist device
RVAD	Right ventricular assist device
BVAD	Biventricular assist device
UMTS 3G	Universal Mobile Telecommunications System, 3. Generation
FDA	U.S. Food and Drug Administration
CE	Communauté Européenne
HTx	Heart transplantation
NYHA	New York Heart Association
INTERMACS	Interagency Registry for Mechanically Assisted Circulatory Support
ICS	Intercostal space

1 Introduction

Cardiovascular disease is the leading cause of worldwide morbidity rates. Chronic ischemic heart disease, acute heart failure and myocardial infarction are among the primary causes of mortality in Europe (45% of all deaths), the United States of America (34,3%) and worldwide (45% of noncommunicable diseases) (Lloyd-Jones et al. 2010; WHO|NCD mortality and morbidity [Internet] 2016; Wilkins et al. 2017).

There are different options for treating heart failure depending on the severity, cause and course of heart failure. They include adjustments to patients lifestyle (e.g. more sports, diet), drug administration and surgical interventions.

Surgical therapies includes but are not limited to coronary artery bypass grafting, implantation of stents in affected coronary arteries, the repair or replacement of an failing heart valve and finally the heart transplantation, which serves as a gold standard for terminal end stage heart failure in refractory patients. The discrepancy between the number of patients waiting for a heart transplant and the number of donor hearts at hand, shows that this therapy is not available for everyone who needs it (Eurotransplant – Statistics [Internet] 2016). Implantation of long term left ventricular assist devices, offers an alternative treatment for patients falling in this gap or are not eligible for heart transplantation for reasons like comorbidities (Mancini and Colombo 2015). According to the seventh INTERMACS annual report, over 13,000 patients received implants for left ventricular support in the United States of America in 2014, out of whom 955 were implanted pulsatile flow LVADs and 12,030 – continuous flow LVADs respectively (Kirklin et al. 2015). Next to these implantable long term VADs, there are catheter-based, para- and extracorporeal blood pumps. Catheter based rotational pumps like Impella 2.5, RP (Abiomed) or HeartMate PHP (Abbott) provide temporary mechanical circulatory left of right ventricular support in case of e.g. acute cardiogenic shock or percutaneous coronary intervention. Paracorporeal systems, like Excor (BerlinHeart GmbH) are mainly implanted in children with heart failures. Other blood pumps (peristaltic or rotary pumps, e.g. Rotaflow, Maquet, or Centrimag, Abbott) are used in extracorporeal membrane oxygenation systems (ECMO) or heart lung machines for short and midterm support of the circulatory system. Despite this high variety of blood pumps in mechanical circulatory support, this chapter offers a focused overview of the current implantable, rotary left ventricular assist devices (LVAD, also abbreviated as VAD), along with their characteristic designs and implantation strategies. Current challenges involving LVAD implantation have also been discussed.

2 Left Ventricular Assist Devices – Indications and Implantation

A left ventricular assist devices (LVAD) is used for hemodynamic support of the left ventricle in patients suffering from terminal refractory left ventricular failure.

Heart failure standard of care in the form of mechanical circulatory support by left ventricular assist devices may differ between countries and is often dependent on the funding available for LVAD implantation programs (Birks 2010). The clinical indications for VAD implantation may vary with patients. Such indications include VAD support either until a suitable donor heart is transplanted (bridge to transplant or BTT), or until the patient stabilizes such that eventual entry on the heart transplant waiting list is possible (bridge to candidacy or BTC), or until a decision on further treatment options for patient into question can be made (bridge to decision or BTD). VAD implantation may also serve as an alternative lifelong treatment for patients on cardiac transplant lists (destination therapy or DT) or until myocardial recovery occurs (bridge to recovery or BTR). The LVAD is then usually explanted, in other cases it remains in place, the outflow graft is ligated and the driveline is removed (Rodriguez et al. 2013; Frazier et al. 2015; Khvilivitzky et al. 2012). A special application of LVADs is the support of both, the left and the right ventricle (biventricular assist device, BVAD) or as a total artificial heart (TAH). Both implantation scenarios are very rare and off-label uses (Frazier et al. 2010). The distribution between the implantation purposes differ from country to country mainly due to approval status of the devices and availability of donor hearts. As stated by the INTERMACS registry, the distribution between BTT, BTR and DT implantations were 53.5%, 45.7%, and 0.2% respectively in 2014 in the US (0.5% of all implantation were rescue and other) (Kirklin et al. 2015). This chapter focuses on long-term, implantable VAD system with the main implantation purpose BTT, BTR and DT.

Costs of LVAD therapy depends on several entries like device costs, hospitalization frequency, duration, costs, as well as follow-up length and costs. Literature presents wide spread data for total LVAD costs and should be interpreted carefully. Total LVAD costs found in literature ranges from $316,078 to $1,025,500 (Seco et al. 2017), a German-French group presented accumulated 2-years costs of €281,361 ± 156,223 (Aissaoui et al. 2017). The key component of a ventricular assist device is the blood pump. The pump establishes a parallel blood flow path (ventricles > cardiac support pump > aorta ascendens) to physiological bloodstream (ventricles > aortic valve > aorta ascendence). The pump draws blood from the left ventricle by an inflow cannula which is connected to the apex by a suture ring with a fixing and sealing mechanism, and giving it back into the systemic circulation by means of an outflow graft. Typically the outflow graft is sewn to the ascending aorta. In a few cases it can also be useful to anastomose the descending aorta (Zucchetta et al. 2014). The blood pump is connected with a powersupply by means of a cable (driveline). The driveline passes from the pump, through the musculus rectus abdomini and fascial layers into the abdominal region of the patient. The cable exits the body through a small incision in the skin (Slaughter et al. 2010). The cable sheath (usually made of silicone or polyurethane) is covered in the implanted part with a woven or non-woven material, which ensures an optimal ingrowth (Dean et al. 2015; Camboni et al. 2016). The driveline is immobilized close to the exit site to the skin by means of a fixing system and to protect the exit site from mechanical manipulation. The exit site of the cable is protected from possible infections, by a mandatory sterile dressing. The pump is externally connected to a control unit (controller). Constant power supply through the controller is ensured either by two batteries or a battery and an AC adapter. Some VAD manufacturers still offer other options, such as a 12 V AC adapter, which provides power supply through a car battery. Peripheral components (such as controller and batteries) may be carried in a portable system (a bag, rucksack, etc.), giving the patient mobility for several hours. To enable constant power supply the patient receives a replacement controller and spare batteries. The batteries are charged at home using a special battery charging station.

Additional devices for adjusting the VAD-speed and other VAD parameters are available at the clinical centers: Every complete VAD system contains a monitor which can be connected to the controller with a cable. One manufacturer (ReliantHeart, Inc.) provides an additional remote monitoring system that transmits the VAD parameters to a server by means of a UMTS mobile phone standard (3G). The parameters can then be accessed by the clinical VAD team using a web-based interface.

The implantation procedure is individual for each VAD type. The Instruction of Use (IFU) of the specific LVAD provides all requirements and implantation and application instructions to be followed by the physician. The following section should give an simplified principle of the implantation steps of VADs:

- The chest is opened by median sternotomy or minimally invasive techniques
- The sewing ring is sutured to the apex with felt pad sutures
- The myocardium within the suture ring is punched out as an access for the inflow cannula (also in reverse order to the fixation of the suture ring)
- The ventricle is checked for thrombi, any existing thrombi are removed
- Positioning and fixation the inflow cannula of VADs in sewing ring
- Placement and anastomosis of outlet graft at the aorta ascendens
- Subcutaneous placement of the connecting cable, with the exit point at the right or left upper quadrant of the abdomen
- Fixation of the cable
- After hemostasis the thorax and the cable exit point are closed and the wounds are dressed

Prior to LVAD application, it is necessary to prepare the pump in the sterile field in the operating room. The sterile system components

removed from the sterile outer packaging are visually inspected for integrity. Inlet and outlet cannula are mounted as required and the driveline is connected to the control unit and power line. A test run is performed in a bowl with sterile dextrose solution. The pump, sewing ring, outflow graft and driveline are usually soaked with antibiotic solution dependent on the pump type.

A default access for pump implantation is full sternotomy. After the pericardium is opened the heart and great vessels are exposed. The heart lung machine (HLM) is cannulated right-atrial and aortic. This approach provides a good overview of the heart and adjacent large vessels, the larger surgical field allows more options for treatment. This approach is favorable, if concomittant interventions such as heart valve replacement and repair, closing of an atrioventricular septal defect or implantation of epicardial pacemaker leads are required.

There are also less invasive techniques available with two access points to the thorax defined by the apex of the left ventricle (pump inlet placement) and upper mediastinum (outlet graft anastomosis) (Schmitto et al. 2014; Hanke et al. 2015). The opening to the apex is performed through a left thoracotomy at the level of the 6th intercostal space (ICS). The exact position of the left ventricular apex and thus the thoracotomy is detected by echocardiography before incision. For the opening of the upper mediastinum two approaches are possible: an upper hemisternotomy that is only partially opening the sternum, or a right-sided thoracotomy at the level of 1–2 ICS. After opening the thorax, the pericardium is only partially opened as far as it is necessary to provide access. The pericardium surrounding the right ventricle is left largely uninspected and the heart remains in its original position. Both facilitate the prevention of a possible right heart failure in the course. This technique is linked to additional benefits such as less adhesion complications, less bleeding complications, shorter ICU stays, potential reduction of infections, and cosmetic aspects. The implantation is performed using an extracorporeal circulation, heart-lung machine (HLM). A cardioplegia of the heart is not always carried out ("beating heart" approach).

There are several strategies for placement and anastomosis of the outlet graft includingthe anastomosis to the descending aorta, and placement of outlet graft in the sinus transversus pericardii or a bulge in the pericardial cavity (Hanke et al. 2016a, b).

The driveline is typically implanted in a large arc in the abdominal fascia and/or in the muscle sheath of the rectus, it exits the body in the abdomen (usually upper right or left quadrant). Here there are different tunneling techniques with one, two or three small incisions to implant the longest possible part of the driveline cable as an infection barrier. The driveline exit site is then supplied with a sterile wound dressing and a cable fixation, which is changed regularly. The patient retains the sterile dressing procedure even after the wound has healed, in order to constantly protect against infection and (micro) injuries (Slaughter et al. 2010; Fleissner et al. 2013).

3 Left Ventricular Assist Device – Design Aspects of the LVAD

Various types of blood pumps are currently used in clinical treatment. These mechanical pumps are used for extracorporeal circulation, as part of a cardiopulmonary bypass, extracorporeal membrane oxygenation system, or dialysis system, as an implantable version for a ventricular assist or as a total artificial heart (Der Deutsche Herzbericht [Internet] 2016). The application timespan can vary from a few hours for the short-term usage up to several years for long-term usage. Depending on the application, blood pumps can be built as positive displacement pumps or rotary pumps. Implantable ventricular assist pumps for long-term applications in terms of LVAD application nowadays employ only rotary pumps and will be discussed in this section. The VADs design implements wide-spread user specification areas, including hemodynamic function, hemo- and biocompatibility, durablility, usability during the implantation and explantation and daily in later handling, storage and transport conditions before implantation and during subsequent application (Girdhar et al. 2012; Schmitto et al. 2014; Geidl et al. 2009; Sabashnikov et al. 2013; Pagani et al. 2009; Schmitto et al. 2015).

The historical development of implantable cardiac assist pumps started with the pulsatile displacement pumps with pneumatic or electromechanical drives from the 1970s ("1st generation"), which, while still paracorporeal, were often not fully implantable. Rotary pumps with mechanical rotor bearings ("2nd generation") came up in the 1980s and 1990s, while last generation ("3rd generation") rotary pumps with contactless bearing concepts were first reported in the 1990s and 2000s (Reul and Akdis 2000; Heart Assist Devices – Texas Heart Institute [Internet] 2016; Tang et al. 2009). The currently approved systems in use for adults are 2nd and 3rd generation systems, which are significantly smaller and lighter than their predecessors from the first generation. They can be implanted in the mediastinum above the diaphragm, smaller pump types may be implanted within the pericardium. These turbine-like machines transmit energy through the swirl on the blood to move the blood forward. The designs vary between axial-flow rotors, diagonal- or mixed-flow rotors, and radial- or centrifugal-flow rotors. In general, as the size and the hydraulic power of axial to radial designs increase, the number of revolutions per minute decreases correspondingly.

The forces acting on the rotor from the blood flow and the motor drive are leveled with a suitable hemocompatible bearing. There are two bearing design principles applicable for for axial, radial or mixed rotor forms: mechanical contact bearings, or free-floating, contactless bearings which may be hydrodynamic, passive-magnetic or active-magnetic.

Mechanical bearings are used in the 2nd generation LVAD, which arefriction type, "lubricated" mechanical bearing forms such as a ball-cup bearing antagonizing axial and radial forces on the rotor. They are relatively easy to manufacture and maintain the rotor stable in its position. Disadvantages of these contact bearings include heat development, high shear forces or insufficient wash out and stagnation areas, resulting in subsequent insufficient haemocompatiblity (hemolysis and thrombus formation). Appropriate operation of the bearing is only assured when completely immersed in blood (or blood substitute).

Wearless rotor bearings are typical for 3rd generation LVADs. Hydrodynamic bearing surfaces are designed to produce a local pressure in a fluid film between rotating rotor and housing, thus creating a fluid force. This is achieved with tilted surfaces or spiral grooves. Such bearings solely operate in moving liquid environments with a specific viscosity range. With increasing rotational speed a fluid film is built up and the bearing functions effectively. Disadvantage of this bearing design includes operating point dependency, narrow gaps, which are required for moderate hydrodynamic forces, subsequent tight manufacturing tolerances, which require a complex and expensive manufacturing process, and generation of high shear stresses on the blood, resulting in elevated blood damage as well as activation of coagulation.

Magnetic bearing types contain permanent magnets or active magnetic systems. While permanent magnet deposits do not produce stable equilibriums of forces and are therefore used mainly in hybrid bearings, active magnetic systems with the help of distance sensors are able to control rotor-position in housing and work with larger rotor to housing gap dimensions. These design characteristics result in excellent hemocompatibility (Loree et al. 2001; Schmitto et al. 2017; Wieselthaler et al. 2010). As far as disadvantages are concerned, complexity (many active components, including sensors and regulation hardware and software) and the associated overall size of pump itself and its external system components should be mentioned. Table 1 provides an overview of actual LVADs in clinical application.

3.1 Additional Components

Along with the pump, additional components and tools complete the LVAD system. Surgical tools include a circular knife or punching system for opening of the left ventricular apex. Depending on the manufacturer and system another tool

Table 1 Information on clinically relevant VADs

LVAD (manufacturer)	Pump type	Generation	CE/FDA approval	Characteristics
HeartAssist 5 (ReliantHeart, Inc.)	Axial	2.	2014/IDE trial	Implantable blood flow sensor, remote monitoring
HeartMate II (Abbott.)	Axial	2.	2005/2010	First continuous VAD with FDA approval
HeartMate 3 (Abbott.)	Centri-fugal	3.	2015/IDE trial	Latest VAD with CE approval
HVAD (Medtronic)	Centri-fugal	3.	2009/2012	First LVAD with minimally invasive implant approval
Incor (BerlinHeart GmbH)	Axial	3.	2003/–	First implantable VAD with active-magnetic bearing
Jarvik 2000 (JarvikHeart, Inc.)	Axial	2.	2005/clinical trial	Retroauricular implantable plug for power supply

Berlin Heart [Internet] (2016), Welcome to Reliant Heart [Internet] (2016), HeartWare [Internet] (2016), Thoratec – Innovative Therapies for Advanced Heart Failure [Internet] (2016), Jarvik Heart Inc. The Jarvik 2000 [Internet] (2016) and Food (2016)

(dynamometric key) is necessary to fix the pump inlet in the sewing ring. For intramuscular and subcutaneous implantation of the driveline, a tunneling tool (trocar) is used, that may be pre-bent and has a tip along with a connecting mechanism for the cable connector. A small incision to penetrate the skin is created with either a surgical standard tool (scalpel or scissors) or a small circular knife, which is included in the pump-set. Finally, a sterile extension cable is often used, which is later removed, in order to connect a non-sterile control unit with a sterile cable in the sterile field.

4 Achievements and Current Research Topics

Since the first use of cardiac assist pumps, physicians and developers have learned a lot about the systems and their interaction with the human body. In addition to improvements and adjustments in patient management and operating techniques, this experience led to numerous technical improvements and new developments which in its turn brought radical changes into the concepts of the blood pump. Fatigue strength was improved immensely with the transition from pulsatile displacement pumps to centrifugal pumps and non-contact bearing concepts. The downsizing of the systems has improved implantability and reduced surgical trauma, especially when combined with new surgical techniques. Advancements in electrical engineering such as battery, microprocessor technology and (electro) magnets have contributed to both the internal and external components of the VAD systems to be smaller and lighter. Though the control and regulation of the pumps have become more complex but also more potent and consequently an increased quality of life for patients could be achieved. The hemocompatibility, biocompatibility and interaction with the (hemodynamic) system were substantially improved by adapting materials and surfaces, rotor and housing design taking into consideration hemodynamics and blood flow in the system including global and local shear stresses as well as residence times. This technical progress has been flanked by new manufacturing and development processes as well as further developments in the field of materials science.

Despite the rapid technical and clinical advancements, LVAD therapy still has to deal with serious complications. As the latest annual report of US-based VAD register INTERMACS (over 15,000 patients included) shows, the overall complication rate has decreased (Kirklin et al. 2015). The rate of hemolysis, strokes, renal dysfunction and lung failure, however, increased. Major complications accompanying the months after implantation include infection, bleeding, system malfunction, stroke or death.

These statistics provide a good overview of the challenges arising during the therapy with implantable cardiac support pumps in the future.

Firstly, it is not enough to focus solely on a technical optimization of the devices, but it also is necessary to examine the relation between the pump and physiology of patients along with a deeper understanding of infections and (anti-) coagulant events. Current research topics deal with new and optimized diagnostic procedures for early complication detection and intervention or complication prevention. Secondly, new technical and/or pharmaceutical therapy options need to be developed to address encountered complications fast and in a conservative manner. The psychological and ethical as well as quality of life aspects of a VAD implantation are addressed in additional research areas. To avoid infection and improve the quality of life of patients with ventricular assist pumps, ongoing work is focused on systems that allow transcutaneous energy transfer (TET). Feasibility was shown in few patients, today's and future developments in battery and pump technology may contribute for successful translation in clinical practice (Mehta et al. 2001). Telemonitoring is another current research topic, which will allow clinicians to view patient data online and thus assist them immediately. As a consequence (as known from other areas of heart failure therapy), patients may benefit from less routine clinic visits, early detection of complications and subsequent early and presumably more safe and cost-saving therapy (Welcome to Reliant Heart [Internet] 2016; johan.van.der.heide[at]itea3.org J van der H. 14003 Medolution [Internet] 2016).

Palliative Care in the Management of Patients with Advanced Heart Failure

Susan E. Lowey

Abstract

Globally, there are 18-million individuals living with heart failure, a disease that is responsible for 12–15 million office visits and 6.5 million inpatient hospitalizations each year. As HF becomes advanced or end-stage, patients often live in a cycle of frequent transitions between care settings, and with unmet needs, including distress from inadequately managed symptoms. Prognostication in patients with heart failure can be challenging due to the unpredictable exacerbating-remitting illness trajectory that is associated with this progressive disease. Recurrent hospitalizations, worsening functional status and refractory symptoms, despite optimal therapies, are among the most salient predictors indicating that patients with advanced heart failure are nearing the end of life. Palliative care is a specialized form of medical care that has been shown to help improve severity of symptoms, facilitate discussions regarding medical decision making/advance care planning, and provide support for patients and their families. Palliative care can be used alongside curative treatments and has been shown to improve patient satisfaction and quality of life. Anorexia-cachexia syndrome, dyspnea, fatigue, pain and depression are among the most common symptoms experienced by patients suffering from advanced heart failure. Palliative care can help alleviate these symptoms and also facilitate conversations about decision making surrounding resuscitation status and use or deactivation of medical devices, such as an implantable-cardioverter-defibrillator (ICD). Clinical practice guidelines from the American College of Cardiology and American Heart Association report that aggressive life-sustaining treatments and therapies should not be utilized in patients with advanced heart failure who have refractory symptoms that are not responding to medical therapy. The focus of care should switch to controlling symptoms, reducing hospital admissions and improving health-related quality of life, which can be supported by the incorporation of palliative care into the treatment plan.

1 Introduction to Advanced Heart Failure

The heart is one of the most complex organs in the body. It is at the center of the circulatory system pumping oxygen-rich blood to all parts of the body (U.S. Department of Health and Human Services, National Heart Lung and Blood Institute 2011). The performance and health of the heart muscle is vital to ensure survival. Over time, the ability of the heart to adequately pump blood to other parts of the body can weaken. It can affect either the left or right side of the heart or both (U.S. Department of Health and Human Services, National Heart Lung and Blood Institute 2015a). This condition is known as heart failure and it is the progressive outcome from a variety of cardiovascular diseases, such as coronary artery disease, hypertension, arrhythmias and cardiomyopathy (U.S. Department of Health and Human Services, National Heart Lung and Blood Institute 2015b). Congestive heart failure occurs when blood backs up into various organs, such as the lungs and kidneys, due to the inefficiency of the heart to pump. This can affect the function of those organs and can cause significant distress from presenting symptoms. Although not all heart failure is classified as congestive, its effects can contribute to a host of adverse symptoms and stressors on the body of those who are affected (American Heart Association 2017a).

According to the American College of Cardiology/American Heart Association (ACC/AHA), the progression of heart failure is categorized into 4 stages (Hunt et al. 2009). Individuals who have risk factors for heart failure but have no structural heart disease are classified as stage A, whereas patients who have risk factors and the presence of asymptomatic heart disease are classified as stage B. Stage C encompasses the largest percentage of patients and includes patients who have active symptomatic disease. Stage D represents advanced or end-stage heart failure and is characterized by the presence of refractory symptoms despite the implementation of available medical therapies (Hunt et al. 2009). This paper will focus exclusively on the management of patients who present with advanced, or stage D, heart failure and the use of palliative care interventions in their overall treatment plan.

1.1 Prevalence

Heart failure has become an all too common chronic illness affecting nearly 6 million people in the United States and nearly 18 million people globally (World Health Organization 2017a). Heart disease is the leading cause of death worldwide affecting men and women alike, regardless of ethnicity or racial origin. Of the 6 million people who are diagnosed with heart failure, approximately 10% have advanced, or stage D, heart failure (American Heart Association 2017b). Heart failure has no cure and although there are treatments available to manage the disease, it is a progressive disorder that will eventually worsen despite the best medical therapies.

This disease is costly, both in terms of mortality and economics. One in every three deaths in the United States is the result of heart disease, contributing to the deaths of 2240 people each day (American Heart Association 2017c). Heart failure is responsible for 12–15 million office visits and 6.5 million inpatient hospitalizations each year (Hunt et al. 2009). According to the American Heart Association, the estimated cost of cardiovascular disease in 2010 was $863 billion and is expected to rise to $1044 billion by 2030 (American Heart Association 2017c). Patients with heart failure live with many distressing symptoms that can affect their functional status and quality of life (Heo et al. 2014). Heart failure affects older adults more than any other age category, with 80% of patients who are hospitalized with this disease aged 65 years or older. The incidence and prevalence of heart failure will escalate alongside the projected growth of the older adult population expected to reach 83.7 million by the year 2050 (United States Census Bureau 2014).

1.2 Illness Trajectories in Advanced Heart Failure

An illness trajectory is the common course or pattern of progression that is associated with a specific type of illness. The term trajectory is defined as "a path or course", therefore illness trajectory can be defined as "a course of illness" and is the usual pattern or progression of an illness or disease (Merriam-Webster 2017a). It is important to understand which illness trajectory is most commonly associated with heart failure in order to be able to anticipate prognosis and inform the patient and family what to expect. Many patients want to know what will happen to them when they are diagnosed with an illness. This is especially true if the disease is not fully curable and the patient will have to live with the illness for the rest of his/her life.

Illness trajectories were first studied by Glaser and Strauss (Glaser and Strauss 1965) who examined the various illness trajectories that people who were dying often went through. Three trajectory types were classified: surprise deaths, expected deaths, and entry-reentry deaths. Surprise deaths were usually unexpected and occur without any warning, such as a car accident. Expected deaths occur in individuals diagnosed with a known terminal illness in which death was the expected outcome with disease progression. Entry-reentry deaths reflect the trajectory that is most aligned with heart failure and describes a typically slower illness trajectory characterized by intermittent acute exacerbations followed by periods of remission. There is a slower decline associated with this type of trajectory and while patients may recover from an exacerbation, they often do not return to their previous level of functioning, losing a little more function with each subsequent exacerbation.

2 Prognostication in Advanced Heart Failure

The exacerbating-remitting illness trajectory can make prognostication difficult in patients with advanced heart failure, as it is difficult to predict with any certainty when the next exacerbation will occur. Prognostication in heart failure can be challenging because of the unpredictability with the course of the illness and severity of exacerbations. Previous research has examined this topic with much variation in their results. In a sample of 1433 patients with advanced heart failure, the estimated 1-year survival was 71.9% (Costanzo et al. 2008) whereas another similar study found the 6-month survival to be only 67% (Allen et al. 2008). The estimated 1-year survival was found to be 25% in a randomized control trial that compared two cohorts of patients; one undergoing destination ventricular assist device (VAD) therapy compared with a cohort receiving only medical management (Rose et al. 2001). Despite this variation, heart failure research has continued to grow and subsequently findings have supported the most salient clinical indicators to help physicians with accurate prognostication of patients with heart failure.

2.1 Predicting Prognosis in Advanced Heart Failure

Although prognostication can be difficult due to an unpredictable illness trajectory and other factors that may be involved, there are several key components that can assist providers with predicting prognosis for a patient with heart failure. Previous research has shown several indicators that strongly correlate with a limited prognosis in patients with heart failure (Reisfield and Wilson 2007). These include: decreased left ventricular ejection fraction equal or less than 45%, elevated blood-urea nitrogen and/or creatinine 1.4 mg/dl or higher, recent cardiac hospitalization, ventricular dysrhythmias that are resistant to treatment, reduced functional status, anemia, hyponatremia, cachexia, and presence of other co-morbidities (Reisfield and Wilson 2007).

More recent research has supported the use of biomarkers for the diagnosis, treatment, and prognostication in patients with heart failure

(Schmitter et al. 2014). Three well-established biomarkers for heart failure include the brain natriuretic peptide (BNP), N-terminal pro-hormone of brain natriuretic peptide (NT-proBNP), and mid-regional sequence of pro-atrial natriuretic peptide (MR-proANP) (Schmitter et al. 2014). Another recent study found increased levels of pro-atrial natriuretic peptide (MR-proANP) to be associated with 10-year all cause mortality and adverse clinical outcomes in community dwelling patients (Odermatt et al. 2017). Since many patients with advanced heart failure die following a visit to emergency care, Lee and colleagues (Lee et al. 2016) conducted the first phase of their ACUTE study to examine the validity of an emergency heart failure mortality risk tool. This will help physicians to accurately identify level of risk among patients who present to the emergency room with symptoms of acute heart failure (Lee et al. 2016).

2.2 Conversations About Goals of Care

Goals of care are the desired outcomes patients have for their medical care and are based on their values and beliefs (Vermont Ethics Network 2011). Goals of care can change over time as patients' circumstances and stage of illness changes and therefore it is important for providers to ask patients about their individual goals of care periodically throughout the illness trajectory. Understanding the unpredictable nature of this the illness trajectory associated with heart failure can be a useful starting point in helping inform patients about what they might expect as their illness progresses. Previous research has demonstrated the lack of these types of conversations early enough in patients' illness trajectories (Hupcey et al. 2016). Often the conversation about goals for care does not occur until the patient is already in the advanced stage of disease. It is important to understand that patients' care preferences may change from a previous hope for a cure and focus on extending length of life, to a new aim on improving comfort and quality of life. When this shift in care preferences occurs, a conversation about the incorporation of palliative care should be initiated.

It is vitally important for providers to have a good understanding about what palliative care is and what it is not, in order to provide accurate and honest information to the patient and family. Family members may be present and involved in conversations about goals of care and there may be discrepancies between what the patient wants and the wishes of the family. Since this can pose a challenge, several family meetings alongside social work, may need to be held before there is resolution in a clear plan of care moving forward. The initiation of palliative interventions can occur alongside of curative medical therapies, and that is an important point to share with patients and families during goals of care conversations.

3 Palliative Care

3.1 Origins of Palliative Care

Palliative care originates from the term "palliate" and is defined as "to reduce the violence of (a disease) and/or to ease (symptoms) without curing the underlying disease" (Merriam-Webster 2017b).

The World Health Organization defines palliative care to be "an approach to care that improves the quality of life for patients with life-limiting illnesses and their families through the prevention and relief of physical, psychosocial and spiritual suffering" (World Health Organization 2014). Although most end-of-life care programs and hospices utilize the underlying philosophy of palliative care, it in itself has become a specialty of care found in over half of all 100+ bed hospitals in the United States (National Hospice and Palliative Care Organization 2014). This equivocates to a 138% increase since the year 2000. Palliative care programs and services are found in both inpatient and outpatient health care settings.

Although palliative care first began alongside the hospice movement, it is its own specialty of care that is widely used by patients who are diagnosed with serious illnesses. It uses a team-based approach to assess and treat adverse symptoms that accompany serious illnesses (National Hospice and Palliative Care Organization 2014). The goal of palliative care is to mitigate or lessen distressing symptoms that affect patients, which will ultimately benefit their quality of life. In addition to a focus on symptom management, palliative care often bridges the gap between medical care and end-of-life care by initiating difficult conversations surrounding prognosis and goals of care. It helps patients with decision making and care planning. Lastly, palliative care helps to provide emotional support for patients and families who are living with serious life threatening illnesses (National Hospice and Palliative Care Organization 2014).

3.2 Provision of Palliative Care

Palliative care can be incorporated into the care of patients who have been diagnosed with a serious life limiting illness. It can be used by patients of any age or alongside any stage of illness because the overarching goal is to improve quality of life (Center to Advance Palliative Care 2011). There is no pre-determined life expectancy required to be eligible to receive palliative care. This differs from hospice care, which requires patients to have a life expectancy of 6-months or less in order to qualify for its services (Center to Advance Palliative Care 2011). Some healthcare organizations may offer one or more sub-specialties of palliative care focused on a specific population. Geriatric and pediatric palliative care are two examples of sub-specialties that focus on improving the quality of life for older adults and children, respectively. Palliative care is covered by Medicare, Medicaid and most private insurances or HMO's (Start the Conversation.Org 2017).

In addition to the requirement of a 6-month life expectancy, the other marked difference between palliative care and hospice are the regulations governing curative versus comfort care. Palliative care can be used alongside life-sustaining or curative treatments in patients who are diagnosed with a serious life limiting illness. This differs from hospice care in that hospice requires patients to forgo all curative or life-sustaining medical treatments and elect to receive solely comfort care measures (National Hospice and Palliative Care Organization 2014).

Palliative care might be a better option than hospice for patients who are living with certain chronic illnesses, such as heart failure. This is because some of the regulations that stipulate what is covered or allowable treatments by hospice may not be consistent with patients' wishes or goals of care. This pertains to patients, such as those with heart failure, who have periodic exacerbations of illness that require inpatient care and the administration of medications that are not routinely covered by hospice because they are considered to be curative in nature. Patients with advanced heart failure may find more benefit with the provision of palliative care interventions alongside their treatment plan rather than electing solely hospice care. This is because many of the interventions routinely used for symptom management are considered curative and would not be reimbursable through the current regulations of the hospice benefit (Lowey et al. 2014).

3.3 Indication for Palliative Care

The benefits of palliative care for patients with heart failure have been recognized by the American Heart Association, American College of Cardiology and the Heart Failure Society of America (Diop et al. 2017). The ideal timing for initiation of palliative care is not well understood despite consensus statements and panels that have advocated for its delivery alongside curative medical care. What we do know is that patients who are diagnosed with ACC/AHA Stage D heart failure and/or patients who develop symptoms classified by the New York Heart Association as Class III or IV, may benefit from palliative interventions (Teuteberg 2016).

Additionally, discussion surrounding palliative care should be initiated with "patients who have more frequent inpatient hospitalizations for heart failure exacerbations, present with refractory angina, have recurrent implantable cardiac device (ICD) shocks, and levels of anxiety or depression that adversely affect quality of life" (Teuteberg 2016). Lastly, early conversations with patients to establish their goals of care and periodic re-visitation of these goals, is an essential component that will enable providers to determine when their patients would most benefit from the incorporation of palliative care into their treatment plan.

4 Management of Symptoms in Advanced Heart Failure

4.1 Anorexia/Cachexia

Anorexia is a common symptom that accompanies many types of advanced illnesses. It is defined as the "reduction or loss of desire to eat" (Wholihan 2015). In acute diseases, anorexia can be corrected or reversed when the illness resolves. In progressive advanced illnesses, such as heart failure, anorexia can be more challenging to manage. If patients are not able to consume enough calories, it will lead to protein-calorie malnutrition and subsequent weight loss (Wholihan 2015). Unresolved anorexia can lead to cachexia, and the presence of both together has been coined anorexia-cachexia syndrome in progressive disease or cardiac cachexia when associated primarily with heart failure (von Haehling et al. 2009). Cardiac cachexia is estimated to arise in 16–36% of patients with advanced heart failure (Wholihan 2015). Cachexia is defined as wasting away from lack of adequate nutritional intake and/or progressive weight loss (Wholihan 2015). Decreased appetite typically accompanies both anorexia and cachexia, however the latter can occur without the presence of a decreased appetite (Wholihan 2015). Wasting of skeletal muscle and fatigue often accompany anorexia-cachexia syndrome (Wholihan 2015) which may be difficult to treat in patients who are nearing the end of life.

Early signs of anorexia-cachexia syndrome include: reduced appetite, alterations in taste, and early satiety (Wholihan 2015). These signs can lead to weight loss, wasting of muscle and adipose tissue, fatigue and decreased functional status (Wholihan 2015). Decreased food intake will lead to metabolic alterations, decreased immune response and systemic inflammation (Wholihan 2015) which can develop into a devastating cycle and progressive worsening of patients' underlying condition. In addition to its physiological effects, anorexia-cachexia syndrome contributes to psychological and spiritual distress for the patient and family. It can have profound effects on quality of life. Assessment should include a thorough nutritional intake and appetite evaluation. There are several validated tools available to assess nutritional status including the Subjective Global Assessment for Nutrition (Wholihan 2015), which focuses exclusively on nutrition or the Memorial Symptom Assessment Scale (Wholihan 2015), which focuses on several symptoms including appetite.

Palliative management of patients with anorexia-cachexia syndrome should be focused on reducing the distress caused by anorexia and subsequent weight loss in an effort to improve comfort and quality of life. Non-pharmacological interventions include: encouraging small meals served at room temperature, initiating more heavily caloric or nutritional foods/liquids first in the meal, avoiding foods and liquids with little or no nutritional value, introducing over-the-counter nutritional supplements, and supporting patients and families to continue to offer cultural dishes and maintain family mealtime rituals (Wholihan 2015). Pharmacological interventions include megestrol acetate, which has shown to stimulate appetite and promote weight gain. The majority of these studies were in cancer patients, and therefore the benefit in non-cancer illnesses such as heart failure, are not well known (Wholihan 2015). Some studies have found a positive correlation between fluid retention and megestrol use, however, larger multisite studies are needed to provide stronger validation of this

side effect in heart failure patients (von Haehling et al. 2009).

The use of artificial nutrition and hydration is a common topic that arises during conversations about management of anorexia and cachexia. Although administering nutrition and fluids through artificial means might have good benefits for patients with an acute trauma or illness, the benefits for patients with advanced or terminal illnesses are less known. We do know that the use of artificial nutrition and hydration can contribute to several unwanted complications among patients with advanced disease. This includes: nausea and vomiting, loose stools, aspiration, shortness of breath, edema and dumping syndrome (End of Life Nursing Education Consortium (ELNEC) n.d.). Patients who are nearing or at the end of life may have little to no benefit from artificial feedings and have been found to contribute to increased discomfort and further reduction in quality of life (End of Life Nursing Education Consortium (ELNEC) n.d.). Providers should evaluate the patient's goals of care in conjunction with stage of illness before deciding whether artificial nutrition or hydration should be initiated.

4.2 Confusion

It is not atypical for patients with heart failure to present with cognitive impairments, confusion or delirium. This has been found to be related to decreased cardiac output and reduced cerebral blood flow (Whellen et al. 2014). These cognitive deficits can be compounded by the age of most heart failure patients, as normal age related changes may also be present. Patients may be subject to higher rates of hospitalization, greater functional deficits and increased mortality (Heidrich and English 2015). Certain medications, such as benzodiazapines, opioids and even some cardiac medications, such as beta blockers and ACE inhibitors, can further contribute to confusion and delirium. Among hospitalized patients, delirium has been reported in 14–56% of patients and up to 80% of patients who were mechanically ventilated in ICU's (Heidrich and English 2015).

The Confusion Assessment Method (CAM) and Memorial Delirium Assessment Scale (MDAS) are two clinical instruments that can easily be used to evaluate patients' cognition in the clinical setting (Heidrich and English 2015). In patients who are not actively dying, palliative management includes removing the source that is contributing to confusion or delirium, such as reducing medication dosages or treating underlying medical conditions, such as an infection. Terminal restlessness is a term used to describe increased agitation, confusion and restlessness experienced by some patients as they near the end of life (Heidrich and English 2015). If the patient is exhibiting other signs that indicate their condition is rapidly progressing and they are actively dying, palliative management would focus on reducing the distress associated with the symptom/behavior and ensuring the safety of the patient and those around him/her. Antipsychotic medications, particularly haloperidol, is the medication of choice for management of terminal restlessness or agitation (Heidrich and English 2015). This medication typically has fewer side effects than anticholinergics or benzodiazepine medications, and can be given in a variety of routes. Lorazepam should ideally not be used because it has been demonstrated to worsen delirium in older adults (Heidrich and English 2015).

4.3 Cough

Cough can be a common occurrence in patients with heart failure. Cough can be dry or productive, depending on the origin. Patients with heart failure can develop a cough due to pulmonary congestion, the presence of an underlying infection or result from the use of an ACE inhibitor used to manage their heart condition (Whellen et al. 2014). Cough is often worse at night, when the patient is lying down. Frequent coughing can lead to irritation in the respiratory tract and trachea, pain, nausea from retching, and even fractured ribs (Dudgeon 2015). It can contribute to

poor sleep, nutrition and increased fatigue, which can greatly decrease the patient's quality of life.

Management for cough begins by evaluating the underlying cause or source of the cough. This includes ruling out any underlying infection or escalating exacerbation. For patients whose cough is caused by ACE inhibitor, an angiotensin receptor blocker (ARB) can be substituted (Katz and Konstam 2009). Palliative treatment for a non-productive cough can include: antitussive medications, such as dextromethorphan, opioids, and inhaled anesthetics for severe cases (Dudgeon 2015). Treatment for a productive cough can include: expectorants, mucolytics, antihistimines, and anticholinergics to decrease sputum production. Oxygen and chest physiotherapy may also be used (Dudgeon 2015).

4.4 Dyspnea

Dyspnea, also referred to as shortness of breath or breathlessness, is a common and distressing symptom experienced by patients with advanced heart failure. A recent systematic review found that 60–88% of patients with cardiac disease experience some type of dyspnea (Solano et al. 2006). Breathlessness has been described by patients as a profound heaviness or weight sitting on their chest and the inability to take in enough air to breathe (Lowey et al. 2013). This can be a frightening experience and has been associated with increased levels of anxiety and depression (Lowey et al. 2013). The cause of dyspnea is often multidimensional and its treatment can be difficult in patients with advanced heart failure. Dyspnea may become refractory in advanced or end-stage heart failure, which means that the underlying cause cannot be reversed and the focus of care should shift to interventions aimed at palliation (Abernathy et al. 2003).

In palliative care, the gold standard management for refractory dyspnea in end-of-life care is the use of an opioid medication (Lanken et al. 2008). Caution should be taken when prescribing an opioid medication to patients with heart failure, because their increased age and presence of other co-morbidities can contribute to the build-up of toxic metabolites (Dudgeon 2015). Benzodiadapines have also been shown to help reduce anxiety that is associated with breathlessness. The benefits associated with administering opioids and benzodiazapines for patients who are nearing the end of life or actively dying, may outweigh the risks, since the focus of palliative care is on maximizing comfort and improving quality of life (End of Life Nursing Education Consortium (ELNEC) n.d.).

Some non-pharmacological interventions may help alleviate the sensation of breathlessness in patients with advanced heart failure. Several systematic review articles on this topic found that interventions that promote muscle strengthening, such as cardiac rehabilitation and respiratory muscle training, have produced the most positive results in clinical trials (Buckholz and von Gunten 2009; Bausewein et al. 2008). Activities that promote energy conservation, such as the use of walking aids, have also been found to help reduce dyspnea. Although the literature lacks strong evidence that supports the benefit for complementary therapies, such as acupuncture, some of these therapies have shown promise (Buckholz and von Gunten 2009). Lastly, since the presence of anxiety is strongly associated with the dyspnea experience, interventions that support emotional and cognitive factors can be beneficial. This includes counseling, psychotherapy, and relaxation techniques. Eliciting changes in the patient's environment, such as ensuring enough surrounding open space and keeping the air well circulated through the use of a fan and/or open window, have been reported to promote comfort with breathing by patients (Dudgeon 2015). More large multi-site controlled trials that examine the benefits of these and other non-pharmacological therapies are needed.

4.5 Edema

Fluid overload associated with poor cardiac output and issues with perfusion can contribute to the development of edema and/or ascites in patients with advanced heart failure (Whellen et al. 2014). This can be very uncomfortable

and contribute to or worsen other symptoms, such as pain and shortness of breath (Adler 2009). Edema is especially prevalent in right-sided heart failure, which causes a buildup of blood behind the heart which precipitates increased systemic venous pressure (Katz and Konstam 2009). The presence of excess fluid in soft tissues causes swelling, which can be classified as pitting or non-pitting edema. "Cardiac edema" is edema that is most pronounced in the lower extremities in patients with right-sided failure (Katz and Konstam 2009). Chronic edema caused by an underlying illness can develop into lymphedema (Fu and Lasinski 2015).

Treatment for edema involves the administration of diuretic medications, elevation of the affected extremity and compression stockings (Adler 2009). Medications and foods that contribute to increasing levels of sodium and/or fluids should be avoided (Whellen et al. 2014). Evaluation of daily weights with subsequent titration of diuretic medications should also be part of the treatment plan.

4.6 Fatigue

Fatigue is one of the most common and chronic symptoms associated with many serious diseases. Research that has examined symptom clusters, which are described as "concurrent and related symptoms that may or may not have a common etiology" has found the presence of fatigue in 7 out of the 9 studies that were evaluated (Bookbinder and McHugh 2010). It is a common and prevalent symptom that is associated with heart disease, chronic obstructive pulmonary disease, cancer, renal disease, HIV/AIDS and multiple sclerosis (O'Neil-Page et al. 2015).

Two theoretical models have been reported in the literature that offers an explanation for the underlying pathophysiology of fatigue: the accumulation and depletion hypotheses. The accumulation hypothesis suggests that fatigue is caused by the body's inability to dispose of waste products that have accumulated in the body. Whereas the depletion hypothesis suggests the opposite; that the lack of certain substances that are vital for the body to function, are reduced or missing (O'Neil-Page et al. 2015). The presence of other co-morbidities, such as anemia, dehydration, cachexia, electrolyte imbalance, thyroid dysfunction and infection have also been identified as contributing factors associated with the development of fatigue (Adler 2009).

Palliative management of fatigue can be complex due to the multi-factorial components that may be involved. The first step is a thorough evaluation of fatigue severity, onset, duration, usual pattern or presentation, alleviating and exacerbating factors, and impact on functional abilities and quality of life (Yennurajalingam and Bruera 2007). There are several validated scales available to assist with the evaluation and diagnosis of fatigue including: the Multidimensional Fatigue Inventory, Multidimensional Fatigue Symptom Inventory, and the Edmonton Symptom Assessment Scale (Yennurajalingam and Bruera 2007). In palliative care, if reversal or discovery of the underlying condition causing fatigue is not possible, management should be aimed at treating the associated and distressing symptoms. This can include the management of pain, depression, delirium, and anorexia (Yennurajalingam and Bruera 2007).

Pharmacological management of fatigue includes the administration of corticosteroids, methylphenidate, or modafinil (O'Neil-Page et al. 2015; Yennurajalingam and Bruera 2007). Research has also found some benefit with the addition of megestrol, normally used to promote appetite, also improves fatigue and sense of wellness (Yennurajalingam and Bruera 2007). Non-pharmacological management includes the use of energy conservation, which was identified as the most frequently utilized treatment for fatigue (Yennurajalingam and Bruera 2007). Resistance training and exercise were also noted to have benefits (Yennurajalingam and Bruera 2007).

4.7 Insomnia

Insomnia and problems related to sleep are common among patients with advanced heart failure and are most often related to the presence of orthopnea or paroxysmal nocturnal dyspnea. Previous research found the prevalence of insomnia among patients with cardiac disease to be as high as 44% (Evangelista et al. 2009) with 50% of patients diagnosed with sleep disordered breathing, such as obstructive sleep apnea (Whellen et al. 2014). The primary treatment for patients with sleep disordered breathing is continuous positive airway pressure (CPAP). This therapy, however, may not be well tolerated by patients in advanced stages of the disease.

Palliative management of insomnia includes trying to remediate the underlying cause, if possible, and then focusing on alleviating any adverse effects. Pharmacological management could include medications used for anxiety/depression, such as benzodiazapines, if those symptoms are found to result from sleep deprivation. Low dose zolpidem can also be trialed for patients whose symptoms are affecting quality of life (Whellen et al. 2014). Providers should educate patients to be wary of side effects from these medications, particularly in older adults. Patients should be encouraged to maintain bedtime routines and to minimize noise and external lighting at bedtime. The room temperature should be tailored to individual patient preferences.

4.8 Pain

Patients with heart failure can be subject to experience various types of pain. Some pain can be related to their cardiac health, such as chest pain associated with angina, while others may be related to osteoarthritis or peripheral vascular disease. One study found 89% of end-stage heart failure patients have pain (Evangelista et al. 2009). Pain is classified by its etiology (somatic, visceral, or neuropathic) and also by pattern of presentation, which can be acute or chronic. (Coyle and Layman-Goldstein 2001).

Patients with heart failure should be asked about their current location of pain, duration, intensity, quality, aggravating and alleviating factors and current pain management regimen (End of Life Nursing Education Consortium (ELNEC) n.d.). Once the origin of pain is determined, the provider can determine the most optimal pain management plan for the patient. It is ideal to include both pharmacological and non-pharmacological interventions in the pain management plan. In palliative care, pain that is acute and determined to resolve in a short period of time is treated using a short-acting analgesic whereas pain that is chronic should include the use of both a long-acting and short-acting analgesic medication (End of Life Nursing Education Consortium (ELNEC) n.d.). Since the majority of patients with advanced heart failure are older adults, pain medications should be used according to the World Health Organization (WHO) three-step ladder for pain in adults (World Health Organization 2017b). The aim of pain management is to treat pain with the lowest type of analgesia that will mitigate the pain and limit unwanted side effects.

Opioid medications are the most widely used pharmacological treatment for patients who have moderate to severe pain (Adler 2009). Combination medications and non-steroidal inflammatory medications should be avoided in older adult patients, such as those with heart failure (Adler 2009). Although providers should use caution when prescribing narcotic medications, particularly in older adults because it may contribute to falls, delirium, and urinary retention (Eliopoulos 2014), the focus of palliative care is to improve quality of life, and the benefits for reducing symptoms should be weighed against any minimal risks.

4.9 Anxiety & Depression

The chronic and progressive nature of advanced heart failure includes periods of exacerbations when the disease worsens. The unpredictable nature of exacerbations can contribute to feelings of anxiety and depression among patients. Depression has been found to be present in 21–36% of patients with heart failure and with even greater prevalence among patients who have advanced disease (Adler 2009). The presence of depression and anxiety have been shown to correlate with greater symptom burden and more frequent hospitalizations (Goodlin 2009) and patients who report depression have greater fatigue and other symptoms than patients without depression.

The evidence suggests that many of the traditional medications used to treat depression can contribute to adverse effects in patients with heart failure. Selective serotonin reuptake inhibitors (SSRI's) can place patients at risk for fluid retention and/or hyponatremia and these medications can also take several weeks to be fully titrated (Goodlin 2009). Tricyclic antidepressants are another class of medications that can be used instead of SSRIs. They have however, been found to contribute to prolonged QT intervals at higher doses and also have a 1–2 week lead time for full titration to occur (Goodlin 2009). To date, the best evidence suggests the use of methylphenidate due to its minimal adverse effects with this patient population (Goodlin 2009). Benefit from this and/or other psycho-stimulant medications can be seen in 1–2 days rather than weeks, as with the before mentioned classes of medications. Benzodiazapines have also been found to be effective in reducing anxiety among patients with heart failure at any stage of the disease (Goodlin 2009).

Non-pharmacological interventions for depression and anxiety include measures aimed at providing emotional support, such as support groups and mindfulness education programs (Sullivan et al. 2009). These interventions promote patients to increase their sense of control related to heart failure symptoms, which can subsequently reduce feelings of anxiety and depression (Sullivan et al. 2009).

5 Quality of Life and Functional Status

Patients with advanced heart failure can experience a wide range of adverse and uncomfortable symptoms that accompany disease progression. This can significantly impact the quality of daily life and contribute to physiological, psychological and spiritual distress. Worsening of the heart also leads to functional limitations and disability which can both have a profound effect on patients and their caregivers. Limitations can include all of the activities of daily living (ADLs). There are six basic ADLs which are: bathing, dressing, eating, toileting, transferring (ambulating) and continence (Eliopoulos 2014). The symptoms associated with heart failure can impact any or all of the patient's ability to complete their ADLs. This can then contribute to other issues and concerns, which in turn can worsen the patient's overall health and well being. Additionally, loss of these functional abilities not only impact the patient, but their family members, many of whom may be the assisting the patient by providing informal care.

The loss of a patient's functional ability and subsequent loss of independence in being able to carry out the activities of daily living, are both losses that can contribute to feelings of grief. Grief is a universal experience that individuals go through when dealing with a loss. Although losses are often defined in terms of a loss of a family member or friend, non-human types of losses, such as loss of independence, can also precipitate feelings of grief (End of Life Nursing Education Consortium (ELNEC) n.d.).

5.1 Caregiver Support

There has been a multitude of research aimed at understanding the caregiver experience and interventions aimed at providing better support for this population. The burden associated with caregiving can impact both physical and mental health of caregivers, which can ultimately impact the care of the patient (Pressler et al. 2013). Caregivers may also experience a financial impact as a result of the time devoted to caregiving (Pressler et al. 2013). Caregivers for patients with heart failure have been found to experience increased levels of depression and anxiety and report decreased quality of life (Pressler et al. 2013).

Early intervention and assistance to the caregiver is vital because of the extended length of time that most caregivers will be providing care to their loved ones with heart failure. McMillan and colleagues conducted an intervention for the caregivers of hospice patients with advanced heart failure and found caregivers have greater benefit with early intervention rather than when their loved one was in the later stages of disease (McMillan et al. 2013).

6 Ethical Challenges

Patients who live with serious and progressive illnesses are often faced with making medical decisions as their illness worsens and they near the end of life. Some of these decisions involve a determination of what the patient wishes or wants done for them medically in the event they are no longer able to make decisions. As difficult as it is to engage in advance care planning, it is most ideal for the patient to make these decisions known before they become incapacitated (Martinez-Selles et al. 2017). This future care planning should ideally include discussion about patient preferences for resuscitation status, withholding and/or withdrawing care, artificial nutrition/hydration and use/discontinuation of device therapy (Martinez-Selles et al. 2017).

6.1 Resuscitation Status and Advance Directives

An advance directive is a legal document that states the types of medical care a patient wants in the event that they are no longer able to make their own decisions (Patients Rights Council 2013). Instituting a living will, identifying a health care proxy and designating a durable power of attorney for health care are three of the most common activities that can be done with advance care planning. These documents or designations enable the patient to identify their wishes for medical care beforehand and/or identify an individual to make those medical decisions on behalf of the patient (Patients Rights Council 2013).

Do Not Resuscitate (DNR)/Do-Not-Attempt Resuscitation (DNAR) In previous years, the acronym (DNR) was used for do-not-resuscitate, which meant that a patient elected to forgo medical intervention if they went into cardiopulmonary arrest (Breault 2011). Another acronym (DNAR), do-not-attempt resuscitation, has recently been added by the American Heart Association (Breault 2011). This is viewed as a less "harsh" term used for the decision to not intervene medically in the event a patient goes into cardiac arrest. If a patient has elected their resuscitation status to be DNR/DNAR, they have decided against initiation of cardiopulmonary resuscitation if they go into cardiac arrest. This includes the use of chest compressions, administration of cardiac medications and the placement of a respiratory/breathing tube (Breault 2011).

The majority of patients with advanced heart failure are older adults. Advanced age was found to be a factor associated with having poor outcomes with use of CPR (Berry and Griffie 2015). CPR was found to only be successful in about 18% of hospitalized patients (Berry and Griffie 2015) with an even lower success rate among patients with advanced illnesses, such as cancer or end stage heart failure.

Allow Natural Death (AND) Allow natural death is a term being used in some health care institutions in place of the traditional DNR/DNAR terminology. Patients who have an AND order want only comfort measures taken for symptom management as they go through the dying process (End of Life Nursing Education Consortium (ELNEC) n.d.). The goal of AND is to ensure that the patient is as comfortable as possible while allowing the natural process of dying to progress (End of Life Nursing Education Consortium (ELNEC) n.d.).

6.2 Withholding and Withdrawing Care

Withholding and/or withdrawing care is a controversial topic that has been debated in the literature (Manalo 2013). Both relate to the use of medical interventions at the end of life and can range from minor, such as the use of a non-life sustaining medication, to more complex, such as mechanical ventilation. Withholding medical care means that a medical treatment or intervention available is not initiated whereas withdrawing medical care denotes the cessation or removal of existing treatments that are already being used (End of Life Nursing Education Consortium (ELNEC) n.d.). The rationale behind withholding or withdrawing medical interventions is based on an evaluation of the benefits and burdens for the patient associated with the treatment. Sometimes treatments are determined to be futile in which patients do not receive any beneficial outcome from the intervention (Martinez-Selles et al. 2017). Some life-sustaining treatments could even worsen patients' suffering and decrease their quality of life.

Educating patients with advanced heart failure about illness progression and what they might expect is essential so that patients can identify goals of care. Any interventions used for the patient are solely for comfort or palliative care. This reinforces the importance of patients having an advance directive in place because this can help to decrease the initiation and use of futile medical care from the outset (End of Life Nursing Education Consortium (ELNEC) n.d.).

6.3 Artificial Nutrition and Hydration

Artificial nutrition or hydration (ANH) is defined as a medical intervention that delivers nutrition and/or hydration through artificial means. This involves administering food or fluids through a non-oral route, such as subcutaneously or intravenously (Arenella n.d.). According to the American Hospice Foundation, ANH should not be considered more than basic care rather than as a medical treatment (Arenella n.d.). Previous research suggests that dying patients derive some benefit from not being able to eat or drink. It has been found to reduce nausea and subsequent vomiting, shortness of breath and edema (Brody et al. 2011), some of which are common symptoms found among patients with advanced heart failure.

6.4 End of Life Decisions Regarding Device Therapy

An implantable-cardioverter-defibrillator (ICD) is a medical device utilized in patients at risk for sudden cardiac death with known ventricular tachycardia or fibrillation (American Heart Association n.d.). ICDs help to prevent cardiac arrest in patients at risk for ventricular arrhythmias and newer models can also dually serve as a pacemaker device (American Heart Association n.d.). Providers should discuss the benefits and risks associated with this device in patients who may be viable candidates for this option. Patients who already have an ICD whose illness has progressed and who are at the end of life should re-evaluate the usage of this device. The ICD should be deactivated in patients who are actively dying in order to avoid the receipt of multiple shocks which can contribute to great suffering and significant distress at the end of life (Martinez-Selles et al. 2017). The

deactivation of the ICD will not hasten death and patients should be informed that resynchronisation therapy will continue even in the absence of defibrillation. Conversations surrounding the discontinuation of an ICD device can be distressing and patients and families should be well supported during these difficult decisions. Management of symptoms using palliative care is especially important to be included in the treatment plan for patients who elect ICD deactivation (Martinez-Selles et al. 2017).

6.5 Active Death Help/Physician-Assisted Suicide

Active death help or physician assisted suicide is common terminology used to describe the purposeful ending of one's life (American Academy of Hospice and Palliative Medicine n.d.). A patient living with a terminal illness may request a prescription from a physician to obtain a lethal dose of medication which the patient will self-administer to end his/her life (American Academy of Hospice and Palliative Medicine n.d.). This differs from palliative care because its goal is to improve overall quality of life, through symptom management and relief of suffering without the intentional hastening of death (American Academy of Hospice and Palliative Medicine n.d.). Most professional associations governing medical providers in the realm of end of life care take a neutral or antagonistic position towards active death help (American Academy of Hospice and Palliative Medicine n.d.).

7 Clinical Practice Guidelines

According to the American College of Cardiology (ACC)/American Heart Association (AHA) Guidelines (Yancy et al. 2017; Yancy et al. 2013), aggressive life-sustaining treatments and therapies should not be utilized in patients with advanced or end-stage heart failure who have refractory symptoms that are not responding to medical therapy. Patients who are in their last months of life should not receive treatments that do not contribute to their recovery or improve their quality of life. This includes intubation, the use of mechanical ventilation, and implantation of a cardiac defibrillator (Yancy et al. 2013). The focus of therapy for patients with stage D disease is to: control symptoms, reduce hospital admissions, improve health-related quality of life, and to establish end of life goals (Yancy et al. 2013). It is during this stage that the incorporation of palliative care or hospice should be initiated and the deactivation of ICDs should be instituted.

8 Conclusion

Palliative care should be incorporated into the management plan for patients with advanced heart failure. It has been demonstrated to help reduce severity of symptoms, encourage advance care planning and identification of goals of care and reduce patient and family distress affecting quality of life. Understanding the common illness trajectory for patients with heart failure can help providers inform patients about what to expect with illness progression. Palliative care can be initially be instituted alongside curative treatments, and its focus in the overall plan of care can increase as the patient's condition worsens and curative treatments offer less of a benefit. Clinical practice guidelines support the provision of palliative care as an option for the management of patients with ends-stage heart failure.

Athlete's Heart and Left Heart Disease

Cesare de Gregorio, Dalia Di Nunzio, and Gianluca Di Bella

Abstract

Physical activity comprises all muscular activities that require energy expenditure. Regular sequence of structured and organized exercise with the specific purpose of improving wellness and athletic performance is defined as a sports activity.

Exercise can be performed at various levels of intensity and duration. According to the social context and pathways, it can be recreational, occupational, and competitive. Therefore, the training burden varies inherently and the heart adaptation is challenging.

Although a general agreement on the fact that sports practice leads to metabolic, functional and physical benefits, there is evidence that some athletes may be subjected to adverse outcomes. Sudden cardiac death can occur in apparently healthy individuals with unrecognized cardiovascular disease.

Thus, panels of experts in sports medicine have promoted important pre-participation screening programmes aimed at determining sports eligibility and differentiating between physiological remodeling and cardiac disease.

In this review, the most important pathophysiological and diagnostic issues are discussed.

Keywords

Athlete's heart · Cardiomyopathy · Exercise · Functional evaluation · Left ventricular hypertrophy · Physical training · Sports · Sudden cardiac death

Acronyms

AH	Athlete's heart
CVD(s)	Cardiovascular disease(s)
ECG	Electrocardiogram
ECHO	Echocardiography
HCM	Hypertrophic cardiomyopathy
LA	Left atrial/atrium
LV	Left ventricle/ventricular
PHA	Physical activity
pVO2	Peak oxygen uptake
SA	Sports activity
SCD	Sudden cardiac death

1 Introduction

Physical activity (PHA) comprises all muscular activities that require energy expenditure. Regular sequence of structured and organized exercise

C. de Gregorio (✉), D. Di Nunzio, and G. Di Bella

e-mail: cdegregorio@unime.it

with the specific purpose of improving wellness and athletic strength is named sports activity (SA). Both PHA and SA can be performed at various level of intensity. According to the social context and pathways, sports can be differentiated into recreational, occupational, and competitive (Bauman et al. 2002).

In developed countries, daily time is more organized than in the past: people are spending more time in PHA, irrespective of how much they are used to do in the workplace. This is also a result of successful information campaigns promoting wellness, in an attempt to prevent the general population from cardiovascular diseases (CVD), reduce risk factors in young people and sarcopenia in the elderly, and promote rehabilitation after acute events (King et al. 2002; Bauman et al. 2002; Giles-Corti et al. 2005; Elferink-Gemser et al. 2011; Abdullah et al. 2016; Harada et al. 2017).

Although there is a general agreement on such benefits from SA, athletes may be subjected to traumas requiring a training break or showing disproportionate cardiac adaptation, unlikely with a physiological remodeling. Some of these conditions may be at risk for arrhythmias and sudden cardiac death (SCD), thus requiring differential algorithms, especially in young athletes (Asif and Drezner 2013; Corrado et al. 2003, 2011a, b; de Gregorio 2012; Risgaard et al. 2014; Link 2017). The fact that professional athletes may harbor potentially lethal heart diseases has been a matter of concern to the cardiovascular medicine. Astonishing SCD in the arena has a terrible impact on the general thought, at times encouraging media and newspapers to spread the message that SA can be risky. However, SA per se does not represent a risk factor for SCD but it can be triggering arrhythmic events in the presence of misjudged CVD, chest traumas or drugs abuse (Corrado et al. 2003, 2011a, b; Risgaard et al. 2014; de Gregorio and Magaudda 2017; Link 2017).

In general, the incidence of SCD in male athletes was largely unexplained until publication of an Italian study demonstrating that arrhythmogenic right ventricular cardiomyopathy and coronary anomalies are often responsible for a large number of events in apparently healthy athletes, in whom training burden and exercise intensity are important determinants (Corrado et al. 2011a, b). Also full-contact SAs can be life-threatening in male athletes (de Gregorio and Magaudda 2017).

More recently, a particular prognosticator has been identified based on cardiac magnetic resonance imaging. It has been demonstrated that athletes with right bundle branch block and ventricular arrhythmias may show a so-called "stria" pattern (subtle intra-myocardial mid-layer linear image of delay enhancement), as a consequence of (subclinical) acute myocarditis (Zorzi et al. 2016).

Therefore, pre-participation screening has become mandatory to recognise CV anomalies in both competitive and uncompetitive athletes. However, some criticisms have arisen about its cost-effectiveness, chiefly in those countries where screening does not have a reasonable economical coverage. The introduction of eligibility criteria has significantly diminished the number of athletes at risk of SCD but also increased the number of false positive verdicts (Corrado et al. 2003; de Gregorio 2012; Leikin et al. 2012; La Gerche and Heidbuchel 2014; Risgaard et al. 2014; Maron et al. 2016;).

Disqualification might have a destroying impact on professional athletes' career. To date, there is no legal precedent holding a physician liable for refusing or admitting an athlete. In a famous old lawsuit, some cardiologists were blamed of negligence because of misdiagnosed cardiomyopathy in a basketball player. Against another medical opinion that disqualified the athlete from competitions, the athlete played in spite of everything and died on the arena. The court, awkwardly, was unable to establish the case as malpractice (Mitten 1993).

Almost restrictive criteria have been adopted by the 2013 European Guidelines (Biffi et al. 2013a, b; Heidbuchel et al. 2013) for professional athletes. On the contrary, the 2015 American recommendations were less stringent due to the fact that incidence of SCD among young American athletes was as far as that achieved by European and Italian population registries, after the introduction of the pre-participation screening programmes (Maron et al. 2009, 2015; Leikin et al. 2012; Corrado et al. 2015).

However, studies carried out by the University of Padua (Italy) have shown the importance of nationwide clinical and electrocardiographic screening in all young sports players. Urinalysis, spirometry and exercise ECG test (and echocardiography, if necessary) are performed in competitive athletes only (Corrado et al. 2003, 2010, 2011a, b; Biffi et al. 2013a, b).

Pathophysiology of AH and differential diagnosis with left heart disease will be discussed in this review.

2 Classification of Sports

An ideal classification of SAs should endorse three important requirements: clarity, easy availability and precision. However, there is no agreement about which criteria should be used to classify individual characteristics and athlete's needs.

According to physiological standards, in 1969 Antonio Dal Monte proposed a classification based on the energy source of the muscular mass during exercise (anaerobic or aerobic), revised many times and then published in a book (Dal Monte and Faina 1999). From then, further innovative criteria have been proposed worldwide until publication of the recent US classification (Mitchell et al. 2005).

Sports disciplines are classified according to the cardiovascular involvement and muscle strength, which are both crucial determinants for sports eligibility. The American Task force included both static (measured as the progressive increasing in voluntary muscle contraction) and dynamic [gradual improvement in peak oxygen uptake (pVO2) with submaximal muscle contraction] components in competition. The rise in pVO2 is expression of increased cardiac output and global heart efficiency. As the static component increases, blood pressure and peripheral resistances increase as well, both resulting in a higher cardiovascular demand. This classification is almost clear, but it can fail to classify highly trained athletes performing strong disciplines (Mitchell et al. 2005; Levine et al. 2015).

In a different way, the Italian task force (Biffi et al. 2013a, b) approved a four-task classification of SAs, as follows:

(a) **Group A,** neurogenic disciplines with mild increase in heart rate and trivial effects on cardiac output and blood pressure, due to predominant emotional involvement of the athlete (e.g. bowling, golf, shooting, recreational fishing);
(b) **Group B** disciplines are characterized by a greater increase (even submaximal) of heart rate, with minor impact on the peripheral vascular resistances and blood pressure (e.g. riding, aviation, motorsport, skydiving);
(c) **Group C** consists of disciplines characterized by prevalent blood pressure rising than cardiac output. Thus, heart rate and peripheral resistance range from medium to maximal (e.g. climbing, athletic, cycling, swimming, skiing, surfing, artistic gym).
(d) **Group D** includes all sports with mid-high cardiovascular involvement. This subgroup includes two subsections according to cardiovascular parameters:
   – **D1)** variable trend of heart rate, peripheral resistance, and cardiac output (e.g. soccer, football, water polo, volleyball, hockey).
   – **D2)** characterized by a regular increase in heart rate, blood pressure and a decrease in peripheral resistance (e.g. biathlon, rowing, cycling, skiing, swimming).

SAs can also be classified according to the type and intensity of exercise performed, being divided into a predominant dynamic (isotonic) or static (isometric) component. Dynamic exercise usually consists with forces developing from changes in muscles length and joint movements. Static exercise chiefly consists of intramuscular work force devoid of significant changes in fibre length or joint movements. However, isotonic and dynamic exercise does not necessarily mean aerobic exercise, because aerobic or anaerobic characteristics depend on intensity, duration and

pulmonary capacity. High-intensity static exercises are usually anaerobic, while high-intensity dynamic exercises can be performed in either aerobic or anaerobic modality. The aerobic threshold, in fact, corresponds to lactate serum concentration of at least 2 mmol/L, whereas the anaerobic threshold of 4 mmol/L. Some SAs, like skiing, running and soccer, are highly dynamic, but often above the aerobic threshold. The cardiovascular demand is challenging because of mixed dynamic and static components. Aerobic and anaerobic stages can be unpredictably coexisting at the same time. The interval between the aerobic and anaerobic threshold defines such activity as intermediate with a mild increase in blood lactate which does not limit athletic performance (Jetté et al. 1990; Levine et al. 2015).

3 Training Burden

Despite accuracy is required, each classification of sports disciplines should be as flexible as possible. In fact, athletes from the same category can deserve really different completion and placement. Sports practice has important physical effects with an involvement of almost all parts of the body, mainly of the CV and respiratory systems.

Physical training is a process whereby sportive performances are maximized and improved: it consists of repetitive and/or continuous exercise aimed at enhancing performance, resistance, ability, and delaying fatigue. Athletes improve their performance by increasing frequency, duration and intensity of training.

Sharma et al. (2000) established a minimum burden of 5 h per week in organized exercise sessions for identifying trained athletes.

Besides, the scientific approach to define the training burden requires an objective and quantifiable method. In particular, the training load has been defined as "external" when the amount of exercise is unconditioned by the individual perception of stressful activity. On the contrary, an "internal" workload concerns exercise-induced physiological/psychological internal environment. It was also termed as the "milieu interieur" in biological homeostasis by Bernard (1966) and then by Noble (2008).

Likewise, the "external" perception does not represent the actual workload imposed by exercise. In fact, two athletes performing the same exercise may perceive a different feeling of effort according to their strength. On the other hand, similar competence may lead to different game performance and ensuing physical stress, based on training and genetic background (Hopkins 1991; Noble 2008; La Gerche et al. 2014).

Therefore, the correct recognition of training burden remains challenging for physicians. However, it appears to be a critical issue when deciding whether the athlete has adequate, insufficient or excessive cardiac adaptation to exercise. In fact, this is such a necessary background when differentiating physiological from pathological LV remodelling (Fig. 1).

4 Cardiac Adaptation to Exercise (Athlete's Heart)

Changes in cardiac morphology and function are physiological responses to regular exercise. The original definition of AH dates back to late nineteenth century, when a dilatation of the heart was seen in Nordic skiers and crew runners from a university college (Darling 1899).

During the same period, Morganroth and colleagues described two types of left ventricular (LV) remodeling by using M-mode echocardiography, as follows: a) concentric hypertrophy (LV wall thickness greater than the chamber volume), as the consequence of strength exercise, and b) eccentric hypertrophy (LV dilatation greater than wall thickness) after endurance exercise. The stimulus for hypertrophy was attributed to blood pressure rise with increased peripheral vascular resistance during strength exercise, both resulting in high ventricular systolic stress. On the contrary, the blood volume overload during endurance exercise may lead to wall stretching and fibrils' elongation, and then to LV dilatation (Morganroth et al. 1975).

It is important to understand the concept of ***LV hypertrophy*** that corresponds to an increase in

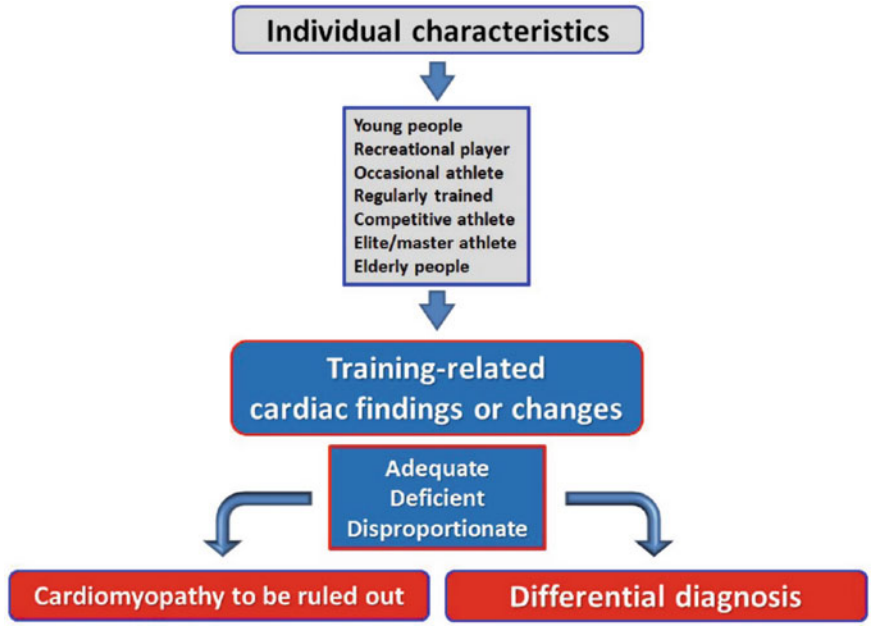

Fig. 1 General approach to the athlete for differentiation between AH and cardiac disease

LV mass. Thus, the term hypertrophy should indicate a change in muscle mass and/or chamber volume. However, generally speaking, it means LV wall thickening.

Based on the Laplace's equation

$$\text{LV systolic stress} = \frac{(\text{LV radius}^* \text{SBP})}{\times/2^* \text{LV wall thickness}}$$

the increase in LV wall thickening counteracts the internal LV systolic stress. This is a natural pathophysiological model of compensatory hypertrophy. However, clinical concern arises when explaining such adjustments in resistance athletes who usually perform different training modality. Moreover, due to a decrease in both cardiac output and systemic vascular conductance, post-exercise hypotension may occur in some individuals, as a consequence of central disregulation, and this further has an influence on the LV remodeling (Romero et al. 2017).

More recent theories suggest that regularly trained athletes show a well-balanced LV remodeling (Haykowsky and Tomczak 2014). However, approximately 30% of Olympic endurance athletes (eg. marathoners) show biventricular dilatation, sometimes belonging to the "grey-area" subset. Scuba apnea divers may present with a mild dilatation of the ventricular chambers, possibly associated with transient wall motion abnormalities due to their performance in hypoxic conditions (de Gregorio et al. 2006; Gempp et al. 2013).

Myocardial hypertrophy is more evident in master Afro-American than Caucasian athletes, irrespective of their training modality (Beaudry et al. 2016; Oláh et al. 2016; D'Ascenzi et al. 2017).

In fact, ethnicity is a well documented determinant of cardiac remodelling, especially in younger athletes: different blood pressure modulation, endothelial function, arterial stiffness, angiotensin-converting enzyme polymorphisms and insulin-like growth factor-1 expression, are all related to ethnicity and can lead to a different adaptive response to exercise. Accordingly, the prevalence of repolarisation anomalies (at times, surprising) is more frequent in black athletes (Prior and La Gerche 2012; Drezner et al. 2013; Maron et al. 2016; Dores et al. 2017; Sharma et al. 2017). ST-T wave changes suggestive of LV hypertrophy have also been found in

240 highly-trained black women (Rawlins et al. 2010).

ECG findings suggestive of LV hypertrophy, left atrial and right atrial enlargement are so common among young athletes and require careful interpretation because they can be expressions of a "juvenile pattern" (Anderson et al. 2014; Leikin et al. 2012; Speranza et al. 2014).

Based on current knowledge, limits for normal LV wall thickness have been established in different groups of athletes: trained adolescents usually show a maximum wall thickness of 12–13 mm (generally limited to ventricular septum), whereas 15–16 mm in those aged between 25 and 30 (Table 1). Intermediate (young) athletes with 13–15 mm septum thickness enter the "grey-zone" of hypertrophy and need further differentiation with hypertrophic cardiomyopathy (HCM). Because of hormonal characteristics, cardiac remodeling is trivial in women, and a septum wall thickness > 13 mm is considered such an exceptional finding (Maron et al. 2009; Corrado et al. 2010; Prior and La Gerche 2012; D'Ascenzi et al. 2017).

Furthermore, the atrial chambers tend to increase in size with exercise. Mild enlargement occurs more frequently in young and highly-trained athletes. Atrial enlargement can be suspected at ECG and diagnosed by echocardiography. Even if the left atrial (LA) diameter has been the unique measurement to consider in the majority of athletes, recent evidences suggest that LA volume corrected for body surface area should be preferred (Kebed et al. 2017).

Pelliccia and collaborators (2005) found an enlarged LA in about 30% of athletes, but this finding was not suggestive of pathological remodelling. More recently, D'Andrea et al. (2010) also reported mild LA dilatation (29–33 mL/m^2) in 24% of 615 endurance athletes, whereas it was moderate ($\geq$ 34 mL/m^2) only in 3% of cases, largely commensurate to the LV end-diastolic volume.

As compared to hypertensive patients with similar atrial chamber enlargement, a normal LA wall deformation (reservoir function) has been demonstrated in trained athletes by strain-echocardiography (Gjerdalen et al. 2015; D'Ascenzi et al. 2016). However, a higher incidence of atrial fibrillation has been reported in some strained athletes. Arrhythmic crisis usually begins at night or after meals, possibly associated with changes in vagal tone. However, atrial fibrillation in the athlete is typically short-termed. Length of training (eg. in veteran athletes), recurrence of premature atrial beats, autonomic nervous system and chronic structural changes following heavy training have been identified as potential triggers (Hubert et al. 2018).

5 Athlete's Heart or Cardiomyopathy?

Beneficial effects of PHA on the heart have been well substantiated in the literature, and training is an essential part of cardiac rehabilitation. However, studies have questioned this paradigm. A potential cellular damage has been seen after exhaustive exercise, and some mechanisms have been also discussed (Ostojic 2016).

Physiological LV hypertrophy should not be associated with myocyte structural anomalies or death. However, intense and lengthy exercise can lead to myocardial inflammation and fibrosis in endurance athletes free of heart disease before competition (La Gerche et al. 2012). Conversely, cardiomyocyte inflammation and myocardial fibrosis are representative of pathological hypertrophy and proceed along with functional decompensation over time. To explain abnormal findings in the athlete, an "ischemic core" hypothesis has been made: the cardiomyocytes would become ischemic when their surface exceeds the distance across which the O_2 diffuses down its concentration gradient from adjacent capillaries. This mechanism, promoted by reiterated intense training, may be leading to spot cellular death and subsequent contractile depression (La Gerche et al. 2012; Ostojic 2016; D'Ascenzi et al. 2017).

A recent study was carried out to assess changes in cardiac troponin I levels and the main biomarkers of skeletal muscle damage after an uphill-only marathon (Supermaratona dell'Etna, Sicily, Italy, 43 km, from ground to 2850 m) and any possible relationship with

Table 1 Markers suggestive of non-physiological left heart remodeling, requiring further evaluation

Findings	Notes
Family history of HCM or SCD	Sudden cardiac death in relatives should be carefully verified and confirmed. Only arrhythmic sudden death or fatal stroke can be related to HCM.
ECG: *Typical pattern of hypertrophy or pathological Q waves (pseudo-necrosis)*	Q waves without previous myocardial infarction can be seen in individuals with either HCM or dilated cardiomyopathy.
ECG: *Negative T waves (other than precordial leads V1 and V2) or high-voltage positive T waves*	
ECHO: *LV wall thickness*	Asymmetric septal, posterior-lateral wall or apical wall hypertrophy is such an unusual finding.
≥ 15 mm (elite/master athletes aged > 30 years)	
≥ 13 mm (elite young athletes aged 20–30 years)	
≥ 12 mm (young women OR young member of a HCM family)	
ECHO: *LV antero-posterior diameter < 45 mm or LV volume index < 50 ml/m^2, and/or narrow outflow tract*	Dynamic obstruction is a typical feature of HCM
ECHO: *Atrial enlargement (>34 cm/m^2)*	Parasternal longitudinal diameter > 40 mm has been demonstrated to be a poor prognostic marker in young patients with HCM, but it can also be found in healthy athletes
ECHO: *Diastolic dysfunction and/or impaired global longitudinal strain (GLS)*	There is no defined GLS cut-off value in athletes suspected to have HCM. In some studies, it was > − 16%.
ECHO: *LV dilatation > 60 mm or > 75 ml/m^2, especially if associated to wall motion anomalies*	Prior myocarditis, familiar dilated cardiomyopathy and coronary anomalies should be ruled out
FOLLOW-UP: *Unmodified wall thickening and ECG findings after detraining*	Also in young patients with HCM, detraining can lead to a decrease in wall thickness and partial normalization of T waves
CARDIOPULMONARY TESTING: *Peak VO_2 < 45 ml/kg/min or < 110% of predicted*	Trained athletes usually show peak VO_2 greater than 45ml/kg/min
CARDIAC MRI: *wall thickness > 15 mm whether associated with delay enhancement or ischemic pattern*	Delay enhancement can be expression of acute myocardial injury (oedema) or chronic fibrosis in patients with heart disease
EXERCISE-ECG: *sign of myocardial ischemia, angina, arrhythmias, or poor systolic pressure rising*	Ischemia can be expression of either coronary anomalies (e.g. tunnelled arteries) or atherosclerosis, even in apparently healthy athletes
HOLTER-ECG: *frequent premature beats, sustained or nonsustained ventricular tachicardia*	

ECG electrocardiogram, *ECHO* echocardiography, *GLS* global longitudinal strain, *HCH* hypertrophic cardiomyopathy, *LV* left ventricle/ventricular *SCD* sudden cardiac death

athletes' physiological parameters. Mean troponin I levels increased significantly in all athletes (mean + 900%), and in 52% of them values were over the normal range, indicating that uphill-only marathon may dramatically increase cardiac and skeletal muscle blood biomarkers of injury, unrelated with common physiological cofactors like age, body mass index, VO2max and training status (Da Ponte et al. 2018).

A particular clinical picture related to SA is the LV noncompaction. It has been described in the general population and also in endurance athletes, as a rare genetic disorder. ***Left ventricular noncompaction*** is characterized by endomyocardial trabeculations and deep recesses due to abnormal embryology of the heart, which lead to a significant (more than 50%) reduction in the compacted layer of the myocardium. As a consequence, some LV wall segments are thinner and trabeculated than the rest of the myocardium, gradually losing their contractile function. In fact, depending on the extent of the noncompacted layer, this anomaly consists with a continuum in LV dysfunction from

asymptomatic (and benign) picture to advanced heart failure with arrhythmic complications. Trabeculations, without any other features of noncompaction or ECG repolarization changes, can be found as a transitory finding in highly trained athletes, especially when a disproportionate preload is imposed by exercise. As per usual, this form of noncompaction reverses with detraining (de Gregorio et al. 2008; La Gerche et al. 2012; Gati et al. 2013; Poscolieri et al. 2014; Dores et al. 2015).

Overall, the most important task for physicians is to differentiate AH from all forms of pathological hypertrophy or dilatation (Table 1 and Fig. 2).

Athlete's heart usually consists of a balanced increase in LV wall thickness and chamber volume, associated with possible mild atrial chambers enlargement but normal or supranormal resting function (Beaudry et al. 2016).

Of note, from large athlete populations we learned that all ventricular wall segments (mainly the septum) are mildly thickened in healthy athletes, whereas isolate apical, inferior or lateral wall hypertrophy is unusual. In these cases, differential diagnosis needs an ECG and echocardiogram, and, at times, cardiac magnetic resonance imaging, to be performed. Differentiation of AH from HCM usually depends on LV wall thickness being in the ambiguous "grey-zone" of hypertrophy (13–15 mm in male and 12–13 mm in female athletes, aged 18–30 years).

The dilemma can be resolved by applying consolidated algorithms, like small LV end-diastolic cavity (<45 mm), diastolic dysfunction, impaired LV strain, atrial dilatation, which are summarized in Table 1 and Fig. 2. However, identification of sarcomeric gene mutation and family history of cardiomyopathy are potential markers of HCM. Individuals with a LV hypertrophy within the grey-zone should observe a 3-month detraining period at least to discriminate between AH (normalization of wall thickness, about 2–3 mm less, and ECG findings) and HCM (persistence of such anomalies). Electrocardiographic abnormalities (i.e., increased R- or S-wave voltages, small Q waves, and repolarisation abnormalities) are frequently seen in healthy young athletes. According to the most recent guidelines, a careful interpretation of the ECG is encouraged in the presence of widespread negative T-waves (more than in the precordial leads V1-V2). Of note, the coexistence of systemic hypertension should also be considered as a confounder (Corrado et al. 2010; Borjesson and Dellborg, 2011; de Gregorio 2012; Calore et al. 2016; Sharma et al. 2017; Zorzi et al. 2017).

Howsoever, HCM remains one of the main causes of SCD among young athletes in the U.S.A. (Maron et al. 2016). Although less challenging than HCM, dilated cardiomyopathy must be differentiated from AH when LV end-diastolic diameter is >65–70 mm (normal finding in less than 15% of athletes). To find a normal LV ejection fraction with no wall motion anomalies generally rule out a pathologic dilatation. As aforementioned, cardiac magnetic resonance and/or computed tomographic scan allow recognising myocardial oedema, ischemia and/or fibrosis as expressions of ischemic heart disease, dilated cardiomyopathy or previous myocarditis (Spence et al. 2011).

6 Conclusions

Regular exercise is responsible for cardiac chamber remodeling (AH) which includes mild LV hypertrophy or dilatation, atrial remodeling and fine modification of the myocardial structure. This is a benign condition and does not require medical treatment. However, an increase in LV mass can also be due to non physiological conditions, such as hypertensive heart, HCM, dilated cardiomyopathy or storage disease. To discriminate between AH and these latter conditions is a crucial step in order to reduce adverse clinical outcomes in athletes. One of the most innovative developments in prevention of SCD is the recent portable ECG technology. The US Food and Drug Administration approved the use of a mobile heart monitoring. The smartphone's app holds an algorithm alerting the patient when an abnormal heart rate or rhythm is detected. Thanks to a wireless connection, the ECG trace can be shared with referral physicians or the hospital. In a recent study, this app was

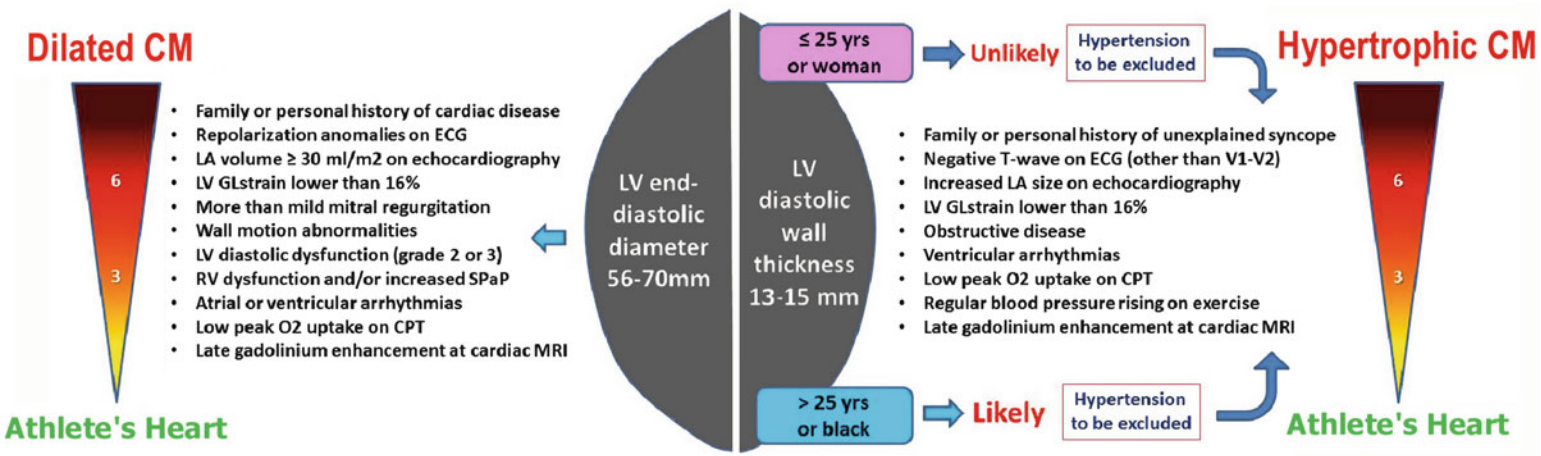

Fig. 2 Differential criteria based on the most important studies aimed at making diagnosis of dilated or hypertrophic cardiomyopathy (CM) in young athletes classified within the grey-area of LV hypertrophy. There are no cut-off values, but all these items have to be considered as a continuum between athlete's heart (AH) and CM

In both dilated and hypertrophic CM, systemic hypertension must be ruled out. CPT, cardiopulmonary testing; GL, global longitudinal; LA, left atrial/atrium; LV, left ventricle/ventricular; MRI, magnetic resonance imaging. Likely and unlikely refer to presence of LV wall thickness of 13 to 15 mm

>99% specific for atrial fibrillation (Haberman et al. 2015).

In spite of current knowledge, some (young) athletes may get a challenging diagnosis, even if advanced technologies are carried out. In such cases, generalists, cardiologists, internists or sports physicians are called to qualify them for competitive SA, but overdiagnosis of cardiac disease can be detrimental to the interest of professional athletes, with ensuing avoidable removal from competitive sports, and loss of psychologic investment and economic opportunities. However, a do-nothing attitude or missing diagnosis of potentially life-threatening CVDs is disappointing and dangerous as well.

Central Sleep Apnea with Cheyne-Stokes Breathing in Heart Failure – From Research to Clinical Practice and Beyond

K. Terziyski and A. Draganova

Abstract

Characterized by periodic crescendo-decrescendo pattern of breathing alternating with central apneas, Central sleep apnea (CSA) with Cheyne-Stokes Breathing represents a highly prevalent, yet underdiagnosed comorbidity in chronic heart failure (CHF). A diverse body of evidence demonstrates increased morbidity and mortality in the presence of CSB. CSB has been described in both CHF patients with preserved and reduced ejection fraction, regardless of drug treatment. Risk factors for CSB are older age, male gender, high BMI, atrial fibrillation and hypocapnia.

The pathophysiology of CSB has been explained by the loop gain theory, where a controller (the respiratory center) and a plant (the lungs) are operating in a reciprocal relationship (negative feedback) to regulate a key parameter (partial pressure of carbon dioxide (pCO_2)). The temporal interaction between these elements is dependent on the circulatory delay. Increased chemosensitivity/chemoresponsiveness of the respiratory center and/or augmented ascending non- CO_2 stimuli from the C-fibers in the lungs (interstitial pulmonary edema), overly efficient ventilation when breathing at low volumes and prolonged circulation time are involved. An alternative hypothesis of CSB being an adaptive response of the failing heart has its merits as well. The clinical manifestation of CSB is usually poor, lacking striking symptoms and complaints. Witnessed apneas and snoring are infrequently reported by the sleep partner. Sometimes patients may report poor sleep quality with frequent awakenings, paroxysmal nocturnal dyspnea and frequent urination at night. Standard instrumental and laboratory studies, performed in CHF patients, may present clues to the presence of CSB. Concentric remodeling of the left ventricle and dilated left atrium (echocardiography), high BNP and C-reactive protein levels, increased ventilation-carbon dioxide output ($VEVCO_2$) and lower end-tidal CO_2 (cardiopulmonary exercise testing), reduced diffusion capacity (pulmonary function testing) and hypocapnia (blood-gas analysis) may indicate the presence of CSB.

CSB and cardiovascular disease are probably linked through bidirectional causality. Cyclic variations in heart rate, blood pressure, respiratory volume, partial pressure of arterial oxygen (pO_2) and pCO_2 lead to sympathetic-adrenal activation. The latter worsens ventricular energetism and survival of cardiomyocytes and exerts antiarhythmogenic effects. It causes cardiac remodeling,

e-mail: k_terziyski@mail.orbitel.bg

potentiating the progression and the lethal outcome in CHF patients. Several treatment modalities have been proposed in CSB. The most commonly used are continuous positive airway pressure (CPAP), adaptive servoventilation (ASV) and nocturnal home oxygen therapy (HOT). Novel therapies like nocturnal supplemental CO_2 and phrenic nerve stimulation are being tested recently. The current treatment recommendations (by the American Academy of Sleep Medicine) are for CPAP and HOT as standard therapies, while ASV is an option only in patients with EF > 45%. BPAP (bilevel device) remains an option only when there is no adequate response to previous modes of treatment. Acetazolamide and theophylline are options only after failing the above modalities and if accompanied by a close follow-up.

1 Historical Perspective

In 1818 Dr. John Cheyne (1818) published a paper "A case of Apoplexy", where he described a specific breathing pattern which he monitored in a patient, suffering from heart failure and a neurologic disorder, without linking it to a specific etiology. Thirty-six years later, in 1854, Dr. William Stokes (1854) published a description of a disturbed breathing pattern in a patient with a "fat degeneration of the heart" and aortic valve defect, emphasizing the role of the cardiac disorder. These two papers present the first scientific description of the periodic breathing, which later became well-known as Cheyne-Stokes breathing.

Despite almost 200 years of history, at present the CSB invokes a vivid contrast between its high social-economic and medical value and still insufficient understanding and recognition of the problem. Its importance is defined by the high prevalence (of heart failure and CSB) among the population, as well as by the negative impact it may imply on the prognosis of heart failure.

2 Definition

Central sleep apnea (CSA) with Cheyne-Stokes Breathing (CSB) is the most common of 8 types of central sleep apnea, according to the newest version of the international classification of sleep disorders (ICSD-3) (AASM 2014). It is usually associated with chronic heart failure (CHF).

Shorter cycle length indicates a different type of CSA (AASM 2014). A typical representation of CSB is shown on Fig. 1. Alternatively, CSB may present with central hypopneas, instead of apneas.

> CSB is characterized with periodic crescendo-decrescendo pattern of breathing alternating with central apneas with a cycle length > 40 s (most commonly 45–60 s). (AASM 2014)

3 Diagnostic Criteria (ICSD-3) (AASM 2014)

According to ICSD-3, the diagnosis CSA with CSB should satisfy the following criteria: the presence of symptoms (A) OR atrial fibrillation/flutter, congestive heart failure, or a neurologic disorder (B) AND specific polysomnography (PSG) characteristics (C) AND the disorder is not better explained by another cause (D).

The symptoms criterion (A) includes one or more of the following: sleepiness; difficulty initiating or maintaining sleep, frequent awakenings, or non-restorative sleep; awakening short of breath; snoring; witnessed apneas.

PSG findings (C) should present ALL of the following: >5 central apneas and/or central hypopneas per hour of sleep; central events are >50% of all events; the pattern of ventilation

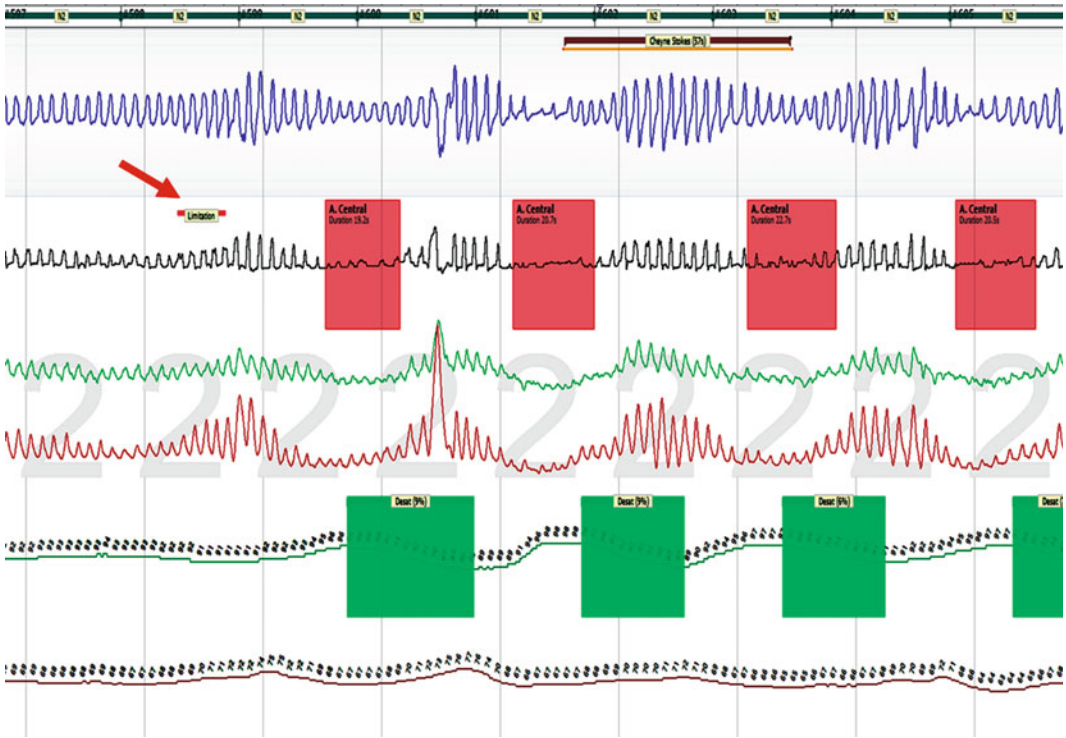

Fig. 1 A typical presentation of CSB. 5-min sample of the "ventilatory part" of a polysomnography (thermistor, nasal cannua, thoracic and abdominal belts, oxygen saturation, heart rate – from top to bottom). Crescendo-decrescendo pattern of ventilation is observed, mirrored by respective fluctuations in effort and followed by desaturations. The length of a single cycle is about 55 s falling within the definition for CSB. Similar variability in heart rate is observed. One may notice the flattening of the nasal flow (red arrow), preceding the start of the CSB sequence
Legend: *CSB* Cheyne-Stokes breathing

meets criteria for CSB. PSG findings are defined according to the newest AASM criteria (Berry et al. 2012; Iber 2007).

An important remark is that the diagnosis CSA with CSB does not exclude the diagnosis OSA (AASM 2014).

4 Prevalence

The prevalence of CSB in CHF is strikingly high, but the condition is being seriously underdiagnosed. Though, a big body of data in support of that has been accumulated, the numbers reported by different studies are varying in a wide range due to the lack of coherence in the methodology, population characteristics (severity of HF, medication therapy, atrial fibrillation, body-mass index (BMI), age), diagnostic and severity criteria, scoring criteria, etc. The difficulties in differentiating central from obstructive hypopneas (Krawczyk et al. 2013) and the frequent coexistence of central and obstructive events in a single CHF patient (Javaheri et al. 1998; Sin et al. 1999; Tkacova et al. 2006) may explain the discrepancy in the ratio OSA/CSA in these studies. The most important of them are presented on Fig. 2.

Furthermore, elements of Cheyne-Stokes breathing pattern with a gradual increase and decrease of ventilation may be present during obstructive events (Tkacova et al. 2006). Tkacova et al. hypothesize that both breathing disturbances are a part of a vicious cycle, involving cardiovascular, pulmonary and autonomous mechanisms, contributing to the progressive heart decline. In general, the obstructive events are concentrated during the first half, while the

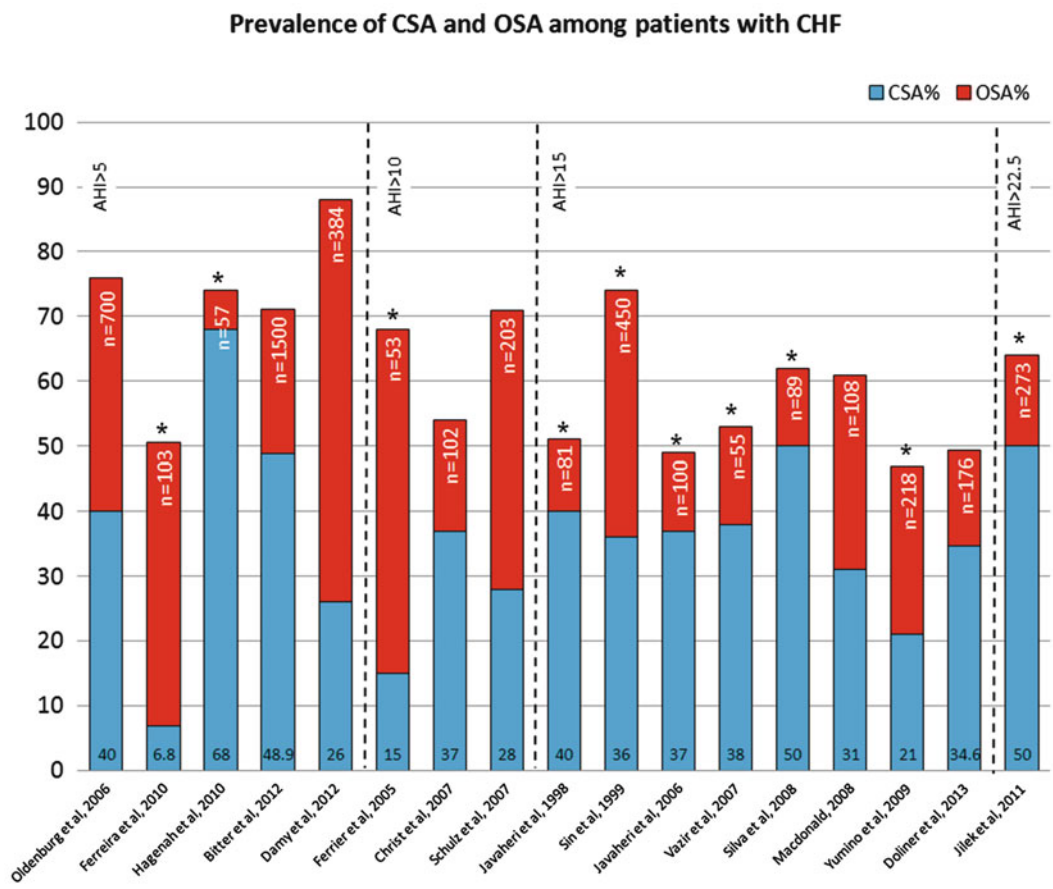

Fig. 2 Prevalence of CSA and OSA among patients with CHF (Javaheri et al. 1998; Sin et al. 1999; Oldenburg et al. 2007; Ferreira et al. 2010; Hagenah et al. 2010; Bitter et al. 2012; Damy et al. 2012; Ferrier et al. 2005; Christ et al. 2007; Schulz et al. 2007; Javaheri 2006a; Vazir et al. 2007; Silva et al. 2008; MacDonald et al. 2008; Yumino et al. 2009; Dolliner et al. 2013; Jilek et al. 2011)
Legend: *CSA* central sleep apnea, *OSA* obstructive sleep apnea, *CHF* chronic heart failure, *AHI* apnea-hypopnea index
Blue bars represent CSA frequency in % (shown as a number at the bottom of the respective bar) of the total number of CHF patients (n = at the top of each bar) in the study (indicated below). Red bars stand for OSA frequency. Combined bar height (blue + red) corresponds to the frequency of sleep disordered breathing in each study. * indicates polysomnography (gold standard study), while its absence – polygraphy (no sleep data). The studies are grouped (vertical dotted line) by the AHI threshold for diagnosing sleep apnea.

central events – during the second half of the night (Tkacova et al. 2001). The shift OSA-CSA is accompanied by a decrease in the arterial partial pressure of CO_2 (pCO_2), increase in the circulation time and duration of periodic breathing cycles. The inversed relation between the latter and the cardiac output (Hall et al. 1996) suggests that the shift from OSA to CSA within a single night is associated with an analogical impairment of the cardiac function, characterized by an increase in the left ventricular filling pressure and a decrease in the cardiac output (Tkacova et al. 2006). The increased venous return due to the rostral fluid shift in supine position is probably a significant contributor to that effect.

5 Etiology

By definition (AASM 2014) CSB has been linked to the presence of CHF.

However, a significant proportion of the CHF patients do not develop CSB. Several risk factors for its occurrence have been identified so far.

1. Age

Patients with CHF and CSB are generally older than CHF patients without the disorder (Bitter et al. 2012; Ancoli-Israel et al. 2003; Javaheri et al. 2017). However, in the study of Bitter et al. CSA regression analysis excluded age as an independent risk factor (Bitter et al. 2012).

2. Gender

Male gender was determined as an independent risk factor for CSA in a large study on 1506 patients with CHF (Bitter et al. 2012). The reasons for gender differences have not yet been fully understood.

Central events usually appear in light sleep, at the wake-sleep transition and especially after an arousal or sleep phase change (Sahlin et al. 2005). Relatedly, males have been found to have a more fragmented and unstable sleep, decreased amount of slow-wave sleep and increased number of wake-sleep transitions, as compared to women (Silva et al. 2008), (Hume et al. 1998). Additionally, central events are usually triggered by a phenomenon, causing hyperventilation hypocapnia, such as an obstructive apnea (Tkacova et al. 2001, 2006; Yumino et al. 2009; Naughton and Lorenzi-Filho 2009). Therefore, the higher prevalence of OSA in men (Young et al. 1993) may contribute significantly to the higher prevalence and severity of CSA in male patients with CHF. The androgens are known to stimulate the deposition of fat in the truncus and the neck region, but also modulate muscle tone of the upper airways during sleep (Phillips and Ancoli-Israel 2001).

Dai Yumino et al. reported approximately 2.5 times higher prevalence of both OSA and CSA in men in a study of 218 stable CHF patients, despite the insignificant differences in BMI, EF and New York Heart Association (NYHA) class (Yumino et al. 2009). Javaheri et al. also reported higher prevalence of CSA with higher obstructive AHI in men (Javaheri et al. 2017).

3. Race and genetic factors

Race has not been found to influence the prevalence of CSB among CHF patients (Javaheri et al. 2017).

Though gene-dependent development of the respiratory center, influencing its functionality and proneness to periodic breathing under provocation (hypoxia, hypocapnia) has been supposed to play a role in CSB generation (Champagnat et al. 2009), studies showing involved genes are scarce and in limited populations (Wang et al. 2016).

4. Anthropometric parameters

Obesity is a classic risk factor for OSA, both in the general population and among CHF patients (Bitter et al. 2012). It could be speculated, that obesity might be among the risk factors for CSA, taking into account the influence of adipokines on respiratory control (Cundrle et al. 2014) and the fact, that obstructive events might trigger CSA in predisposed subjects (Tkacova et al. 2001, 2006; Yumino et al. 2009; Naughton and Lorenzi-Filho 2009).

Neck circumference is a simple anthropometric parameter, used for OSA prediction. As White et al. suggested, it is influenced by the rostral fluid shift during the night, commonly observed in CHF patients. However, the latter affects the lungs as well, increasing pulmonary congestion, which is a part of CSA pathophysiology. Thus, enlarged neck size, although not directly associated with the development of CSA, may be a potentiating factor (White and Bradley 2013).

5. Atrial fibrillation

The relationship between atrial fibrillation (AF) in CHF and presence of CSA has been proven (Sin et al. 1999; Bitter et al. 2012). The association is probably bilateral, since AF may be both a cause and a consequence of CSA, mediated

by circulatory delay and sympathetic-adrenal activation, respectively.

6. Hypocapnia

Hypocapnia is a significant risk factor for CSB in CHF. CO_2 levels in arterial blood were lower in the presence of CSA in the majority of the studies (Bitter et al. 2012; Christ et al. 2007; Szollosi et al. 2008; Bradley et al. 1992). These findings are in consent with the loop gain theory as a mechanism underlying CSB (Lorenzi-Filho et al. 1999; Bradley and Floras 1996; Bradley et al. 2001; Leung and Bradley 2001). Accordingly, nocturnal CO_2 application corrects the disturbance (Lorenzi-Filho et al. 1999; Xie et al. 2002; Andreas et al. 1998; Khayat et al. 2003). It should be noted, however, that the reported data suggest that the majority of the patients with CSA in these studies were nevertheless normocapnic ($pCO_2 > 35$).

7. Others

Low **leptin** concentrations were found in CHF patients with CSA (Cundrle et al. 2014) and subsequently demonstrated as a risk factor for its presence (Cundrle et al. 2017).

Smoking (pack-years) was more prevalent among CHF patients with CSA in 1 study (Javaheri et al. 2017). However, it is not clear if it is a risk factor or an associated factor.

Treatment

Although, as discussed below, the severity of CHF (as measured by NYHA class and ejection fraction (EF)) does not significantly differ between patients with and without CSA (Bitter et al. 2012; Christ et al. 2007; Vazir et al. 2006; Arzt et al. 2003; Meguro et al. 2005), applying contemporary and adequate medication therapy is the important first step towards CSA treatment in these patients. Diuretics and angiotensin-converting enzyme inhibitors reduce the ventricular pre- and afterload and improve the cardiac output (Walsh et al. 1995) and beta-blockers blunt the excessive sympathetic activation effects (Tamura et al. 2007), and therefore could diminish to a certain extent the severity of CSA (Solin et al. 1999). Nevertheless, no differences in the medication profile of the patients with or without CSA were found in the study of Bitter et al. on 1500 CHF patients with optimal treatment (Bitter et al. 2012). The same results were reported in another study on 700 patients (Oldenburg et al. 2007).

6 Pathophysiology of CSB

6.1 Control of Breathing According to the Loop Gain Theory

Control of breathing has been explained by the loop gain theory. Loop gain (LG) is the engineering term describing a system with negative feedback control by quantitative assessment of its (in) stability. LG is a product of the controller gain (CG) and the plant gain (PG) and their temporal interaction (time delay). CG describes the controller response to a certain change ($y = f(x)$) and PG is the resultant effect on the amplitude of the controlled parameter ($x = f(y)$). If LG > 1 the system is unstable due to repeating overshoot/undershoot (the corrective response leads to oversized effects, surpassing the initial changes and creating an abnormal imbalance in the opposite direction). On the other hand, LG < 1 is characteristic to a stable system, reacting with a moderate response to a certain change. It is important to understand that a very small response would not destabilize the system, but rather would need prolonged period of time to restore the equilibrium. The time delay influences the size of the overshoot/undershoot in the first scenario and the time to equilibrium in the second, thus also playing an important role.

Translated to the control of breathing, the controller gain represents the magnitude of the breathing drive produced by the respiratory center with respect to the pCO_2, the plant gain is the efficiency of the lungs to eliminate CO_2 and time delay is the lung-to-chemoreceptor time, a.k.a. circulatory delay (Fig. 3).

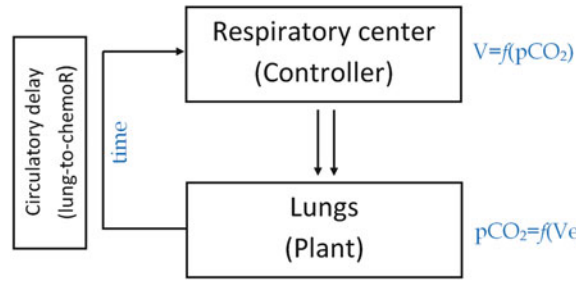

Fig. 3 Components of the loop gain in breathing

The main component of the CG is the chemosensitivity of the respiratory center, i.e. the slope of the function $V = f(pCO_2)$. Significant inter- and intrapersonal variability in the CO_2 sensitivity (Moore et al. 1976; Mountain et al. 1978; Weil 1984; Saunders et al. 1976; Kawakami et al. 1984) has been described with the exact mechanisms behind it still unclear (Orr et al. 2017). An important factor that may influence it is hypoxia (Lloyd et al. 1958). Chemosensitivity represents the "metabolic" control of breathing and may be termed also intrinsic gain. This intrinsic gain is modified by factors such as the upper airway patency to produce the chemoresponsiveness (Orr et al. 2017). One may think of chemosensitivity and chemoresponsiveness as the desired and the actually executed command.

This type of exclusively metabolic breathing control is typical during sleep (Naughton and Lorenzi-Filho 2009), but is not sufficient to respond adequately to various physiologic states and activities during wakefulness (talking, singing, exercising, etc.). Therefore, in addition to the intrinsic gain, other factors, such as the wakefulness/arousal ventilatory drive and conscious cortical overdrive of breathing (descending control) are important for the cumulative CG. Additionally, ascending non-CO_2 stimuli from the C-fibers in the lungs are also an important modulator of the respiratory center, especially under pathologic conditions (Naughton and Lorenzi-Filho 2009; Wellman and White 2011).

The plant gain describes the efficiency of the ventilation to eliminate CO_2 and more specifically the change in pCO_2 in response to executing the ventilatory command ($pCO_2 = f(V)$). It has been shown that lower functional residual volume (FRC) is less effective in terms of buffering of CO_2 changes, thus increasing the PG (Szollosi et al. 2008; Khoo et al. 1982).

As it may be seen (Fig. 3), the PG and the intrinsic part of the CG are in reciprocal relationship. To better illustrate the loop gain mechanism, PG and CG may be plotted on a single graph by inverting the axes of the PG, which would produce the metabolic hyperbole (Fig. 4).

The crossing point between the CG and the metabolic hyperbole is the "static" equilibrium point of the ventilation and pCO_2 if breathing was solely under metabolic control. However, due to the wakefulness drive (WD) it is shifted to the left (at lower pCO_2). Other non-CO_2 stimuli may additionally contribute to that effect. The intersection between the CG and the 0X axis corresponds to $V = 0$ and a pCO_2 level known as apneic threshold (AT). Once, the actual pCO_2 falls below the AT, cessation of breathing occurs. The angle between the CG and the 0X axis corresponds to the chemosensitivity. The steeper the slope is, the greater are the changes in the ventilatory drive per unit of pCO_2 (CG) invoking greater changes in pCO2 at the lungs (metabolic hyperbole). The position at the metabolic hyperbole at which the same changes in the ventilation occur would differently impact the pCO_2 levels due to the non-linear function of the metabolic hyperbole (almost linear in the section around normal pCO_2 and much steeper in the hypocapnic region). Finally, the V/pCO_2 equilibrium in the control of breathing is "dynamic", rather than static and at any given moment is gravitating around the intersection (in blue),

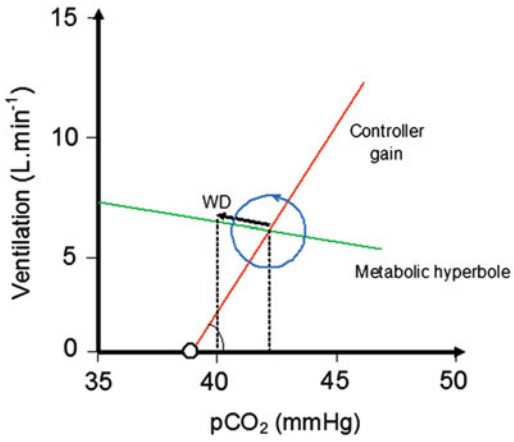

Fig. 4 Control of breathing, according to the theory of loop gain (Modified after Wellman and White 2011)

with the radius of the circle corresponding to the circulatory delay (arbitrary units). Thus, longer circulatory delay would produce greater deviations from the intersection point.

Significant changes in the control of breathing occur during wake-sleep transitions having important implications to periodic breathing. Under normal conditions the eupneic pCO_2 increases by 3–6 mmHg (withdrawn WD), and the AT decreases to prevent breathing pauses (Xie et al. 2002). The cortical descending control during wakefulness supports the breathing even if pCO_2 is below the AT (Khoo et al. 1982; Bradley and Phillipson 1992; Skatrud and Dempsey 1983; Phillipson 1978), while its absence during sleep would result in a central apnea under these circumstances. As a result of the apnea, the pCO_2 gradually increases and after surpassing the AT, the breathing and the equilibrium is restored. If, however, this is accompanied by a (micro)arousal, the momentary level of pCO_2 is relatively hypercapnic for the AT (swiftly changing to levels corresponding to wakefulness). As a result, a fast increase in ventilation, corresponding to the hyperpneic phase of the periodic breathing follows (Xie et al. 1994).

6.2 Causes of CSB in Patients with CHF, According to the Loop Gain Theory

CSB occurs due to increased LG as a result of increased CG, PG and circulatory delay, frequently in combination.

A number of factors may increase the CG in CHF patients. For example, moderate hypoxia affects the chemoresponsiveness increasing the chemosensitivity (the intrinsic gain) (Orr et al. 2017; Lloyd et al. 1958), but also by influencing the upper airway patency (Wellman et al. 2008). The latter may be already disadvantageously altered in patients with obstructive sleep apnea (Wellman et al. 2008). Obstructive events also trigger respiratory associated arousals and hence, an abrupt change in the AT and fluctuations of pCO_2 under and over the AT (Bradley and Floras 1996; Bradley et al. 2001; Leung and Bradley 2001; Lorenzi-Filho and Bradley 2002). Any other cause of sleep fragmentation and increased arousability would elicit the same result. This mechanism may be facilitated further by the inadequate decrease of the AT during sleep, found by Xie et al. in a group of CHF patients (Xie et al. 2002). CHF patients, who are already hypocapnic during wake are especially vulnerable with the withdrawal of the descending effects on the respiratory center (Hanly et al. 1993), (Naughton et al. 1995). On the contrary, application of CO_2 eliminates the central events (Lorenzi-Filho et al. 1999). The chemosensitivity curve may be shifted to the left by non-CO_2 stimuli, other than the WD. The C-fibers reflex is especially important in CHF patients. Pulmonary congestion increases the pulmonary capillary wedge pressure (PCWP) and triggers the reflex resulting in tachypnea and hyperventilation, followed by hypocapnia and central apnea (Paintal 1969; Roberts et al. 1986; Churchill and Cope 1929). PCWP has been correlated with pCO_2 levels and the severity and

number of the central apneas (Solin et al. 1999). Additionally, left ventricle end-diastolic and end-systolic volumes were twice bigger in patients with CHF and concomitant CSB than in CHF only in the study of Tkacova et al. (1997). The presence of CSB has also been associated with left atrium distension (Lloyd 1988) and increased levels of NT-proBNP (Carmona-Bernal et al. 2005; Poletti et al. 2009). In the same regard, optimizing the drug therapy for CHF may result in improving the CSB in some cases (Oldenburg et al. 2009; Olson et al. 2007). The carotid bodies may also play a role in the chemosensitivity, as shown by animal models (Ding et al. 2011; Schultz et al. 2015).

The importance of the interstitial edema is even greater, since it increases the elasticity of the lungs, reducing the FRC (Agostoni et al. 2002) and increasing the plant gain. The importance of PG is underlined by the positive effect of CPAP on CSB, which has been at least partially explained by recruitment of lung volume (Orr et al. 2017).

CHF is also associated with increased arterial circulatory time, causing increased circulatory delay and hence, increasing the LG by mediating "the right changes at the wrong time" (Khoo et al. 1982). Though the importance of circulatory delay is not equivocally accepted, most of the studies support its leading role (Hall et al. 1996; Lorenzi-Filho and Bradley 2002; Naughton et al. 1993; Mortara et al. 1999; Lorenzi-Filho et al. 2008).

An alternative theory for the CSB pathogenesis is the central hypothesis, which describes CSA as an internal oscillation within the CNS and modulating the breathing either indirectly via changes in heart rate and blood pressure or directly through activation of the respiratory center (Yajima et al. 1994).

It is important to note that the importance of the loop gain theory extends beyond being a theoretical canvas of CSB. Recently, it has been successfully used to determine treatment efficacy on central apneas (Stanchina et al. 2015).

6.3 CSB As an Adaptation of the Failing Heart

Naughton et al. proposed the controversial hypothesis of CSB being an adaptive response of the failing heart, rather than a detrimental complication (Naughton 2012). It has been gaining popularity recently with the evidence for increased mortality in CHF-CSB patients when treated with ASV (SERVE-HF) (Cowie et al. 2015). The CANPAP study also failed to produce convincing evidence for a positive outcome in terms of mortality with CPAP treatment in these patients (Bradley et al. 2005), although post-hoc analysis showed otherwise (Arzt et al. 2007). Actually, Naughton et al. structured their hypothesis around several logical arguments related to potential pathophysiological benefits of the hyperpneic phase of CSB, such as: increased FRC; vagal stimulation; improved tissue O_2 extraction (Haldane effect); improved cardiac filling (respiratory pump); increased end-expiratory pressure, etc. (Naughton 2012). It should be noted that the changes in the above-mentioned features are opposite during the apneic phase and the net effect may not be beneficial. For example, it has been proven that CSB is associated with increased sympathetic-adrenal activity (Solin et al. 2003; Carmona-Bernal et al. 2005; Oldenburg et al. 2008a).

Overall, with the lack of experimental studies, directly testing the hypothesis and the proves for higher morbidity, mortality and hospitalization rates in CHF patients with CSB (Ancoli-Israel et al. 2003; Carmona-Bernal et al. 2005; Mansfield et al. 2003) and treatment benefits (Arzt et al. 2007, 2009), this hypothesis should not be accepted as mainstream.

7 Clinical Manifestation

7.1 Signs and Symptoms

Patients with CHF report a number of somatic complaints, such as generalized fatigue, insomnia, impaired neuro-psychologic functions (Bitter et al. 2012; Braunwald 1988). Although most of the symptoms could be attributed to the cardiac dysfunction, some of them could possibly be granted to the disturbed sleep structure and, to a certain degree, result in the presence of daytime sleepiness. The clinical manifestation of CSA/CSB itself is usually poor, lacking striking symptoms and complaints. Witnessed apneas and snoring are infrequently reported by the sleep partner. Sometimes patients may report poor sleep quality with frequent awakenings, paroxysmal nocturnal dyspnea and frequent urination at night (Javaheri 2006a).

One may pay attention to the fact that the diagnosis CSA with SDB does not need the manifestation of any symptoms (criterion A – sleepiness; difficulty initiating or maintaining sleep, frequent awakenings, or non-restorative sleep; awakening short of breath; snoring; witnessed apneas) in the presence of CHF or AF (criterion B) (ICSD-3 (AASM 2014)), once gain demonstrating the low clinical profile of these patients.

7.2 NYHA Functional Class and Echocardiography

Most of the studies failed to present any significant differences in the NYHA functional class and the ejection fraction between patients with and without sleep-disordered breathing (Christ et al. 2007; Javaheri et al. 2017; Vazir et al. 2006; Arzt et al. 2003; Meguro et al. 2005). Though a correlation between the severity of the CHF and CSA frequency has been reported (Arzt et al. 2003), CSB showed high prevalence among patients with heart failure with preserved ejection fraction (HFpEF) (Berger et al. 2002; Herrscher et al. 2011).

Other EchoCG parameters, however, were found to differ between groups with and without CSA. Javaheri et al. (2017) related concentric remodeling of the ventricle (expressed by elevated left ventricular mass/volume ratio) to be associated with CSA. Left atrial size has also been linked to CSB (Oldenburg et al. 2007; Calvin et al. 2014) through increased chemosensitivity. Calvin et al. speculated that the association between the enlarged left atrium and the enhanced CO_2 chemosensitivity, found in CHF patients, is partially mediated by the J-reflex (Calvin et al. 2014). Right ventricle involvement was also reported (Calvin et al. 2014; Javaheri et al. 2007). Right ventricular systolic pressure is increased in CHF patients in the presence of CSA (Calvin et al. 2014), probably mediated by the hypoxia induced pulmonary hypertension (Javaheri et al. 2007).

7.3 Laboratory Parameters

Increased BNP levels in CHF are associated with poor outcome (Berger et al. 2002; Richards et al. 2001; Omland et al. 2002). The BNP was even further increased in patients with CSB (Carmona-Bernal et al. 2005; Poletti et al. 2009).

C-reactive protein levels are elevated in CHF (Pye et al. 1990; Kaneko et al. 1999; Sato et al. 1999) and influence its prognosis (Anand et al. 2005). In a study on 996 patients with CHF, Schmalemeier et al. reported a significant correlation between the CRP and the severity of CSA (Schmalgemeier et al. 2014). However, the reported effects of the therapy for CSA in CHF on the CRP levels have been controversial (Koyama et al. 2010; Bitter et al. 2012).

7.4 Cardiopulmonary Exercise Testing (CPET)

No clear proof for an association between exercise capacity and the presence of CSA in CHF is present so far. Peak oxygen uptake (VO_{2peak}) was reported to be lower with CSA as an absolute measure (Meguro et al. 2005; Roche et al. 2008)

or percent of predicted (Vazir et al. 2006; Roche et al. 2008) in some studies or without significant differences in others (Arzt et al. 2003). No difference was found in the anaerobic threshold (Roche et al. 2008). The most consistent finding is the increased ventilation-carbon dioxide output ($VEVCO_2$) in CHF with CSB (Arzt et al. 2003; Meguro et al. 2005; Roche et al. 2008; Cundrle et al. 2015). End-tidal CO_2 was lower at peak and at 50% of the exercise intensity in the group with CSB in the study of Cundrle et al. (2015). Periodic pattern of breathing may be observed in the first 4 min of a CPET (Roche et al. 2008).

7.5 Arterial Blood Gases

As already mentioned hypocapnia is a typical finding in CSB patients (Bitter et al. 2012; Christ et al. 2007; Szollosi et al. 2008; Bradley and Phillipson 1992). On the other hand, lower pO_2 is not present (Bitter et al. 2012) or not an independent risk factor (Bitter et al. 2012) in CHF with CSA.

7.6 Pulmonary Function Testing (PFT)

Reduced diffusion capacity of the lungs has been found to be an independent risk factor for CSA and correlated moderately with the AHI in the study of Szollosi et al. (2008). Despite the fact that low lung volumes have been implicated in the pathogenesis of CSB (see above), no difference in PFT parameters in patients with CSA has been reported.

7.7 Periodic Breathing During Wakefulness

CSB may be observed during wakefulness as well (Poletti et al. 2009; Mortara et al. 1999; Brack et al. 2007; Leite et al. 2003) and is associated with increased mortality and poor transplant-free survival (Brack et al. 2007). It has been attributed to low cardiac index and increased circulatory time (Mortara et al. 1999) and linked to increased sympathetic-adrenal activity and BNP levels (Poletti et al. 2009) and lower EF, exercise capacity and hypocapnia (Leite et al. 2003).

8 Consequences of CSB

Breathing disturbances, present in patients with stable CHF, are not just an acute pathological condition, but provoke chronic effects, which could promote a number of diseases, as well as further deterioration of cardiac function. In fact, Somers et al. (Somers 1999) hypothesize that CSA and cardio-vascular disease are linked through bidirectional causality as a part of a vicious cycle.

CSB is accompanied by cyclic variations in heart rate (tachycardia-bradycardia), blood pressure (hypertension-hypotension), respiratory volume (hyperpnoea-hypo/apnea), partial pressure of arterial oxygen (pO_2) (hypoxia-hyperoxia) and carbon dioxide (pCO_2) (hypercapnia-hypocapnia). The pathophysiological mechanisms, responsible for the adverse prognosis in CSA patients include hypoxia with/without hypoxemia, (micro)arousals from sleep, increased negative intrathoracic pressure. Each of them, and especially their combination, leads to sympathetic-adrenal activation.

Hypoxia, followed by an apnea or hypopnea, could provoke bradycardia or even several-seconds asystole (Guilleminault et al. 1983), whereas severe hypoxia could provoke acute ventricular arrhythmia (Leung et al. 2004). It should be noted that mild hypoxia was not related to ventricular arrhythmia in the same study (Leung et al. 2004). The combination between hypoxia and tachycardia impairs myocardial contractility, as it leads to a decreased myocardial oxygen delivery and an increase in the left ventricular afterload (Serizawa et al. 1981). The frequent desaturations and multiple arousals elicit structural changes to the heart as well as left and right ventricular hypertrophy (Ancoli-Israel et al. 2003) and contribute to the development of systemic oxidative stress in OSA (Lavie and Lavie 2009), and may invoke similar effects in CSB.

The arousals, following each respiratory disturbance contribute to the increased instability of respiratory control (Phillipson 1978; Naughton et al. 1993; Xie et al. 1994), increased release of catecholamines (Naughton et al. 1995; Horner et al. 1995), and overactivation of the sympathetic nervous system (Solin et al. 2003; Carmona-Bernal et al. 2005; Oldenburg et al. 2008a). Naughton et al. found increased nocturnal urinary norepinephrine levels and increased daytime norepinephrine plasma levels in patients with CHF and CSB, as compared to those without CSB and an association between the norepinephrine levels with increased frequency of arousals (Naughton et al. 1995). Sympathetic overactivation leads to a decreased survival of cardiomyocytes, exerts antiarrythmogenic effects and worsens ventricular energetism. It relates to myocyte hypertrophy, apoptosis and focal myocardial necrosis, which are factors for cardiac remodeling (Costanzo et al. 2015). All of these potentiate the progression and the lethal outcome in CHF patients (Mansfield et al. 2003).

Although the increased negative intrathoracic pressure is a typical consequence of OSA, it could also be present in CSA as well, even though to a lesser extent, as a result of pulmonary congestion and decreased compliance of lungs.

The Inflammatory Pathway According to the cytokine hypothesis, the activation of the immune system plays an important role in the pathogenesis of CHF, pointing out the participation of some pro-inflammatory cytokines for the development of the ventricular dysfunction (Seta et al. 1996; Vasan et al. 2003). Besides, the increased levels of some inflammatory markers show an independent correlation with adverse events and mortality (Anand et al. 2005) and those patients exhibit more severe CHF. Several studies suggest that the presence of obstructive sleep apnea leads to increased levels of some markers of systemic inflammation (Ciftci et al. 2004; Dyugovskaya et al. 2002; Schulz et al. 2000), which could be associated with a further progression of the cardiac dysfunction, forming a vicious cycle. Some markers of systemic inflammation are elevated in CSB (Schmalgemeier et al. 2014), so the aforementioned mechanism may play a role in CSB, as well.

The pathogenesis of the negative consequences of CSB on CHF is summarized in Fig. 5.

8.1 Quality of Life

Patients with CHF have a considerably decreased quality of life as compared with individuals, matched by age and gender (Lesman-Leegte et al. 2009). Undoubtedly, heart failure affects quality of life (QoL) to a greater extend, compared with other chronic conditions (Jaarsma et al. 2010). The influence of the CSB on QoL in patients with CHF is still debated with some studies reporting no effect (Ferrier et al. 2005), while others finding considerable worsening in the group with CSB (Carmona-Bernal et al. 2008), but the correlation with objective indices of its severity was poor (ODI) to moderate (AHI).

8.2 Morbidity and Mortality

The negative impact of the combination CHF/CSB is supported by a diverse body of evidence for increased morbidity and mortality in the presence of CSB (Ancoli-Israel et al. 2003; Carmona-Bernal et al. 2005; Mansfield et al. 2003; Lanfranchi et al. 1999; Hanly and Zuberi-Khokhar 1996). These findings were confirmed when corrected for the CHF severity (Ancoli-Israel et al. 2003; Carmona-Bernal et al. 2005; Mansfield et al. 2003; Hanly and Zuberi-Khokhar 1996). The severity of SDB probably plays an important role, as demonstrated in the study of Lanfranchi et al where only severe CSA (AHI $\geq$ 30) was associated with adverse prognosis (Lanfranchi et al. 1999).

Obstructive sleep apnea is a risk factor for arterial hypertension (Nieto et al. 2000). However, the impact of CSA on blood pressure, though expected (Fig. 5) has not been proven yet. In two studies (Bitter et al. 2012; Yumino et al. 2009) arterial hypertension was more

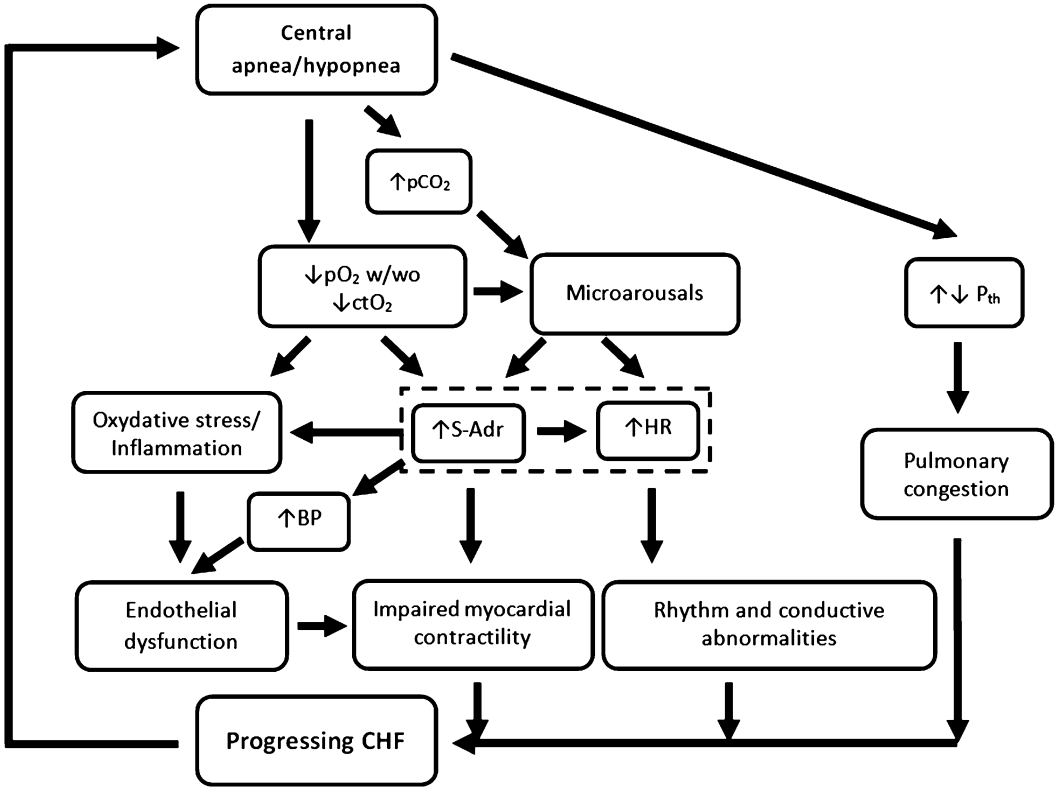

Fig. 5 Pathophysiology of the detrimental effects of CSB on chronic heart failure
Legend: pCO_2 – partial pressure of carbon dioxide, pO_2 – partial pressure of oxygen, ctO_2 – oxygen concentration (in arterial blood); P_{th} – intrathoracic pressure; S-Adr – sympathetic-adrenal activity; HR – heart rate; BP – blood pressure

prevalent in CSA compared to CHF patients without sleep disordered breathing, but the difference was not significant. No difference was found in the prevalence of diabetes mellitus as well (Bitter et al. 2012).

9 Diagnosis and Polysomnographic Pattern

The diagnostic process of patients with CHF, suspected to have CSA, follows the standard steps and includes a profound clinical interview, assessment of the HF condition and a sleep study, each of them having its importance for an adequate diagnostic outcome. A detailed description of the day-time and night-time symptoms is collected, preferably with the participation of the bed-partner, although a negative history of the latter does not exclude a clinically significant disorder. The recommended type of diagnostic study is the standard in-laboratory polysomnography (type 1 device), as it provides detailed information on sleep structure, respiratory and electro-physiological parameters. The polysomnographic characteristics of CSA include:

From the respiratory part: crescendo-decrescendo ventilatory pattern, accompanied by a partial (hypopnea) or complete cessation of breathing without thoracic and abdominal effort, followed by a decrease in the oxygen saturation. Respiratory effort is best measured by esophageal pressure, but currently this method is rarely used in clinical practice.

From the EEG part: CSB usually occurs during the transition from wakefulness to NREM 1 and 2 sleep stages. It is alleviated in a non-supine body position (Szollosi et al. 2006), while during slow wave sleep and REM sleep the ventilation tends to normalize. Usually a CSB sequence is preceded by an obstructive event or an arousal. Unlike obstructive events, ending with arousals, EEG arousals in CSB appear at the peak of the hyperventilation phase of the CSB cycle.

The severity of CSA is usually expressed by measuring the apnea-hypopnea index (AHI), which is calculated as the number of apneas and hypopneas, divided by the hours of sleep. Another metrics, although quite less commonly used, is the percentage of sleep time in which CSA/CSB occurs (Naughton and Andreas 2010).

10 Predictors

There is enough body of evidence that the presence of CSA/CSB in CHF patients worsens the overall prognosis (Ancoli-Israel et al. 2003; Carmona-Bernal et al. 2005) and needs targeted treatment (Arzt et al. 2007, 2009), therefore, a reliable screening system for its timely detection is required. Presently, the golden standard for diagnosing CSA/CSB is laboratory polysomnography, an expensive, laborious and highly specialized procedure, which can differentiate the various types of SDB (AASM 2014), (Ferrier et al. 2005) and determine the need of treatment. In order to optimize polysomnography use, a predictive system could be created, aiming at selecting the appropriate patients.

We have proposed a pathophysiological approach to the selection of some predictors, based on parameters, reflecting the etiology, the pathogenesis and the consequences of CSA/CSB in CHF (Draganova et al. 2016) – Table 1.

11 Therapy of CSB

Treatment of CSB aims at improving the cardiac function, quality of life and life expectancy in these patients. Despite the variety of treatment modalities proposed, it is important to note that, so far, guidelines do not offer a uniform treatment strategy for CSA in patients with CHF.

11.1 Optimization of CHF Therapy

Although according to some authors severity of CHF (as measured by NYHA class and ejection fraction) does not significantly differ among patients with and without CSA (Bitter et al. 2012; Christ et al. 2007; Vazir et al. 2006; Arzt et al. 2003; Meguro et al. 2005), applying

Table 1 Pathophysiological approach to prediction of CSB in CHF (With permission from Draganova et al. 2016)

PREDICTORS				
Etiologic	**Pathogenetic**			**Symptomatic**

	✓ Cardiopulmonary exercise testing (CPET) ✓ Hypoxic provocation			✓ ECG/ HRV ✓ CPET

Legend: *EchoCG* echocardiography, *NYHA* New York Heart Association, *ESS* Epworth sleepiness scale, *MLHFQ* Minnesota Living with Heart Failure Questionnaire, *ECG* electrocardiography, *HRV* heart rate variability

contemporary and adequate medication therapy, is the important first step towards CSA treatment in these patients. The diuretics, aiming at reducing the cardiac filling pressures, together with angiotensin-converting enzyme inhibitors to reduce ventricular afterload and improve cardiac output (Walsh et al. 1995) and beta-blockers to blunt the sympathetic nervous activation effects (Tamura et al. 2007), could to a certain extent diminish CSA severity (Solin et al. 1999).

Other therapeutic approaches, applied in advanced CHF like resynchronizing therapy (RT), may also have a beneficial effect on CSA. RT improves cardiac pumping function, which is a prerequisite for improved quality of life and sleep, as well as decreased mortality rate (Abraham et al. 2015). A meta-analysis, comprising 170 patients with CHF after RT, shows a considerable decrease of AHI in CSA patients, but not in patients with OSA (Lamba et al. 2011). Atrial overdrive pacing on top of RT in some of the patients in the same study, has led to a minor additional improvement of CSA (Lüthje et al. 2009).

However, despite the optimal CHF therapy, the presence of CSA requires specific treatment. The golden standard is application of positive airway pressure during sleep, although other treatment modalities have been tried.

11.2 Non-positive Airway Pressure Modalities

11.2.1 Nocturnal Oxygen Supplementation

Noxturnal home O_2 therapy (HOT) has been successfully used to treat CSA in CHF patients (Shigemitsu et al. 2007; Seino et al. 2007; Toyama et al. 2009; Sasayama et al. 2006; Nakao et al. 2016). The possible mechanisms involved are improvement in oxygen delivery to cardiomyocytes and influencing the controller gain by decreasing hypoxemia and increasing the cerebral CO_2 (Badr 2009). The effect of O_2 therapy on AHI in CHF with CSA is comparable to CPAP (Teschler et al. 2001). Additional benefits of the therapy are decrease in the nocturnal norepinephrine and the BNP levels (Shigemitsu et al. 2007), improved physical capacity (Toyama et al. 2009; Hanly et al. 1989; Andreas et al. 1996; Staniforth et al. 1998; Krachman et al. 1999) and quality of life (Seta et al. 1996) and lower hospitalization rate and duration (Seta et al. 1996). Unlike reported previously (Hanly et al. 1989; Staniforth et al. 1998; Krachman et al. 1999), EF increased after 3 months of HOT in the study of Toyama et al. (2009).

It should be noted, however, that noxturnal oxygen supplementation may not eliminate upper airway obstruction (frequently co-existing with central event), unless it is caused by an increased loop gain (Wellman et al. 2008).

11.2.2 Nocturnal Supplemental CO_2

Nocturnal inhalation of small amounts of CO_2 or the artificial increase of dead space (and, thus pCO_2) leads to suppression of CSB by shifting pCO_2 above the apneic threshold (Lorenzi-Filho et al. 1999; Xie et al. 2002; Andreas et al. 1998; Khayat et al. 2003). However, sleep quality and quality of life are not improved (Szollosi et al. 2004).

To avoid undesirable side effects of the CO_2 implementation, such as increased sympathetic activity, Mebrate et al. proposed a system with dynamic delivery of CO_2 (Mebrate et al. 2009). Yet, CO_2 therapy is not recommended for clinical use.

11.2.3 Theophylline

Theophylline is a respiratory stimulant (Eldridge et al. 1985; Javaheri et al. 1989) and has been able to decrease the periodic breathing and the AHI and improve oxygen saturation during sleep in the study of Javaheri et al. (1996). No improvement in cardiac function or sleep architecture was found (Javaheri et al. 1996).

11.2.4 Acetazoleamide

The positive effect of Acetazoleamide on high-altitude central sleep apnea and idiopathic CSA (White et al. 1982; DeBacker et al. 1995; Sutton et al. 1979; Hackett et al. 1987) is probably mediated by reduction in the pulmonary

congestion and lowering the apneic threshold through neural plasticity. Analogously, its use in CSA with CHF has been tested in a single small randomized trial on 12 CHF patients. Acetazoleamide for 6 nights has led to a decrease in periodic breathing by 38%, improved the quality of sleep and reduced of daytime sleepiness (Javaheri 2006b).

11.2.5 Phrenic Nerve Stimulation

A novel approach to eliminate CSB is the unilateral transvenous stimulation of the phrenic nerve. A pulse generator is implanted to stimulate the diaphragm during sleep, aiming at maintaining normal respiratory excursions (Ponikowski et al. 2012). Abraham et al. reported a 55% decrease in AHI (on behalf of the central events) at 3 months and a considerable improvement of sleep efficiency, oxygen saturation and quality of life (Abraham et al. 2002).

11.2.6 Heart Transplantation and Supportive Devices

Data showing the effect of heart transplantation and supportive devices are still limited to case reports and no reliable conclusions are possible. Heart transplantation was demonstrated to eliminate CSB in several studies (Fox et al. 2014; Vermes et al. 2009), in the first case the resolution was delayed over time (Fox et al. 2014). Ventricular assistant device eliminated successfully CSB in several cases (Vermes et al. 2009; Vazir et al. 2010).

11.3 Positive Airway Pressure Modalities

11.3.1 CPAP

At present, CPAP therapy is considered the gold standard in the treatment of CSA in CHF. It reduces AHI and improves the saturation profile (Naughton and Lorenzi-Filho 2009; Bradley et al. 2005; Arzt et al. 2007, 2009; Mansfield et al. 2003; Kaneko et al. 2003). According to its effect on AHI, the patients are divided into "responders" and "non-responders" (Javaheri 2000). With adequate titration CPAP increases transplant-free survival among these patients (Arzt et al. 2007; Sin et al. 2000). However, this effect is observed only in responders to the therapy (AHI on CPAP <15) (Arzt et al. 2007). It should be noted, that CPAP response is time-dependent (Arzt et al. 2009) and typically AHI decreases with less than 50% at the first night of treatment (Arzt et al. 2009; Teschler et al. 2001). In the study of Arzt et al., an additional reduction of 42% in the AHI (to the initial 47%) were observed after 12 weeks in the absence of any changes to the therapeutic pressure or medications (Arzt et al. 2009). Therefore, response assessment after at least 2 weeks of CPAP treatment is recommend (Arzt et al. 2009).

Additional benefits of the CPAP are improvement in EF (Bradley et al. 2005; Mansfield et al. 2003; Sin et al. 2000) physical capacity (Bradley et al. 2005), quality of life (Bradley et al. 2005) and sympathetic activity (Bradley et al. 2005; Mansfield et al. 2003; Kaye et al. 2001). CPAP does not affect sleep macroarchitecture, while data on arousals are controversial (Yumino et al. 2009; Kaneko et al. 2003).

CPAP treatment effects are consistent with the loop gain theory. It decreases plant gain by increasing the FRC which serves as a buffer for pCO_2, preventing large swings in it (Sands et al. 2011; Krachman et al. 2003). Controller gain is decreased as well, due to improved oxygenation of the blood affecting chemosensitivity (Lloyd et al. 1958; Arzt et al. 2009). It alleviates cardiogenic pulmonary edema and thus, decreases the non-CO_2 stimuli to the respiratory center (Lenique et al. 1997). The stability of the upper airway may also be improved in some patients (Jobin et al. 2012). Additionally, CPAP serves as a "cardiac assist device", decreasing the preload and the afterload to the heart (Naughton and Bradley 1998; Mehta et al. 2000; Steiner et al. 2008; Philip-Joët et al. 1999). Increasing blood oxygen levels also bears the benefits of reduced sympathetic-adrenal activity (Naughton et al. 1995; Kaye et al. 2001) and improved myocardial oxygen.

Table 2 Treatment recommendations for CSB (AASM)

Treatment modality	Statement	Recommendation
CPAP	CPAP therapy is indicated for the initial treatment of CSAS related to CHF.	STANDARD
O_2	O_2 therapy is indicated for the treatment of CSAS related to CHF.	STANDARD
ASV	ASV is indicated for the treatment of CSAS related to CHF with EF > 45%.	OPTION
BPAP	BPAP therapy in ST mode may be considered only if there is no response to adequate trials of CPAP, ASV, and O_2 therapies.	OPTION
Acetazolamide/ theophylline	Acetazolamide and theophylline have limited supporting evidence but may be considered after optimization of standard medical therapy, if PAP therapy is not tolerated, and if accompanied by close clinical follow-up.	OPTION

11.3.2 BPAP

Bilevel positive airway pressure (BPAP) supports a lower pressure during exhalation, thus facilitating the expiration and increasing tidal volume. In theory, the latter may cause hypocapnia and hence, provoke periodic or worsen breathing in CHF patients with CSA. Additionally, a large difference between the inspiratory and the expiratory pressures (>7 cmH_2O) causes periodic breathing in most healthy individuals (Badr 2009).

Consistent with the abovementioned, worsening of central breathing disturbances with BPAP was shown in the study of Johnson et al. (Johnson and Johnson 2005). On the contrary, several small studies demonstrated positive effect of the therapy (Köhnlein et al. 2002; Willson et al. 2001; Dohi et al. 2008; Kasai et al. 2005), with even superior results compared to CPAP (Köhnlein et al. 2002; Willson et al. 2001).

However, the scarcity of data and the contradictory results pose questions to BPAP therapy in CHF patients with CSA.

11.3.3 Adaptive Servoventilation

Adaptive servo-ventilation (ASV) is a relatively new approach in the CSA therapy in CHF. Its key characteristic is the variable pressure support to prevent hyperventilation, adding to the cardiocirculatory benefits of the CPAP (Teschler et al. 2001). Low expiratory pressures improve the cardiac output and also the compliance to the therapy (Hastings et al. 2010). Meanwhile, the servo-controlled inspiratory support stabilizes the ventilation at about 80% of minute ventilation during rest, avoiding the risk of hyperventilation and improving the efficacy in eliminating central events (Naughton and Lorenzi-Filho 2009). Indeed, studies have shown superiority of ASV over CPAP in eliminating CSB and better compliance (Teschler et al. 2001; Philippe et al. 2006).

ASV therapy has been shown to improve physical capacity, EF, N-pro-BNP levels in CHF patients (Oldenburg et al. 2008b). A positive effect of ASV on echocardiographic parameters has been reported even in patients with heart failure with preserved ejection fraction (Bitter et al. 2010). Additionally, ASV decrease sympathetic-adrenal activation, reduces nicturia and improves sleep architecture and quality of life (Philippe et al. 2006; Pepperell et al. 2003). In that regard ASV also proved superior to CPAP (Teschler et al. 2001; Philippe et al. 2006).

Despite these promising initial data, the results of the biggest multi-center randomized trial on ASV so far – SERVE-HF (Cowie et al. 2015) were disappointing. ASV therapy does not result in a significant improvement in quality of life or symptoms of CHF. More importantly, a considerable increase in cardiovascular and all-cause mortality with ASV treatment were found (Cowie et al. 2015). The results of another large-scale study (SAVIOR-C) show no effect of ASV therapy on EF and plasma BNP levels (Momomura et al. 2015).

The results of the SERVE-HF study provoked an update in the AASM recommendations for treatment of CSA in CHF (Aurora et al. 2012, 2016) which are summarized in Table. 2.

12 Future Perspectives

Though, CSB in CHF has been an extensively studied area lately, a lot of uncertainties remain. Naughton et al. have questioned the necessity of treatment of CSB, proposing an adaptive nature of the disorder (Naughton 2012). This hypothesis was reinforced the SERVE-HF study results (Cowie et al. 2015). It may be even the case of magnitude determining the adaptive or pathological nature of SDB. In that regard, the lack of uniform threshold for its presence and lack of severity metrics may be strongly impeding progress on the topic. Even the use of AHI as a key parameter by analogy to OSA has to be questioned (Naughton 2016). The recent changes in hypopnea definition (Berry et al. 2012) lead to scoring more events (Duce et al. 2015; Ward et al. 2013), though that does not seem to impact the proportion of central and obstructive events in CHF (Ward et al. 2013). Novel therapeutic approaches taking into account the pathophysiology of CSB were attempted (Mebrate et al. 2009; Ponikowski et al. 2012) and need further investigation. Phenotyping patients based on the loop gain seems especially promising in improving therapeutical efficacy (Stanchina et al. 2015). Early diagnosis is of no less importance and reliable laboratory markers for prediction of CSB are still needed.

The Evolution of mHealth Solutions for Heart Failure Management

Evanthia E. Tripoliti, Georgia S. Karanasiou, Fanis G. Kalatzis, Katerina K. Naka, and Dimitrios I. Fotiadis

Abstract

In the last decade, the uptake of information and communication technologies and the advent of mobile internet resulted in improved connectivity and penetrated different fields of application. In particular, the adoption of the mobile devices is expected to reform the provision and delivery of healthcare, overcoming geographical, temporal, and other organizational limitations. mHealth solutions are able to provide meaningful clinical information allowing effective and efficient management of chronic diseases, such as heart failure. A variety of data can be collected, such as lifestyle, sensor/biosensor, and health-related information. The analysis of these data empowers patients and the involved ecosystem actors, improves the healthcare delivery, and facilitates the transformation of existing health services. The aim of this study is to provide an overview of (i) the current practice in the management of heart failure, (ii) the available mHealth solutions, either in the form of the commercial applications, research projects, or related studies, and (iii) the several challenges related to the patient and healthcare professionals' acceptance, the payer and provider perspective, and the regulatory constraints.

1 Introduction

Mobile telecommunication technologies have penetrated multiple sectors, such as commerce, media, and finance with health being the one with the greatest potential (Clarke 2014). The acceleration of the electronic health records (EHRs) uptake by the Health Information Technology for Economic and Clinical Health Act legislation and the access of patients to mobile devices enabled the advent of the mobile health technology (mHealth) (Mennemeyer et al. 2016). Specifically, the last years, the concept of mHealth as "the use of mobile computing and communication technologies in healthcare and public health" is continuously gaining place and expanding. Governments are interested in involving mHealth as a complementary approach for improving healthcare delivery and achieving the health-related Millennium Development Goals (MDGs) in low- and middle- income countries (http://www.who.int/topics/millennium_development_goals/accountability_commission/en/). This interest has enhanced the development and application of several mHealth systems in Europe and worldwide, which provide early evidence for mobile and wireless technologies potential.

One of the key factors for this rapid mHealth growth is the healthcare transformation and the penetration of the mobile technology in the everyday life. The number of smartphone devices surpassed the world population, which accounts for 7.22 billion (https://www.gsmaintelligence.com/research/?file=357f1541c77358e61787fac35259dc92&download). About 80% of the world's population has access to a smartphone device with advanced technical capacities (Martínez-Pérez et al. 2013a). From 2011 to 2014, there was a remarkable increase from 35–64% in the proportion of Americans who owned a smartphone (http://www.mobihealthnews.com/42077/pew-64-percent-of-us-adults-own-a-smartphone-now). Smartphones may include several sensors, such as accelerometers and cameras, which can be used in different application areas. The spread and sophistication of such devices are growing rapidly. Wearable devices, such as smart watches, wristbands, and clothing, have been designed and fabricated incorporating physiological sensors, and they are able to collect and transmit data to the smartphones in order to be analyzed locally or to the Cloud. Taking into account the popularity, availability, and technological capacity of the smartphones, their integration with the mHealth has the potential to address the issue of disease management.

The mHealth technology is able to address specific needs and serve a wide range of purposes of heterogeneous audiences, including healthcare professionals, caregivers, patients, or even healthy people (http://www.springer.com/gp/book/9783319233406). The mHealth solutions are evaluated in diverse scenarios: (i) timely access to emergency and general health services, (ii) patient monitoring and management, (iii) reducing drug shortages at healthcare institutions, (iv) improving clinical diagnosis, and (v) assisting in overall adherence. One of the key characteristics of mHealth is the ability to serve the patients not only in the everyday life but also during hospitalization or even rehabilitation. The acquisition and collection of patient-specific information and the use of mHealth strategy in the clinical practice have been shown to be an easy and efficient way for improving service delivery in healthcare systems and in turn for providing health benefits to the patients (http://www.who.int/goe/publications/goe_mhealth_web.pdf).

1.1 mHealth in Chronic Diseases

Chronic diseases are among the leading cause of mortality and morbidity (Durstine et al. 2013; Viswanathan et al. 2012). The management of

chronic diseases requires a long-term treatment. Patients spend about 1 h per year with their healthcare professional and around 10,000 h to manage their health and disease symptoms by themselves. Self-management involves the management of symptoms and disease monitoring to prevent further complications. This can be achieved through the adherence to the suggestions provided by the experts. The adherence is one of the key factors for improved health outcomes and quality of life; however 50% of the patients with chronic diseases are non-adherent (Burkhart and Sabaté 2003). This burden is higher in the developing countries (Beaglehole et al. 2008). According to the World Health Organization (WHO), "increasing adherence may have a greater effect on health than improvements in specific medical therapy" (http://www.who.int/chp/knowledge/publications/adherence_introduction.pdf). Given the growing prevalence of chronic diseases combined with the increasing adoption of smartphone devices, the use of mHealth for patient self-management and disease monitoring seems promising. Several studies have shown the benefits gained for the patients after the adoption of mHealth systems. A meta-analyses on mHealth interventions for self-management of diabetes (Free et al. 2013) showed that significant improvements in the control of glycemic levels for diabetes patients can be achieved. The interactive approach of mHealth for monitoring blood glucose, diet, physical activity, and medication adherence was revealed by Saffari et al. (2014). Various analysis on diabetes self-management approaches through the utilization of mHealth showed that the monitoring of specific features, such as measured hemoglobin A1c, can result in significant health outcomes (Krishna and Boren 2008). Parkinson's disease is a movement disorder of the central nervous system affecting about 6.3 million worldwide (Liu et al. 2017; Darweesh et al. 2016). The integration of sensors in smartphone sensors resulted in a powerful tool, allowing the accurate measurement and evaluation of different movement-related metrics, and it has gained the interest of researchers (Patel et al. 2008, 2009, 2010).

1.2 mHealth for Cardiovascular Diseases

Cardiovascular disease (CVD) is a chronic disease with a high prevalence (http://www.who.int/healthinfo/global_burden_disease/GBD_report_2004update_full.pdf), and it consists a clinical field in which mHealth could provide several advantages. A variety of unhealthy lifestyle behaviors are related to CVD. The on time and continuous monitoring of these factors could significantly lower individuals CVD onset risk. For example, obesity is associated with several physical and mental health conditions, such as CVD, and according to evidence, a weight loss of 3–5% may delay or even prevent CVD onset and progression (https://www.researchgate.net/publication/12144466_Long-term_weight_loss_and_changes_in_blood_pressure_results_of_the_Trials_of_Hypertension_Prevention_phase_II; Look AHEAD Research Group and Wing 2010). In recent years, the use of smartphones and the provided functionalities for weight loss interventions have increased exponentially (Bacigalupo et al. 2013; Stephens and Allen 2013). In addition, for those at risk, the access to diagnostic tools, which are able to detect the disease at an earlier stage and provide outpatient monitoring with the associated improved care delivery and quality of life (QoL), has great promise. This can be achieved by the incorporation of informative ECG tools in smartphone-enabling technologies, which provides diagnostic ability in a scalable and cost-efficient way (Eapen et al. 2016).

1.3 mHealth and Heart Failure

Heart failure (HF) is a chronic cardiovascular life-threatening condition. It is characterized by high rates of hospitalizations, readmissions, and outpatient visits. These facts transform HF to a substantial economic burden for healthcare systems. The statistics show that (i) 26 million adults globally are diagnosed with HF, (ii) 3.6 million are newly diagnosed, every year, and (iii) 3–5% of hospital admissions are attributed to HF incidents. Recent studies reveal that the direct and indirect costs are up to 2% of all the healthcare expenditure (Ponikowski et al. 2014; Authors/Task Force Members et al. 2012; Blecker et al. 2013). All these, in combination with the fact that the HF population is rapidly growing, make the improvement of the HF management the main objective and priority of cardiovascular healthcare systems. The available approaches and interventions assisting HF patients in disease management include (i) nurse or healthcare professional group consultations (Feldman et al. 2009), (ii) -internet-based tools (Nolan et al. 2014), (iii) printed materials (Taylor-Clarke et al. 2012), and (vi) mHealth applications (Martínez-Pérez et al. 2013b) being the most promising (Karhula et al. 2015).

The mHealth-based interventions can have several characteristics that give them the potential to be more effective, among which the most important are (i) *interactivity* that allows the bidirectional communication and the care delivery, as a form of personal coach, (ii) *personalization* that makes the mHealth interventions customizable to the individual's needs, (iii) *timeliness* which permits the evaluation and delivery of targeted information at the right time point, (iv) *context sensitivity* expressing the ability of interventions to be adapted on the circumstances and/or the individual's environment, and (v) *ubiquity and accessibility* of the technology to all segments of population (Dicianno et al. 2015).

The use of mobile technology in HF management has attracted the interest of several researchers, resulting thus to the presence of a large number of reviews in the literature. The reviews focus on the description and comparison of different existing, in the last decade, mHealth interventions, as well as on their impact (Louis et al. 2003; Martínez et al. 2006; Chaudhry et al. 2007a; Maric et al. 2009; Cajita et al. 2016). The aim of this study is to present a short review of the mHealth HF interventions including also commercial available mHealth HF interventions and mHealth research projects related to HF patient management.

2 Heart Failure Clinical Problem and Current Practices

HF is a clinical syndrome that results from any structural or functional impairment of heart function, including (i) dilated and familial cardiomyopathies, (ii) endocrine and metabolic causes of cardiomyopathy (obesity, diabetic cardiomyopathy, thyroid disease, acromegaly and growth hormone deficiency, alcoholic cardiomyopathy, etc.), (iii) tachycardia-induced cardiomyopathy, (iv) myocarditis, (v) peripartum cardiomyopathy, (vi) cardiomyopathy caused by iron overload, (vii) amyloidosis, (viii) cardiac sarcoidosis, and (ix) stress cardiomyopathy. The HF patients suffer from a variety of symptoms, such as dyspnea, fatigue, low exercise tolerance, retention of pulmonary and/or peripheral fluid, urinary disorder (Tannenbaum and Johnell 2014), fast or irregular heartbeat (Pastor-Pérez et al. 2010), and breathing difficulties during sleep (Sharma et al. 2011), at rest, or at exercise (Bozkurt and Mann 2003). According to the ESC guidelines (Authors/Task Force Members et al. 2012), the procedure for evaluating the disease in HF patients in a non-acute setting includes the following steps:

Step 1: *History and physical examination*. The healthcare professional, during the first step of the HF evaluation process, estimates the probability of HF based on the following parameters: (i) family history, (ii) NYHA class, (iii) weight, (iv) duration and severity of symptoms,

(v) received medication, (vi) history of rehospitalization, (vii) lifestyle of the patient (nutrition and exercise), (viii) medical condition – comorbidities, and (ix) adherence to treatment.

Step 2: *Electrocardiogram* (*ECG*). The resting ECG provides information regarding the presence of abnormalities, such as atrial fibrillation and left ventricular (hypertrophy and repolarization). In case all elements (collected during first and second step of the diagnosis process) are normal, HF is unlikely; otherwise laboratory tests (third step) should be performed.

Step 3: *Laboratory tests*. Laboratory tests include routine blood and urine analysis and examination of natriuretic peptide (NT-proBNP) (Ewald et al. 2008; Maisel et al. 2008), cardiac troponin T or I (Horwich et al. 2003), and other emerging biomarkers. Based on these measurements, the experts are able to identify the patients who need echocardiography. Echocardiography is the method that is followed in patients with suspected HF, due to its high accuracy, increased safety, and low cost.

Step 4: *Noninvasive and invasive testing*. Other imaging modalities, such as chest X-ray, stress echocardiography, cardiovascular magnetic resonance imaging, *single photon emission computed tomography radionuclide ventriculography*, and positron emission tomography, can complement echocardiography in case specific clinical questions must be answered. Invasive tests, such as coronary angiography, right-heart catheterization, and endomyocardial biopsy, can be performed when they have a meaningful clinical consequence.

Step 5: *Risk scoring*. Certain risk scoring to homogenize the daily clinical practice and to assist the healthcare professionals in making therapeutic decision (Seattle HF, CHARM Risk Score, CORONA Risk Score, EFFECT Risk Score, etc.) is currently used in the clinical practice.

Framingham, Boston, the Gothenburg, and the ESC criteria are among the most common criteria used in the clinical practice for the determination of the presence of HF (Roger 2010). For the estimation of HF severity, the experts use the New York Heart Association (NYHA) or the American College of Cardiology/American Heart Association (ACC/AHA) guidelines classification systems. These criteria/classification systems are based on the combination of information collected through the diagnosis process and allow the experts to determine the most appropriate treatment for the HF patients (Dickstein et al. 2008).

The objectives of treatment in patients with HF are to improve their clinical status, functional capacity, and QoL, prevent hospital admission, and reduce mortality. Among the recommendations for the treatment of HF patients are (Yancy et al. 2013; McKelvie et al. 2013; National Clinical Guideline Centre (UK) 2010) (i) medication treatment, (ii) nutrition suggestions, (iii) exercise training, (iv) education, and (v) adherence.

The evolution in the field of medicine contributed to a widely available amount of medication for HF. In specific HF stages, patients are more likely to be prescribed more than one kind of medication (Paulus and van Ballegoij 2010). Lifestyle modifications (nutrition and physical activity) should also be performed by HF patients on a daily basis. Specific attention should be paid to the weight monitoring since it is a key element in HF self-management (Krum et al. 2011; Writing Committee Members et al. 2013), associated with repeated hospitalization (Chaudhry et al. 2007b) and increased mortality (Fiutowski et al. 2008). Non-adherent behavior places barriers to the exploitation of existing knowledge and thus has a negative impact on the patient's clinical status and overall QoL. Even though the HF patients have at their disposal a plethora of health-based knowledge, the adoption of this knowledge in their life is lacking. Recent evidence reveal that less than 50% of the HF patients are regularly monitoring their weight, while about 33% of HF patients do not take any action (van der Wal et al. 2005). This percentage is in accordance with the fact that patients' nonadherence is among the major factors contributing to the increase of hospitalizations (Fitzgerald et al. 2011).

3 mHealth-Based HF Interventions

The barriers, reported in the previous section, can be overcome by the use of mobile technology. mHealth enables the promotion of health intervention and can positively affect health-related behavior in real time (Riley et al. 2011). A large pool of primary and review studies are available in the literature describing, comparing, and evaluating the mHealth solutions, with the mHealth-based HF solutions attracting the highest number (Kitsiou et al. 2013). The clinical, structural, behavioral, and economic effects of mHealth solutions on HF are among the objectives of primary studies, while the systematic review focuses on different aspects. A systematic review of mHealth-based HF interventions was presented recently by Cajita et al. (2016). This study describes the already available interventions and their impact in terms of all causes of mortality, cardiovascular mortality, HF-related hospitalizations, length of stay, NYHA functional class, left ventricular ejection fraction, QoL, and self-care. According to the authors, the most commonly presented solutions are those that are able to remotely monitor the HF patient's status, using a mobile communication device in combination with a blood pressure sensor, weight scale, and an ECG recorder. Similar observations are reported in (Scherr et al. 2006; Piotrowicz et al. 2012), which indicate the feasibility of portable home-monitoring devices connected to a smartphone to monitor the HF patients with high diagnostic quality and integrity of vital measurements. Specifically, the study of Ledwidge et al. (2013) showed that the weight could be monitored through a wireless weight scale. Specifically, the patient's daily weight data were transmitted to a mobile phone and analyzed by an algorithm to predict the clinical deterioration in HF patients. The TEMA-HF 1 RCT used a telemonitoring system for enabling the healthcare professionals and the HF clinic communication (Dendale et al. 2012). The study included 160 HF patients from seven hospitals who used different sensors for measuring the daily weight, blood pressure (BP), and heart rate (HR). In case the predefined limits were exceeded, automatic alerts were created. The results of TEMA-HF 1 RCT showed that this telemonitoring system achieved a reduction in the hospitalization rate. A telemonitoring system which was used in 50 HF patients showed its value and impact on self-care, disease management, and health-related outcomes (Seto et al. 2012a). The quantitative outcomes revealed the empowerment of the HF patients and the ability of the clinicians to monitor and manage their patients in a more efficient and effective way. Another, similar study suggested that the use of the mobile phone telemonitoring approach could result in improved patient's medication regimen (Seto et al. 2012b). Additionally, this mHealth system provided the HF patients with automated suggestions related to lifestyle behavior. 120 patients from eight clinical centers who participated in the MOBITEL prospective, randomized study (Scherr et al. 2009) were equipped with a smartphone device, a weight scale, and a sphygmomanometer for BP and HR measurements. All the measured vital parameters were transmitted to the mHealth application, while the patients were able to manually insert the perceived medication. Then, the data were collected and analyzed to a secure website, which enabled the numerical and graphical data representation. This mHealth system allowed the remote monitoring of the patients by the physicians, and in case the transmitted values exceeded the personalized limits and/or early warning signs of decompensation existed, an automatic alert was created. The inclusion of the ECG sensor in mHealth systems has also been examined by several studies. Yap et al. (2012) used a chest belt of an ECG device and a specific mHealth application. Leijdekkers and Gay (2008) showed that a self-test mHealth application enables the HF patients to evaluate their clinical condition and support them in avoiding heart attacks, without the need of a healthcare professional. The main concept included (i) the collection and analysis of the ECG data depending on the patient's status, (ii) informed the patient and suggested a visit to

the doctor, and (iii) automatically alerted the emergency services providing the location and the status of the patient. Based on the findings of the previous studies, Seto et al. (2012b) created a rule-based HF mHealth system for measuring the weight, the BP, the HR, and the ECG. After the data collection by the mHealth application, an analysis by the hospital data servers was followed. The aim of this mHealth solution was to create and send alerts to the patients and the clinicians automatically, taking into account the clinical guidelines.

On the other hand, the systematic reviews aimed to summarize the available evidence (Kitsiou et al. 2015). Kitsiou et al. (2015) reviewed the effectiveness of home telemonitoring interventions for HF patients aiming to inform the policy makers, the practitioners, and the researchers. The authors collected, evaluated, and combined existing evidence from 15 reviews published from 2003 to 2015. The evaluation revealed that (i) a better investigation is needed regarding the process by which home telemonitoring provides improved outcomes, (ii) an optimal strategy should be followed for such systems, (iii) the optimal follow-up duration for achieving the expected benefits should be defined, and (iv) further investigation of the differential effectiveness between chronic HF patients and types of home telemonitoring is proposed. Whitehead and Seaton (2016) examined the effectiveness of mobile phone and tablet apps in the self-management of key symptoms of long-term condition management, among which was HF. The authors concluded that mobile phone and tablet apps have the potential to improve symptom management through enhanced symptom control. However, further innovation, optimization, and rigorous research around the field are suggested for allowing the provision of improved healthcare and outcomes. The design, implementation, and evaluation of mHealth technologies for chronic diseases management, like HF, are approached in the review study of Matthew-Maich et al. (2016). The authors concluded that in order to develop a feasible, well-acceptable, and usable mHealth system, the following should be taken into consideration: (i) A user-center design approach should be followed. (ii) A multidisciplinary approach, in which all ecosystem actors are involved in the disease management process, should be applied. (iii) An iterative development process supported by theoretical background knowledge should be designed. (iv) The evaluation of the end user's experience should be based on feasibility, acceptability, usability, and health-related criteria. (v) Barriers regarding organizational and system readiness to adopt mHealth solutions, the perception of different group of end users, user-technology interface that is used, and the existing sociodemographic disparities should be taken into account.

In consideration of the primary and review studies (Cajita et al. 2016; Kitsiou et al. 2015; Fiordelli et al. 2013), a taxonomy of mHealth-based HF interventions is presented in Table 1.

4 Commercial Available mHealth-Based HF Applications

Transformation of research results to a commercial product lead to commercial available mHealth-based HF solutions. The solutions are presented in the table below (Table 2) along with their privacy policy (Masterson Creber et al. 2016), their Institute for Healthcare Informatics (IMS) functionality scoring (IMS Institute for Healthcare Informatics 2017), their Mobile Application Rating Scale (MARS) score (Stoyanov et al. 2015), and their Heart Failure Society of America (HFSA) guidelines score (Masterson Creber et al. 2016). A short description of IMS, MARS, and HFSA scores is presented in Tables 3, 4, and 5, respectively.

Based on the HFSA guidelines score, the application that addresses all the HF-specific self-care behaviors is the Heart Failure Health Storylines (https://itunes.apple.com/us/app/heart-failure-health-storylines/id1062725794?mt=8). *AskMD* application followed by *WebMD*, *Symple*, *Heart Failure Health Storylines*, and *ContinuousCare Health App*

Table 1 Taxonomy of mHealth-based HF interventions

Dimension		
Functionality	Remote monitoring	Clinical monitoring
		Home monitoring
		Self-monitoring
	Training/education	
	Point of care diagnostic	Embedded software application
		Connected devices
		Sensors
		Mobile attachments
	Behavior modification	Cessation
		Promotion
		Self-management
	Efficiency and productivity	Data collection
		Communication
		Telemonitoring
	Compliance	Treatment
		Medication
		Self-testing
Technical modalities	Mobile features	Text messaging
		Features developed ad hoc for a specific condition
		Add-ons
		Voice
		Video
		Multimedia messaging services
	Type of devices	Mobile devices, including a blood pressure measuring sensor, weight scale, electrocardiogram recorder, or an implantable defibrillator equipped with a heart rhythm monitoring function
		Videoconference equipment
		Automated telemonitoring stations
		Mobile phones
		Tablets
	Technological approach employed for the collection and transmission of data	Central monitoring center/platform
		Automatic data transfer between the participants and the monitoring center
		Manually input and transfer of patients data to the monitoring center
		Algorithms determining whether the patient's values are outside their predefined limits which would then trigger an alert message to be sent to the participants physicians
		Nurses and physicians in their central monitoring centers who regularly monitored the participants status
		Structured approach in contacting participants regarding their status
Design process	User-centered design	
	Multidisciplinary team approach	
Policy consideration	Data management	On-device storage
		On-site servers
		Cloud computing
	Food and Drug Administration regulation	
	Mobile security	

Table 2 The scoring of the commercially available mHealth applications for HF

Application name (platform)[a]	Privacy policy	HFSA guidelines score	IMS	MARS

[a]Applications are available in Android Google Play, Apple iTunes, and Amazon Appstore

had the highest average MARS score. The evaluation of the applications in terms of 4 subscale scores (engagement, functionality, aesthetics, and information) revealed that *AskMD* has the highest score for engagement, functionality, aesthetics, and information, while *Heart Failure Health Storylines* application is on the top of the list for behavior change (Masterson Creber et al. 2016). The commercially available applications were also evaluated regarding the functionalities they provide based on the IMS score. The results indicated that the *WebMD*, *Symple*, and *ContinuousCare Health App* had a total of 11 functionalities, while *Heart Failure Health Storylines* follow with 10 functionalities (Masterson Creber et al. 2016). The five top applications based on the three scores are the following: *Heart Failure Health Storylines*, *Symple*, *ContinuousCare Health App*, *WebMD*, *and AskMD*. A description of the Heart Failure Health Storylines application is provided in Table 6.

Table 3 IMS Institute for Healthcare Informatics functionality scoring criteria

IMS Institute for Healthcare Informatics functionality scoring criteria	
Functionality scoring criteria	Description
1. *Inform*	Provides information in a variety of formats (text, photo, video)
2. *Instruct*	Provides instructions to the user
3. *Record*	Capture user-entered data
Collect data	Able to enter and store health data on individual phone
Share data	Able to transmit health data
Evaluate data	Able to evaluate the entered health data by patient and provider, provider and administrator, or patient and caregiver
Intervene	Able to send alerts based on the data collected or propose behavioral intervention or changes
4. *Display*	Graphically display user-entered data/output user-entered data
5. *Guide*	Provide guidance based on user-entered information, may further offer a diagnosis, or recommend a consultation with a physician/a course of treatment
6. *Remind or alert*	Provide reminders to the user
7. *Communicate*	Provide communication with healthcare provider/patients and/or provide links to social networks

5 mHealth Projects Related to HF Management

Several projects are related to HF management. A short description of indicative projects accompanied with their comparison is depicted in Table 7.

The objective of RENEWING HEALTH (Regions of Europe Working together for Health) project (http://www.renewinghealth.eu/) was to implement, validate, and assess innovative telemedicine solutions for chronic diseases' management. Specifically, the project follows a patient-centered approach with the patient having a central role in the management of his/her own disease. It allows the (i) choice and dosage of medications for improving the medication adherence and (ii) early detection of early signs of worsening.

The exploitation and further deployment of the telemedicine services implemented within the RENEWING HEALTH project are the main objectives of the United4Health project (http://united4health.eu/). The patient-centered approach and the use of telemonitoring for the treatment of patients with diabetes, chronic obstructive pulmonary disease, or CVD diseases are applied to all the service solutions. Services engage patients in the management of their disease, optimize the choice and dosage of medications, promote compliance to treatment, and help professionals to detect early signs of worsening. The patients use medical devices to measure the heart rate, blood pressure, pulse oximetry, and weight. The collected data are wirelessly forward from the medical device to a central gateway, and a clinical operator evaluates them. The telemedicine solution is able to detect abnormal measurements and triggers an alert to the operator to investigate further the collected data and proceed to the appropriate decisions and actions.

The HeartCycle project (http://www.heartcycle.eu/) proposed a disease management solution, based on Phillips commercial platform Motiva® (http://www.healthcare.philips.com/main/products/telehealth/products/motiva.wpd), for supporting and empowering the patients with HF. This is achieved by monitoring and analyzing vital signs and other measurements, including weight and physical activity activities. The patients are using a shirt with an embedded sensor for collecting the patient's vital signs during exercising. The communication between patient and healthcare professional is enabled through the patient's television. Personalized suggestions and educational material related to the patient's disease are projected through television after being analyzed by specific algorithms.

Table 4 MARS – Mobile Application Rating Scale score

Engage	Fun, interesting, customizable, interactive (e.g., sends alerts, messages, reminders, feedback, enables sharing), well targeted to the audience
	1. Entertainment: Is the app fun/entertaining to use? Does it use any strategies to increase engagement through entertainment (e.g., through gamification)?
	2. Interest: Is the app interesting to use? Does it use any strategies to increase engagement by presenting its content in an interesting way?
	3. Customization: Does it provide/retain all necessary settings/preferences for apps features (e.g., sound, content, notifications, etc.)?
	4. Interactivity: Does it allow user input, provide feedback, and contain prompts (reminders, sharing options, notifications, etc.)? Note: These functions need to be customizable and not overwhelming in order to be perfect.
	5. Target group: Is the app content (visual information, language, design) appropriate for your target audience?
Function	App functioning, easy to learn, navigation, flow logic, and gestural design of app
	6. Performance: How accurately/fast do the app features (functions) and components (buttons/menus) work?
	7. Ease of use: How easy is it to learn how to use the app; how clear are the menu labels/icons and instructions?
	8. Navigation: Is moving between screens logical/accurate/appropriate/ uninterrupted; are all necessary screen links present?
	9. Gestural design: Are interactions (taps/swipes/pinches/scrolls) consistent and intuitive across all components/screens?
Aesthetics	Graphic design, overall visual appeal, color scheme, and stylistic consistency
	10. Layout: Are arrangement and size of buttons/icons/menus/content on the screen appropriate or zoomable if needed?
	11. Graphics: How high is the quality/resolution of graphics used for buttons/icons/menus/content?
	12. Visual appeal: How good does the app look?
Information	Contains high-quality information (e.g., text, feedback, measures, references) from a credible source
	13. Accuracy of app description (in app store): Does app contain what is described?
	14. Goals: Does app have specific, measurable, and achievable goals (specified in app store description or within the app itself)?
	15. Quality of information: Is the app content correct, well written, and relevant to the goal/topic of the app?
	16. Quantity of information: Is the extent coverage within the scope of the app and comprehensive but concise?
	17. Visual information: Is visual explanation of concepts – through charts/graphs/images/videos, etc. – clear, logical, and correct?
	18. Credibility: Does the app come from a legitimate source (specified in app store description or within the app itself)?
	19. Evidence base: Has the app been trialed/tested (must be verified by evidence (in published scientific literature))?
Satisfaction	
	20. Would you recommend this app to people who might benefit from it?
	21. How many times do you think you would use this app in the next 12 months if it was relevant to you?
	23. Would you pay for this app?
	24. What is your overall star rating of the app?
Behavior change	
	25. Awareness: This app is likely to increase awareness of the importance of addressing [insert target health behavior]
	26. Knowledge: This app is likely to increase knowledge/understanding of [insert target health behavior]
	27. Attitudes: This app is likely to change attitudes toward improving [insert target health behavior]

(continued)

Table 4 (continued)

	28. Intention to change: This app is likely to increase intentions/motivation to address [insert target health behavior]
	29. Help seeking: Use of this app is likely to encourage further help seeking for [insert target health behavior] (if it's required)
	30. Behavior change: Use of this app is likely increase/decrease [insert target health behavior]

Table 5 HFSA – Heart Failure Society of America – recommended nonpharmacologic management behaviors

Weight	Daily weighing
Check swelling	Checking extremities for swelling
Physical activity	Doing physical activity or exercise
Diet	Eating a low-salt diet
Medication	Taking daily medications
MD appointment	Attending doctor's appointments
Monitor symptoms	Daily monitoring of HF symptoms
Symptom response	Actively responding to symptoms when they change

Table 6 Heart Failure Health Storylines application short description

	Heart Failure Health Storylines *By Self Care Catalysts Inc.* https://play.google.com/store/apps/details?id=com.selfcarecatalyst.healthstorylines.hf&hl=el
Developed in partnership with the Heart Failure Society of America and is powered by the Health Storylines™ platform from Self Care Catalysts Inc.	
Heart Failure Health Storylines provides tools to better manage and monitor heart failure	
Medication reminder: Sends reminders for medication intake in the users mobile device	
Symptom tracker: Allows tracking of symptoms and side effects and provides patterns that should be shared with the healthcare provider	
Daily vitals: User can keep a record of important vital measurements and provides graphical representation of them over time	
Physical activity tracker: Keeps track of physical activity levels	
Sync a device: User can import data from other health and fitness applications	
Daily moods and journal: Track and understand users' emotions and what might be driving them. Additionally, keep a journal for increasing well-being	

The HeartMan project (http://cordis.europa.eu/project/rcn/199014_en.html) developed a personal mHealth system for assisting the HF patients and providing them personalized advice and support. The key components include (i) the development of evidence-based predictive models, (ii) the creation of long-term models which focus on modifiable parameters, (iii) the delivery of a cognitive behavioral approach including mindfulness exercises, and (iv) the use of advanced health monitoring devices for monitoring the physical and psychological state of the patient.

HEARTEN (http://www.hearten.eu/) takes advantage of the cloud technologies for computing and serving information. HEARTEN is a solution which can be used from all actors involved in the management of a HF patient,

including caregivers and other ecosystem actors. The integrated Knowledge Management System and the Dynamic Patient Communication Protocol provide real-time monitoring, notifications, and reminders, overcoming the barrier of non-personalized patient management and treatment. This is achieved through the employment of artificial intelligence and data mining techniques. Furthermore, HEARTEN's alerting mechanism adapts the behavior of its users and can change the channel and route of communication, enabling the active communication and interaction.

6 Challenges to the Development and Adoption of mHealth Solutions

Although the impact of mHealth solutions is well accepted, several challenges for the development and adoption of the mHealth solutions should be addressed (Eapen et al. 2016; Matthew-Maich et al. 2016). Among the factors which support or hinder the implementation of mHealth solutions include (i) the institutional environment such as culture, policies, and readiness to change and integrate such systems, (ii) the availability of a comprehensive business and exploitation plan, (iii) personal factors of the different end users including perceived value of the mHealth solutions, and (iv) factors related to the solution itself, such as usability by the different types of end users. The challenges can be categorized to the following perspectives: (i) patient and healthcare professionals, (ii) payer, (iii) provider, and (iv) regulatory bodies.

Patient and Healthcare Professionals

A barrier to the adoption of mHealth solutions by the patients and the healthcare professionals is that the applied approaches neglect to address the impact of the solution to the workload adjustments, to the practice preferences, and to the existing daily routines of the end users. Healthcare professionals will not be positive to the adoption of such a solution in case they are not convinced about the benefits and the added value in terms of professional role support. Furthermore, the perception that the solution can act as a supportive tool of organizational micromanagement reduces their willingness to adopt the solution. On the other side, patients prefer solutions that can be seamlessly integrated in their daily activities without consuming their functional and time capacity. Beside the perceived value, factors related to the usability of the solution and the level of engagement they provide to the different type of end users are important factors for the adoption of the mHealth solutions. Solutions that are considered time-consuming, unreliable, burdensome, which require the entry of information and/or provide feedback through nonuser-friendly interfaces or even create doubts to the users regarding the protection of health information, remain a central concern.

The dispersion of mHealth solutions is affected by socioeconomic and demographic disparities. For instance, elderly and patients with low income are those most benefited by the mHealth solutions. However, such groups in general have the least amount of access to the mobile devices.

Payers

The adoption/acceptance of a mHealth solution depends on payers. Payers should take into account the healthcare incentives and implementation reimbursement. Beyond the financial motivation, payers can aggregate and synthesize evidence to enhance learning and use of mHealth solutions. Additionally, the interaction of patients with payers through the utilization of mHealth allows patients' outcomes and experiences to be measured. Through mHealth-based care management programs, payers and self-insured employees can manage previously outsourced prevention and wellness programs.

Providers

The mHealth tools focus on providers as the purchasers of the tools. Clinicians present the

lowest rate of mHealth tools adoption. This could potentially be attributed to (i) the clinicians' frustration with current health information technologies, (ii) the poor workflow integration and lack of interoperability that result to the provider's reluctance to health information technology acceptance, (iii) the uncertainty about the reliability of the data, (iv) the lack of adequate decision support, (v) the need of being provided with a holistic personalized care and delivering clinically meaningful support based on data analysis, (vi) the lack of high-quality mHealth evidence-based diagnostic and treatment strategies, (vii) the concern about the related ethical and legal issues, and (viii) the lack of clear reimbursement strategy.

Regulatory Bodies

The rapid proliferation of mHealth products created regulatory challenges. The Food and Drug Administration has issued guidance to assist the manufactures to further understand what items fall under the purview of regulators. It limits its scope to mobile medical applications intended to "be used as an accessory to regulated medical device" or to "transform a mobile platform into a regulated medical device" (https://www.fda.gov/downloads/MedicalDevices/.../UCM263366.pdf).

7 Conclusions

A taxonomy of mHealth-based HF interventions, a comparison of commercially available applications of HF, and a review of research projects related to HF are presented in the current study. Through this overview, the evolution of mHealth solutions for HF management is depicted concluding to several challenges, concerning patients, healthcare professionals, payers, providers, and regulatory bodies, which should be addressed. It is clear that the advancements in mobile technology have spurred growth and innovation in the health sector. More specifically in the field of HF management, this is expressed through the increasing number of researchers and the corresponding studies focusing on the HF management (diagnosis, severity estimation, prediction, adherence estimation, etc.) and the transformation of the studies to European Union funded projects and consequently to consumer applications. Although the rapid evolution of mHealth solutions for HF management, the assessment of the impact of those solutions on patients' life and especially in HF outcomes should be further studied. Some initial studies indicate that, in order for the mHealth solutions for HF to have substantial impact, a multidisciplinary approach should be followed where representatives of healthcare and technology fields should closely cooperate not only between each other but also with patients.

Acknowledgments This work is supported by the HEARTEN project that has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement No 643694.

New Insights in Cardiac Calcium Handling and Excitation-Contraction Coupling

Jessica Gambardella, Bruno Trimarco, Guido Iaccarino, and Gaetano Santulli

Abstract

Excitation-contraction (EC) coupling denotes the conversion of electric stimulus in mechanic output in contractile cells. Several studies have demonstrated that calcium (Ca^{2+}) plays a pivotal role in this process. Here we present a comprehensive and updated description of the main systems involved in cardiac Ca^{2+} handling that ensure a functional EC coupling and their pathological alterations, mainly related to heart failure.

Keywords

Calcium · RyR · Mitochondria · SerCa · Contraction · Heart Failure

1 Introduction

Each heartbeat is the result of calcium (Ca^{2+}) release and reuptake. During this cycle, the presence of this cation is essential to convert electric stimulation (action potential) in mechanic output (contraction), in a process commonly termed excitation-contraction (EC) coupling (Santulli et al. 2017a; Fabiato and Fabiato 1975). The action potential is the electrical signal that depolarizes the plasma membrane of cardiac myocytes, allowing the entrance of a relatively low amount of extracellular Ca^{2+}, which in turn induces high Ca^{2+} release from the sarcoplasmic reticulum (SR) (Lenzi and Caniggia 1953). Cytosolic Ca^{2+} binds to myofilaments, activating contractile machinery (Ebashi et al. 1967; Reddy and Honig 1972). This "Ca^{2+}-induced Ca^{2+} release"

(CICR), represents a positive feedback mechanism that allows the functional coupling between plasma membrane and SR (Katz 1967; Fabiato and Fabiato 1979; Fabiato 1983; Isenberg and Han 1994).

2 Microanatomy of EC Coupling

In cardiac cells, the structural units that mediate CICR are termed "diads" (Page et al. 1971; Soeller and Cannell 1997), consisting in specialized cellular micro-domains each composed by terminal cisternae of SR, also known as junctional SR, localized in close proximity to a tubular invagination of the plasma membrane, the transverse tubule (T-tubules) (Soeller and Cannell 1997; Shacklock et al. 1995; Clark et al. 2001). On the side of plasma membrane, along T-tubules, there are voltage-gated Ca^{2+} channels (T-Type and L-type, also known as dihydropyridine receptors, DHPRs), whereas on the side of SR cisternae there are intracellular Ca^{2+} release channels (ryanodine receptors, RyRs) (Pinali et al. 2017; Crocini et al. 2016; Li et al. 2015; Fameli et al. 2014).

Ca^{2+} channels on T-tubules are activated by depolarization and through them Ca^{2+} from the extracellular compartment goes in the cytosol, and activates RyR channels located on the SR of the same diad (Keizer and Levine 1996; Nakai et al. 1997). It has been estimated that for each Ca^{2+} channel opened on T-tubules, about 4–6 RyR channels are activated on SR, which in turn can activate neighboring RyR channels, resulting in massive release of Ca^{2+} from SR (Wang et al. 2001; Paolini et al. 2004).

3 Troponin, Tropomyosin, and Ca^{2+}: How Force Is Produced

The troponin complex consists of three subunits: tropomyosin-binding (T), inhibitory (I), and Ca^{2+} sensor (C). Troponin-T anchors the other two subunits on tropomyosin. Troponin I, under resting intracellular levels of Ca^{2+}, competes with tropomyosin for a common binding site on actin myofilaments, forcing tropomyosin into a position where it sterically blocks the binding of myosin heads (Lehman et al. 2013; Rao et al. 2014). The binding of cytosolic Ca^{2+} to Troponin-C induces conformational changes leading to the so-called activated state, in which myosin-binding sites on actin are exposed (Wang et al. 1999; Lehman et al. 2009). Then, the formation of cross-bridges between actin and myosin produces the sliding of myofilaments one over the other, eventually resulting in muscle contraction (Brunello et al. 2014; Kawai et al. 2006; Piazzesi and Lombardi 1996).

The inodilator levosimendan is a Ca^{2+} sensitizer that acts via binding the Ca^{2+}-saturated Troponin-C (Gustafsson et al. 2017). In particular, hydrogen-bond donor and acceptor groups on the pyridazinone ring and on the mesoxalonitrile–hydrazone moieties of levosimendan bind to a hydrophobic pocket of the Ca^{2+}-saturated amminoterminal domain of Troponin-C (Robertson et al. 2008). The main consequence of levosimendan binding is that the Ca^{2+}-saturated Troponin-C is stabilized in the presence of the drug, thereby promoting contractile force without an increase in the amplitude of intracellular Ca^{2+} transient. Levosimendan also acts via activation of ATP-sensitive K^+ channels (Grossini et al. 2009). In clinical trials levosimendan exhibited non-consistent results, especially in terms of mortality (Mebazaa et al. 2007; Polzl et al. 2017; Landoni et al. 2017).

Ca^{2+} handling within cardiac myocytes is in a delicate and dynamic equilibrium, which relies on several physiological modulators and subcellular systems, structurally and functionally related. Importantly, the amount of Ca^{2+} extruded by the cell during relaxation must be the same as the amount entering during the contraction (Karlstad et al. 2012). After the contraction phase, several mechanisms contribute to relaxation. Notably, Ca^{2+} is a fundamental determinant also during relaxation, since the correct functioning of channels responsible for cytosolic Ca^{2+} removal strictly depends on Ca^{2+} concentration (Allen et al. 1988; Plummer et al. 2011; Subramani et al. 2005).

4 Ca^{2+} Handling in the Pathogenesis of Heart Failure: New Insights

An accurate cardiac Ca^{2+} handling warrants the appropriate contraction that allows the heart to pump sufficient blood to meet the metabolic demand of the body. Impairment in cardiac pump function characterizes the pathological condition of heart failure (HF) (Karlstad et al. 2012; Kitsis and Narula 2008). Malfunction of the processes involved in Ca^{2+} handling plays an important role in the pathogenesis of HF, and this kind of alteration in myocytes is a primary defect causing contractile dysfunction in HF (Yano et al. 2005). Modifications in the expression and/or activity of Ca^{2+} channels, alongside with alterations of cardiomyocyte architecture (T-tubules), seem to have a determinant role in failing myocytes (Balke and Shorofsky 1998). The involvement of different Ca^{2+} transporters has been related to the stage and etiology of HF; indeed, studies in human failing hearts suggest that patients with ischemic cardiomyopathy are characterized by impaired Ca^{2+} uptake, while patients with idiopathic dilated cardiomyopathy exhibits mainly modifications in Ca^{2+} release (Sen et al. 2000).

Cardiac contraction is the result of isometric force (or ventricular pressure) and rapid shortening to allow ejection of the blood (Caremani et al. 2016; Colomo et al. 1994). Both of them rely on Ca^{2+}, specifically on amplitude/duration of Ca^{2+} transients, and on sensitivity of myofilaments to Ca^{2+}. To allow the generation of Ca^{2+} transients appropriate in terms of duration and amplitude, cardiac myocytes need a high – and at the same time flexible – capacity of Ca^{2+} buffering. Normally the amount of Ca^{2+} bound is in a 100:1 ratio compared to Ca^{2+} free in the cytosol, and during contraction such ratio immediately increases (about tenfold) in favor to free Ca^{2+} (MacGowan et al. 2006). Ca^{2+} buffering should ensure an optimal removal of free Ca^{2+} from cytosol in order to have an appropriate amount of Ca^{2+} available to the contraction in the next beat.

Each cycle of EC coupling needs a dynamic interplay between Ca^{2+} transient and myofilaments. The sensitivity of myofilaments to Ca^{2+} is high when the myofilaments are stretched, *i.e.* in the phase of cardiac blood filling (diastole) (Zhao et al. 2016). Therefore, right after relaxation the myofilaments are more responsive to Ca^{2+} binding. Such autoregulation is a key mechanism underlying the coordination in EC coupling. Hence, when a perfect overlap of high Ca^{2+} transient and high myofilaments sensitivity to Ca^{2+} is obtained, an appropriate force is generated, leading to an optimal contraction.

Although the exact mechanisms involved in cardiac Ca^{2+} handling are not entirely understood, it is known (Benitah et al. 2003) that EC coupling and cardiac performance are mainly based on two mechanisms: (1) Synchronized Ca^{2+} release during contraction; (2) Effective Ca^{2+} reuptake that ensure a good and robust termination of Ca^{2+} dependent contraction.

To satisfy the first point, there are systems that mediate Ca^{2+} flux towards the cytosol, from extracellular compartment or from intracellular Ca^{2+} stores, *i.e.* SR, during EC coupling (Fig. 1). For the second one, there are systems involved in retrograde Ca^{2+} flux, to terminate EC coupling (Fig. 2).

5 Ca^{2+} Fluxes during Systole

Ca^{2+} flux towards the cytosol starts with the entrance of a small amount of Ca^{2+} from extracellular space, triggering EC coupling: the depolarization wave is "transformed" in high Ca^{2+} release from intracellular store for contraction (Nanasi et al. 2017). The individual events of local Ca^{2+} release from SR are named Ca^{2+} sparks and reflect the activation of a cluster of about 6–20 Ca^{2+} channels on SR (Xie et al. 2013). Single Ca^{2+} sparks occur also at rest, and a crucial difference from Ca^{2+} sparks events during EC coupling is the synchronization; indeed, the action potential is able to synchronize several thousand of Ca^{2+} sparks within the same cell (Louch et al. 2013). Thus, individual events of

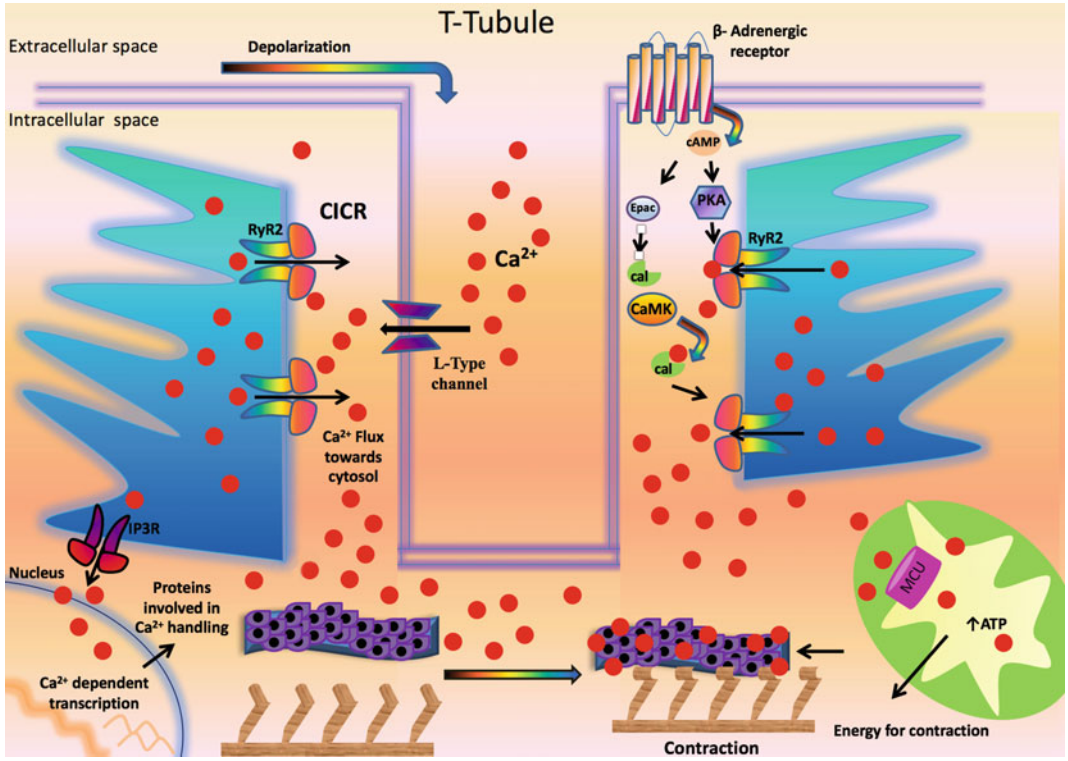

Fig. 1 Role of Ca^{2+} in excitation-contraction coupling in cardiomyocyte. local Ca^{2+} release are overlapping in time and space during EC coupling.

The main cellular complexes mediating Ca^{2+} flux towards cytosol for EC coupling are: voltage sensitive Ca^{2+} channels (T- and L-type) on the plasma membrane and RyRs on the SR.

6 Voltage-Dependent Ca^{2+} Channels

In myocytes there are two main types of voltage-dependent Ca^{2+} channels: T-type and L-type Ca^{2+} channels (Gonzalez-Rodriguez et al. 2015; Shaw and Colecraft 2013). The T-type channels are not preferentially located in the junctional region inside the diads, and the Ca^{2+} current generated by this kind of channels is negligible, with a minimal contribute to EC coupling (Zhou and January 1998). The L-type channels, also known as dihydropyridine receptors (DHPRs), are the main voltage dependent Ca^{2+} channels involved in EC coupling; they mainly localize on the T-tubule, in close proximity of Ca^{2+} channels on SR terminal cisternae (Bodi et al. 2005). DHPRs are activated by depolarization, allowing the Ca^{2+} to enter inside the cytosol and trigger CICR. A strategic auto-regulation of the CICR mechanism occurs at this level: indeed, DHPRs are inhibited by Ca^{2+} itself at the cytosolic side, limiting the amount of Ca^{2+} entry after depolarization. This local inhibitory effect on DHPRs is mediated by calmodulin, which binds the C-terminal domain on the receptor (Pott et al. 2007). Ca^{2+} released from SR in the same sarcolemmal-SR junction has also a modulatory effect on L-type receptors: when SR Ca^{2+} release occurs, the Ca^{2+} flux through DHPRs is reduced (Shiferaw et al. 2003). These events confirm that the Ca^{2+} needed for the contraction primarily derives from SR,

since Ca^{2+} channels on plasma membranes are quickly inhibited after the entrance of small amount of Ca^{2+}.

As mentioned above, action potential is responsible for synchronization of Ca^{2+} release from SR. The specific organization of ion channels on the plasma membrane, and in particular on the specialized invaginations of the T-tubules, plays a pivotal role in EC coupling (Oyehaug et al. 2013; Galbiati et al. 2001). Indeed, the loss of these structures leads to aberrant Ca^{2+} handling with blunted contractility, and such alteration has been mechanistically associated to HF (Wei et al. 2010).

In humans, HF secondary to dilated, hypertrophic, and ischemic cardiomyopathy, is related to aberrant alterations of T-tubule structure and the subsequent not-appropriate organization of voltage-dependent Ca^{2+} channels (Lyon et al. 2009). These anomalies could also be related to impaired function of junctophilins, proteins that are responsible for appropriate positioning of voltage-gated Ca^{2+} channels on T- tubules (Pinali et al. 2017; Schobesberger et al. 2017).

7 Key Role of RyR2 in Cardiac EC Coupling

RyRs are intracellular release channels, deputed to Ca^{2+} release from intracellular stores; the RyR2 isoform represents the most abundant isoform of this family in cardiomyocytes (Tunwell et al. 1996). This name was attributed based on the molecule with a high binding affinity to these receptors: the ryanodine, a natural product, known to induce a paralytic effect on striated muscle (Sutko et al. 1997; Rumberger and Ahrens 1972).

These channels have a tetrameric structure, similar to a mushroom, with the stalk across the SR membrane and the cap towards the cytosol. In this large structure, it is possible to identify at least two functional domains: C-terminus, which represents the ion pore across the membrane, and N-terminus that contains numerous modulatory sites (Gao et al. 1997). Indeed, RyR activity is highly regulated by several molecules – including calmodulin, FK-506 binding protein (FKBP), sorcin, junctin, and triadin (Balshaw et al. 2001; Anthony et al. 2007) – linked to the receptor, which thus represents the scaffold of a large macromolecular complex (Santulli et al. 2017b). Calmodulin and sorcin, two small proteins with high affinity for Ca^{2+}, are able to inhibit RyR when Ca^{2+} levels in the cytosol are higher than a threshold value, preventing further Ca^{2+} release from SR. This phenomenon is involved in EC coupling termination.

RyR has also several sites modulated by Ca^{2+}, Mg^{2+}, phosphorylation, and oxidation, making this receptor also a sensor of intracellular redox state (Hain et al. 1995; Chugun et al. 2007; Xie et al. 2015). Therefore, RyR activity is the result of a multifaceted interactome specialized in Ca^{2+} handling.

Inositol-1,4,5, trisphosphate (IP3) receptors (IP3Rs) represent another example of intracellular Ca^{2+} release channel. Located on the SR as RyR, they are activated by a second messenger, IP3, involved in several pathways. These receptors are closely related to the RyR family, sharing a high structural homology (Santulli et al. 2017a, b; Maltsev et al. 2017). Although there are several stimuli that induce IP3 accumulation, the physiological depolarization of cardiac myocyte, does not seem to activate IP3Rs and their involvement seem to be limited to the regulation of transcription of important modulator of Ca^{2+} handling machinery (*e.g.* CamKII, calcineurin), indirectly contributing to regulate the capacity of the cells to maintain Ca^{2+} homeostasis, indispensable for appropriate EC coupling and contractility (Santulli et al. 2017a; Santulli and Marks 2015). Moreover, IP3R has a different distribution in atrial and ventricular myocytes, compared to RyR2; in particular, IP3Rs are principally located in the atrial myocyte and also in Purkinje fibers (Luo et al. 2008; Mignery et al. 1990). Purkinje fibers are a specialized conduction system, and IP3Rs can modulate the transfer of depolarization wave through ventricular mass.

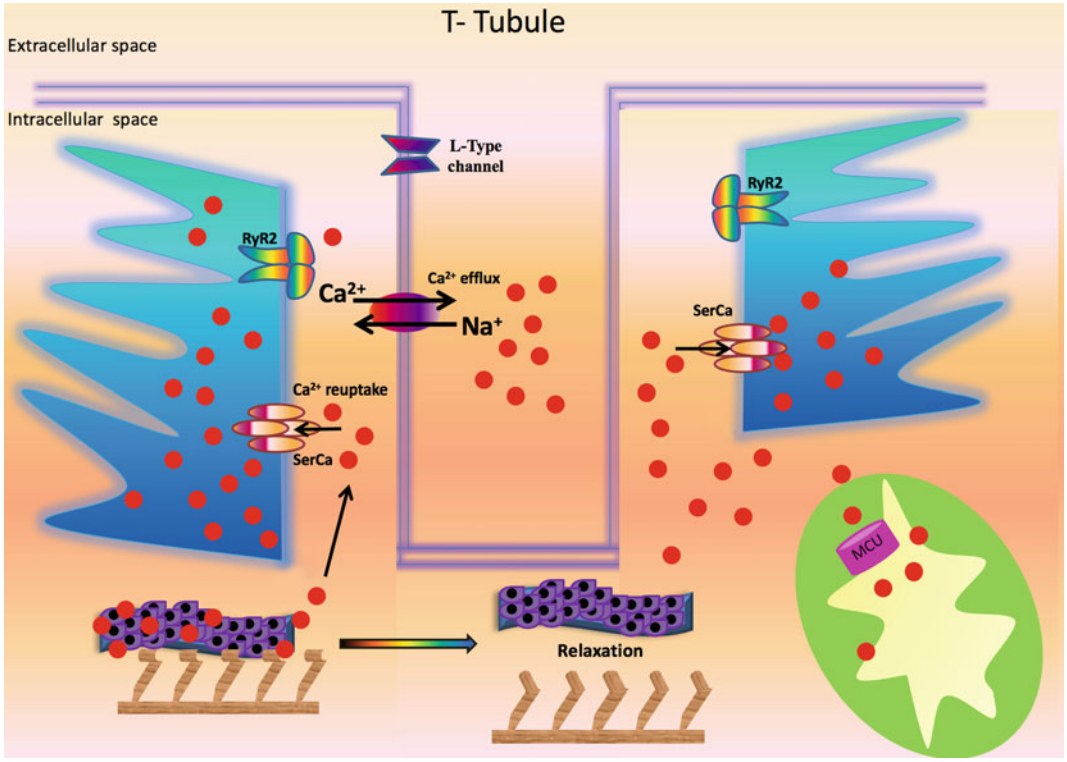

Fig. 2 Mechanistic role of Ca^{2+} in the relaxation phase. Ca^{2+}: calcium; MCU: mitochondrial Ca^{2+} uniporter; Na^{+}: sodium; RyR2: Type 2 ryanodine receptor Ca^{2+} release channel; SERCA: sarco/endoplasmic reticulum Ca^{2+}-ATPase

8 Ca^{2+} Fluxes During Diastole

To ensure muscle relaxation, mechanisms of Ca^{2+} reuptake from the cytosol actively mediate a retrograde Ca^{2+} flux. The main "cytosolic Ca^{2+} scavengers", Sarco-Endoplasmic reticulum Ca^{2+} ATPase (SerCa) and Na^{+}/Ca^{2+} exchanger, achieve this function (Fig. 2). A large portion of Ca^{2+} is pumped by SerCa from the cytosol back to the SR, but the relative contribute of different Ca^{2+} removal systems can depend on the species.

9 Functional Role of Na^{+}/Ca^{2+} Exchanger in Ca^{2+} Reuptake

Na^{+}/Ca^{2+} exchanger mediates reversibly influx or efflux of Ca^{2+}, depending on concentration of free Ca^{2+} inside the cytosol, but normally it works in Ca^{2+} efflux mode (Fujioka et al. 2000; Luongo et al. 2017). In cardiomyocytes this channel represents the major Ca^{2+} efflux system, with a critical role in the regulation of Ca^{2+} cellular content (Zhu et al. 2015; Acsai et al. 2011). Indeed, some alterations of ionic equilibrium inside the cell, that induce increase in Na^{+} intracellular levels, can trigger changes in the activity of the channel, which starts to work in reverse mode, mediating Na^{+} efflux, with influx of Ca^{2+} ions (Kang and Hilgemann 2004).

10 SerCa-ATPase

SerCa ATPase represents a fundamental pump system mediating Ca^{2+} reuptake in the SR/ER (Zima et al. 2014). In cardiomyocytes, SerCa removes the Ca^{2+} from cytosol during relaxation with an active process (ATP hydrolysis), in order to terminate the EC coupling cycle and to restore Ca^{2+} levels inside SR, necessary for the next contraction.

The correct activity of SerCa, and the indirect interplay with RyR2 that promotes Ca^{2+} flux in the opposite direction, are essential to have an EC coupling cycle with appropriate amplitude and synchronization in space and time. Ca^{2+} itself plays a pivotal role in mediating such interplay (Collins and Thomas 2001). SerCa, as well as RyR2, is highly regulated not only directly by Ca^{2+}, but also by other molecules that are sensitive (CaMKII) or not (PKA) to Ca^{2+}. These two kinases, as seen for RyR2, are able to regulate SerCa, but not via direct phosphorylation, but through phosphorylation of the most important regulator of SerCa, phospholamban. Phospholamban (PLB), is an endogenous inhibitor of SerCa that limits the affinity of the pump for Ca^{2+}. PKA can phosphorylate PLB at Ser^{16}, inhibiting PLB and therefore activating SerCa, increasing its pumping rate (Simmerman et al. 1986). CaMKII, whose activation relies also on the exchange protein directly activated by cAMP (Epac) pathway (de Rooij et al. 1998; Lymperopoulos et al. 2014; Parnell et al. 2015), is able to phosphorylate PLB at Thr^{17}, leading also in this case to an acceleration of SR Ca^{2+} uptake (Simmerman et al. 1986). SerCa is also regulated by the metabolic state of the cell in terms of ATP/ADP ratio, and redox-status (Zima et al. 2014). Alterations in expression or activity of SerCa, strongly contribute to HF development and progression, through dysfunctional Ca^{2+} handling. In particular, several studies show that both mRNA and protein levels of SerCa pump are downregulated in HF (Currie and Smith 1999; Armoundas et al. 2007). The decrease in SerCa/PLB ratio results in impaired SR Ca^{2+} uptake (Linck et al. 2000). Moreover, the regulation of SerCa by both PKA (Schwinger et al. 1998) and CaMKII (Schwinger et al. 1999) is significantly impaired in failing hearts.

11 Intracellular Ca^{2+} Leak: Definition, Pathophysiology, and Interventions

RyR2 interactome ensures the appropriate amplitude and kinetics of Ca^{2+} cycling, indispensable for cardiac contractility. Alterations in RyR2 and/or in RyR2 interactome, are among the main identified aspects of HF (Ono et al. 2000; Kohno et al. 2003). All the events that are able to affect the opening frequency of RyR2, determining changes in amplitude or duration of Ca^{2+} release, can predispose to contractility dysfunction (Patel et al. 2000). In particular, the phenomenon of Ca^{2+} leak, defined as inappropriate release of Ca^{2+} from the SR (*e.g.* during the diastolic phase), is determinant in HF progression (Hofer et al. 1996). In pathological conditions such as HF, there is a high release of Ca^{2+} from SR during diastole, reducing the availability of SR Ca^{2+} for the subsequent contraction, thereby impairing contractility (Santulli et al. 2017b).

FKBP12.6, also known as Calstabin2, plays an important pathophysiological role in the regulation of RyR2 function. Indeed, it stabilizes a conformation of the channel that prevents Ca^{2+} leak (Timerman et al. 1996; Lam et al. 1995; Xin et al. 1999; Yuan et al. 2014). There are numerous events, both acute and chronic, that trigger instability of RyR macromolecular complex. One typical example is represented by its phosphorylation, which induces the dissociation from the receptor of its stabilizing molecule, FKBP12.6 (Yuan et al. 2014). Chronic activation of beta-adrenergic system increases PKA activity (Santulli et al. 2013), with consequent phosphorylation of RyR (Takasago et al. 1991). Phosphorylation of RyR by CaMKII has also been reported in HF (Kushnir et al. 2010). Furthermore, ROS-linked oxidation of RyR affects the normal Ca^{2+} handling, compromising the correct contraction of myocytes during HF (Santulli et al. 2015).

Several benzothiazepine derivatives, including *JTV519* (also known as *K201*, 4-[−3{1-(4-Benzyl) piperidinyl}propionyl]-7-methoxy-2,3,4,5-tetrahydro-1,4-benzothiazepine) (Kohno et al. 2003; Hachida et al. 1999a, b; Sacherer et al. 2012) and its substructure *S107* (7-methoxy-4-methyl-2,3,4,5-tetrahydro-1,4-benzothiazepine) (Thevis et al. 2009; Matecki et al. 2016; Lukyanenko et al. 2017) have shown cardioprotective and antiarrhythmic

properties by decreasing Ca^{2+} leak (Santulli et al. 2017a; Xie et al. 2013, 2015).

Henceforth, RyR2 represents the central target of many pathways dysregulated in cardiac pathological conditions, including adrenergic dysfunction, metabolic disorders, ROS production: all of these conditions are accompanied by alterations in Ca^{2+} handling and subsequent impairment in contractility.

12 Role of Mitochondrial Ca^{2+} in Metabolism-Contraction Coupling

Mitochondria play a strategic role in ensuring an adequate EC coupling (Miragoli and Cabassi 2017; Umanskaya et al. 2014; Gambardella et al. 2017; Torrealba et al. 2017). Indeed, cardiac myocytes are critically dependent on constant and appropriate energy supply, alongside with a finely tuned Ca^{2+} handling (Torrealba et al. 2017; Sorriento et al. 2017; Sheeran and Pepe 2017). Mitochondria and SR are functionally and structurally associated and, at the point of interaction (mitochondrial associated membranes) Ca^{2+} transits from SR to mitochondria (Min et al. 2012; Bononi et al. 2017). Ca^{2+} that enters in mitochondria is able to increase their bioenergetics, but at the same time, mitochondria, allowing Ca^{2+} entrance through the mitochondrial Ca^{2+} uniporter (De Stefani et al. 2011; Liu et al. 2017; Granatiero et al. 2017), can act as local Ca^{2+} buffers, actively participating in Ca^{2+} handling (Walsh et al. 2009; Gunter and Sheu 2009; Drago et al. 2012; Morciano et al. 2017). However, mitochondrial Ca^{2+} overload has been shown to be detrimental in various cell types (Liu et al. 2016; Kostic et al. 2015; Charles et al. 2017), and, specifically, it has been proven to play a mechanistic role in the pathogenesis of HF (Santulli et al. 2015). Therefore, our hypothesis is that whereas transient mitochondrial Ca^{2+} uptake promotes ATP production, prolonged or excessive Ca^{2+} uptake can be harmful.

The ability of mitochondria to respond to changes in Ca^{2+} levels, increasing metabolic outcome, and acting as Ca^{2+} scavenger, contributes to the adequate contractile response of cardiomyocytes. Indeed, alterations in these processes can lead to increase in cytosolic Ca^{2+} with potential activation of detrimental pathways that have been associated with HF, including CaMKII (Zhang and Brown 2004). Additionally, alterations in SR-mitochondria contacts have been found in cardiac dysfunction and HF (Lopez-Crisosto et al. 2017).

Whether mitochondrial Ca^{2+} transients exist during physiological EC coupling, in a beat-to-beat fashion, remains to be determined. Anyway, an important aspect of these phenomena is that Ca^{2+} proves once again its ability to act as a messenger, communicating to mitochondria the energetic demand of the cell, for adequate contraction.

Critical Appraisal of Multivariable Prognostic Scores in Heart Failure: Development, Validation and Clinical Utility

Andrea Passantino, Pietro Guida, Giuseppe Parisi, Massimo Iacoviello, and Domenico Scrutinio

Abstract

Optimal management of heart failure requires accurate risk assessment. Many prognostic risk models have been proposed for patient with chronic and acute heart failure. Methodological critical issues are the data source, the outcome of interest, the choice of variables entering the model, the validation of the model in external population. Up to now, the proposed risk models can be a useful tool to help physician in the clinical decision-making. The availability of big data and of new methods of analysis may lead to developing new models in the future.

Keywords

Heart failure · Risk model · Prognosis

1 Introduction

Average outcome of patients with heart failure (HF) is poor, with relevant mortality and morbidity: the absolute mortality rates for HF remains close to 50% within 5 years of diagnosis (Roger et al. 2004; Levy et al. 2002); however, the risk among subgroups of patients may vary several-fold.

Prognosis is one of the main charge of medical practice: clinicians need to understand the likely course of a disease to treat patients with confidence.

Patients and their relatives are concerned about the risk of future events, therefore communicating an accurate prognosis is a basic part of the physician-patient interaction. An accurate

prediction of the future course of the disease could help patients in their decision-making.

Correct prognostication of HF patients is mandatory to select high-risk subjects for mortality, or for hospitalization, allowing the selection of patients who can gain the most benefit from advanced procedures, like heart transplantation and mechanical support, at the same time avoiding overtreatment of low-risk or terminal patients.

Furthermore accurate prognostication of disease trajectory may suggest the modality and frequency of follow up, selecting, for example, patients for tele-monitoring systems, or eventually, to refer patients to hospice for palliative treatments.

Evaluation of risk profile of acute heart failure (AHF) patients, at hospital admission, should help physicians to identify low risk patients that can be safely discharged at home, pursuing both patients best outcome and correct resource allocations.

Finally, in clinical trials, risk stratification is useful to define eligibility criteria associated with higher event rate (when researchers are interested in recruiting a cohort of high-risk patients) or to forecast the likely benefit of a treatment on an individual basis, leading to a personalized medicine with targeted treatments.

However, age, aetiology, comorbidities, different pathophysiological patterns, treatments and non-medical factors may influence disease trajectory, making the prediction of clinical course difficult. Previous studies demonstrated that the holistic medical judgment about prognosis is inaccurate and highly variable; in particular, differences between physician predicted and actual survival of HF patents is remarkable in intermediate risk patients (Yamokoski et al. 2007). Moreover, physicians are unable to predict survival for end-stage patients (Hauptman et al. 2008).

Many individual factors have been associated with poor prognosis in heart failure such as demographic data, functional status, severity of heart dysfunction, biomarkers of neurohormal activation, non-cardiovascular co-morbidities and clinical events. However, the clinical applicability of a single predictor is limited. Then again, for such a complex disease, as heart failure is, a single predictor unlikely fits for all patients; rather a multivariable approach to prognosis is required. Multivariable prognostic models have been developed to overcome the limitations of single predictor approach; they give predictions based on multiple factors and are called prognostic models, prediction models, prediction rules or risk scores (Moons et al. 2012a, b). These models can be used to identify patient cohorts with high, medium, or low risk for death or another relevant clinical outcome.

2 Risk Prediction Models: Development and Validation

Statistical techniques for single-outcome are logistic regression for binary conditions and the Cox proportional hazards model for time-to-event analysis (Hosmer and Lemeshow 2000; Clark et al. 2003a, b). The logistic regression model takes the natural logarithm of the odds as a regression function of k predictors:

$$\ln\left(p/(1-p)\right) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \ldots + \beta_k x_k$$

where p is the probability of event, β_0 is the model intercept term and β_i represents the estimated regression coefficient of each risk factor. In the case of unequal length of follow-up, the prediction of time-to-event requires specific regression techniques. The most popular approach is the Cox proportional hazards model for assessing the hazard function $h(t)$ given a set of k independent multiple predictors

$$h(t; x_1, x_2, x_3, \ldots, x_k) = \lambda_0(t) \times \exp(\lambda_1 x_1 + \lambda_2 x_2 + \lambda_3 x_3 + \ldots + \lambda_k x_k)$$

where $\lambda_0(t)$ is the baseline hazard at time t, λ_i represents the estimated regression coefficient for the k independent covariates. The linear predictor allows the calculation of patient's outcome probability on the basis of subject's risk profile

(values observed for the k variables x_1,x_2,x_3,..., x_k). In the case of more than two possible discrete outcomes, logistic regression may be extended to multinomial logistic regression where each mutually exclusive outcome has its own coefficients (LaValley 2008). In the case of time-to-event analysis with more failure outcomes, competing risks regression models evaluate the relationship of covariates to cause-specific failures (Rao and Schoenfeld 2007).

Developing a Predictive Model Before starting to develop a multivariable model, in order to avoid bias, some relevant issues should be considered: the representativeness of the population of interest, the accuracy of dataset, the missing values handling, the sample size, the number of observed events and the number of predictors (Royston et al. 2009; Bradburn et al. 2003).

The first crucial step is the selection of the data source. Patient's information may be obtained from community, registry, state-wide databases, population cohorts, clinical trials. The next pivotal step is the selection of variables making up the score: a prognostic model is only as good as the variables from which is derived. The aim is to reduce scoring system complexity without lost in predictive performance. Factors highly correlated with others may be excluded considering as predictors those with the highest independent contribute in explaining outcome (Harrell et al. 1996). Well-known predictors already reported as prognostic would be candidates without excluding those not significant at univariate analysis. Stepwise parsimonious technique, as forward selection or backward elimination approach, analyses all candidate variables. All regressive approaches allow the use of categorical predictors and continuous variables. A strong violation of linearity assumption between risk of outcome and continuous factors may lead to erroneous predictions (Royston et al. 2009). Several approaches exist to model non-linear relationships (Harrell et al. 1996). Categorization of continuous variables is possible by using established cut-points that have clinical meaning; more than two categories reduce the loss of information (Clark et al. 2003a, b). Simple bedside risk score may be derived from regression coefficients of original model developed on categorised data. A scoring system with summation of points assigned for each predictor allows an accurate bedside stratification of prognosis without solving the equation. Alternatively, tools are commonly available as web-calculator or mobile app to estimate directly the exact probability of outcome occurrence given patient' features.

Assessing Performance The models' performance is assessed in terms of discrimination and calibration of predictions. The concordance statistic C-index (Harrell et al. 1996) or the area under the receiver-operating curve (ROC) measure the ability of risk scores in distinguish between individuals with and without the outcome. A value of 0.50 could be achieved randomly, whereas an index of 1.0 represents perfect discrimination. Calibration is one of the most important model performance characteristics necessary to produce valid risk estimates and to avoid errors into decision-making. Goodness-of-fit statistics for calibration can be obtained by comparing, for groups of predicted risks, the observed events against the expected values. The underlying hypothesis is that the estimated and observed frequencies agree. A statistically significant finding indicates lack of fit (Hosmer ad Lemeshow 2000).

Often, investigators evaluate the performance of a model when a new predictor is added. Two common measures are used for assessing improvement in model performance (Pencina et al. 2008, 2011): the Integrated Discrimination Improvement (IDI) and the Net Reclassification Improvement (NRI). Figure 1 shows an example of models comparison.

Validating a Prognostic Model A good model should allow a reliable classification of patients into risk groups. External validation examines the generalisability of the model, for which it is necessary to use new data collected from a similar population in a different institution. Model's performance can be assessed using new data

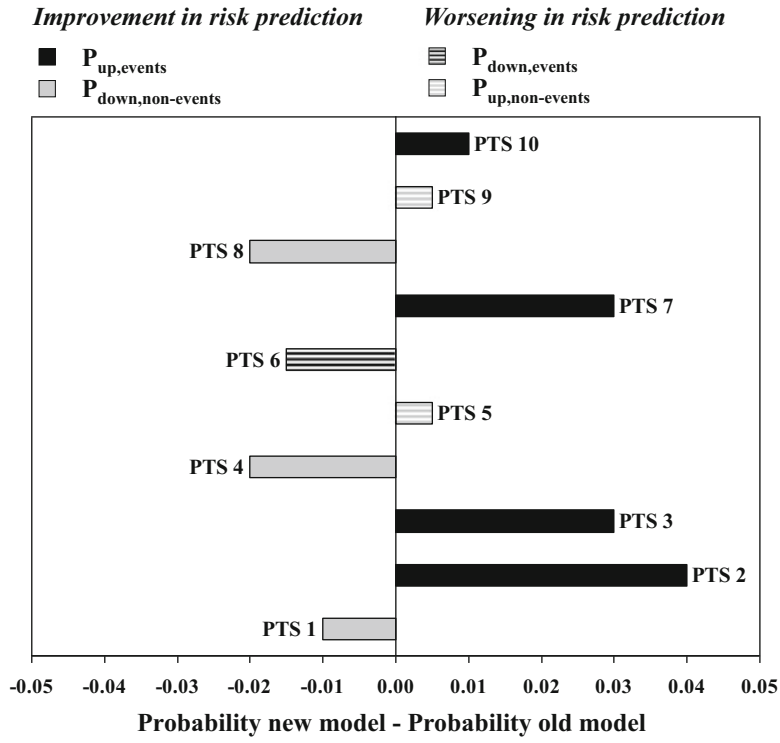

Fig. 1 Ten example patients (PTS) classified by an old risk model and re-classified by a new one including a new predictor. An improvement is obtained on the right of 0 in patients who develop the event (patients 2,3,7,10) and on the left of 0 in those who do not develop the outcome of interest (patients 1,4,8)

from the same source as the derivation sample, but a true evaluation of transportability requires data from another population (Moons et al. 2012a, b). Discrimination and calibration are re-assessed over the validation population. Internal validation is helpful, but it cannot provide information about the model's performance elsewhere. With the internal validation strategy, dataset is randomly split into two parts that separately are used to develop the model and to assess predictive accuracy. The two datasets are very similar and results tend to be optimistic. Non-random splitting may be preferable as it reduces the similarity of the two sets of patients (for example by hospital). If data are limited, the model can be developed using the whole dataset and the performance can be evaluated by cross validation or bootstrapping procedures.

Figure 2 summarizes the scoring system development process.

3 Risk Models in Heart Failure

Acute worsening with functional and clinical deterioration interrupts the trajectory of chronic heart failure; the predictors of prognosis of these two stages may be different, so separated multivariable models for heart failure have been developed. Tables 1 and 2 report the main features of risk scores for chronic and acute heart failure.

3.1 Chronic Heart Failure

Heart Failure Survival Score (HFSS) Keith D. Aaronson et al. (1997) developed a predictive model using data from 268 ambulatory patients with advanced heart failure from a single center

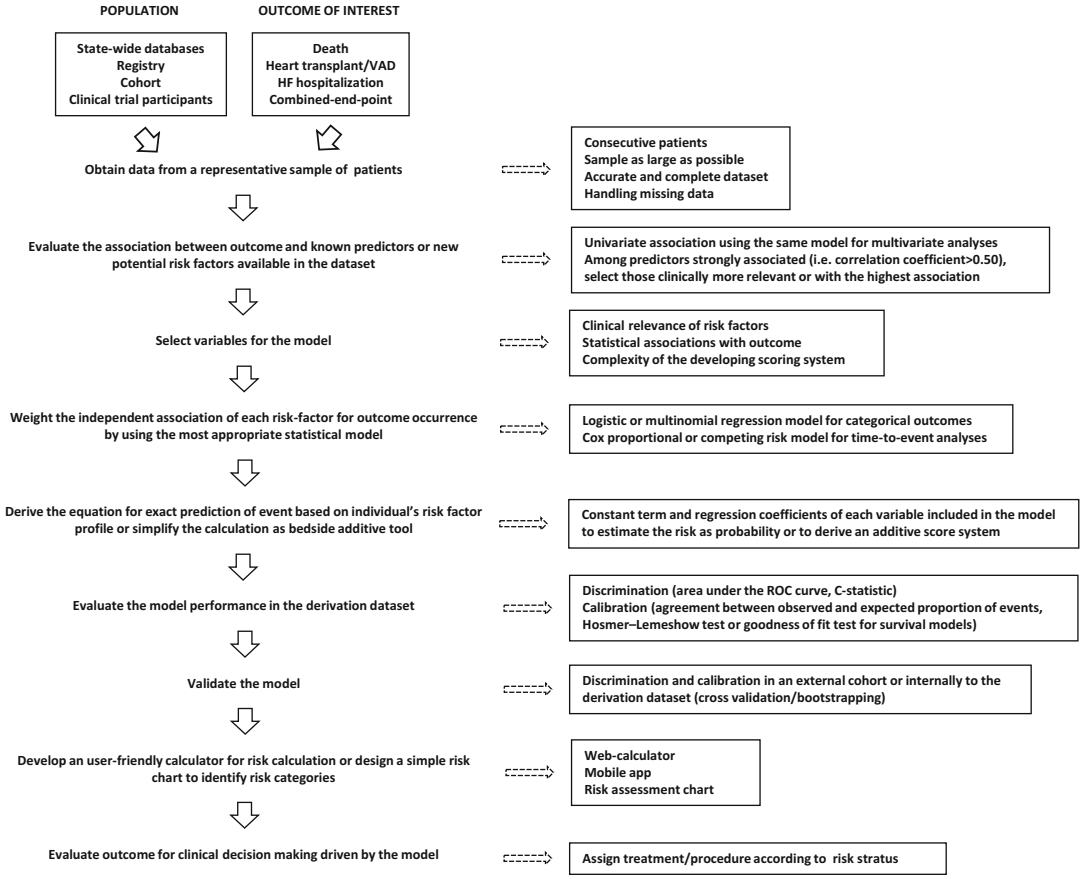

Fig. 2 Scoring system development process

(derivation sample) to predict a composite outcome of death, urgent heart transplant and ventricular assist device implantation. The predictive model contained the following seven variables: ischemic cardiomyopathy, resting heart rate, left ventricular ejection fraction (LVEF), QRS duration $\geq$0.12, mean resting blood pressure, peak $\dot{V}O_2$ and serum sodium. The model has been prospectively validated in 2240 patients from 8 independent single center cohorts (Bilchick et al. 2012; Zugck et al. 2001; Koelling et al. 2004; Parikh et al. 2009; Lund and Mancini 2010). The HFSS was calculated for each patient in the validation sample from the final model; scores were divided in three risk group: low, medium and high risk, with a 1-year survival of respectively 93%, 72% and, 43%. Patients in medium- and high-risk groups should be considered for cardiac transplantation, while transplantation can be safely deferred in patients in the low-risk group. However, C-statistics of HFSS in validation cohorts ranged from 0.56 to 0.78, being far from optimal. The worsening of model's calibration in validation cohorts, with more frequent use of beta-blockers or automatic implantable defibrillators (Alba et al. 2013), raises doubts about the applicability of HFSS to current heart failure patients.

The Seattle Heart Failure Model (SHFM)

Wayne C. Levy et al. (2006) developed and validated a multivariate risk model to estimate survival from death, urgent heart transplantation and ventricular assist device in heart failure patients with both reduced (HFrEF) and preserved (HFpEF) ejection fraction. The model

Table 1 characteristics of risk score for chronic heart failure

Risk score	Variables in the model	C-statistic (derivation cohort)	End point
HFSS	Ischemic cardiomyopathy, resting HR, LVEF, QRS duration ≥0.12 s, mean resting blood pressure, peak $\dot{V}O_2$, serum sodium.	0.74	1-year composite end point (death, urgent transplant, VAD implantation)
SHFM	Age, sex, aetiology, LVEF, blood pressure, serum sodium, cholesterol, haemoglobin, percent lymphocytes, NYHA class, WBCC, creatinine, uric acid, allopurinol.	0.725	1-year composite end point (death, urgent transplant, VAD implantation)
HF-Action	Exercise duration on cardiopulmonary exercise test, quality of life (KCCQ), symptom stability, BUN, sex.	0.70	Composite end point (death, hospitalization)
MAGGIC	Age, sex, BMI, current smoker, SBP, diabetes, NYHA class, LVEF, COPD, HF duration, creatinine, beta-blocker, Ace-inhibitor or angiotensin receptor antagonist assumption	–	1–3 year mortality
MECKY score	Haemoglobin, serum sodium, kidney function, LVEF, peak oxygen consumption, VE/VCO_2 slope	0.804	1-year composite end point (cardiovascular death, urgent heart transplant)
BARLERA	Age, NYHA class, eGFR LVEF, COPD, sex, SBP, diabetes mellitus, haemoglobin level, high uric acid level, aortic stenosis, BMI	0.75	2-year mortality

Abbreviations: *HR* Heart rate, *LVEF* Left ventricular ejection fraction, *NYHA* New York Heart Association, *WBCC* White blood cell count, *KCCQ* Kansas City Cardiomyopathy Questionnaire, *BUN* Blood urea nitrogen, *BMI* Body mass index; *SBP* Systolic blood pressure, *COPD* Chronic obstructive pulmonary disease, *eGFR* Estimate glomerular filtration rate

incorporates easily obtainable clinical and laboratory variables, heart failure medications, and devices. The SHFM was derived in a cohort of 1125 heart failure patients from the clinical trial "the Prospective Randomized Amlodipine Survival Evaluation PRAISE1" (Packer et al. 1996), with the use of a multivariate Cox model. Five other cohorts (n = 9942) were used to prospectively validate the model: ELITE2 (n = 2987), UW (n = 148), RENAISSANCE (n = 925), Val-HeFT (n = 5010), IN-CHF(n = 872). The variables used as a survival predictor were 14: age, gender, aetiology, LVEF, blood pressure, serum sodium, cholesterol, haemoglobin, percent lymphocytes, New York Heart Association (NYHA) class, white blood cell count, creatinine, uric acid and allopurinol.

The 1-year ROC in the derivation cohort was 0.725. In the validation cohorts, the 1-year ROC was 0.682 for ELITE2, 0.810 for UW, 0.682 for RENAISSANCE, 0.694 for Val-HeFT, and 0.749) for IN-CHF. The combined data set of all 6 trials had a 1-year ROC of 0.729. C-index increase from 0.72 to 0.78 when brain natriuretic peptides are added to the model (May et al. 2007).

Because the calculation of estimated survival is impractical for computation by hand, a Web-based calculator (http://www.SeattleHeartFailureModel.org) has been developed, allowing convenient interactive calculation of estimated survival and also of the predicted effects on survival of adding (or subtracting) medications or devices to a patient's regimen.

The HF-ACTION Predictive Risk Score Model The "Heart Failure: A Controlled Trial Investigating Outcomes of Exercise TraiNing (HF-ACTIONtrial)" (O'Connor et al. 2009) included 2331 well-characterized ambulatory patients with HFrEF and NYHA class II to IV. Study participants received guideline-based therapies (β-blockade, 95%; use of an angiotensin-converting enzyme inhibitor, 74%; implantable cardioverter-defibrillator, 40%; biventricular pacing, 18%) and were

Table 2 Characteristics of risk score for acute heart failure

Risk score	Variables in the model	C-statistic (derivation cohort)	End point
In-Hospitals risk models			
ADHERE	BUN, creatinine, SBP	0.75	In hospital death
AHFI	Sex, CAD, diabetes, lung disease, SBP, HR, respiratory rate, temperature, BUN, sodium, potassium, WBCC, acute myocardial infarction o myocardial ischemia at ECG, pulmonary congestion or pleural effusion radiographic examination	–	In hospital death
OPTIMIZE-HF	Creatinine, sodium , age, HR, liver disease, previous CVA/TIA, peripheral vascular disease, race, left ventricular systolic dysfunction, COPD, SBP, previous HF hospitalization	0.75	In hospital death
GWTG-HF	Older age, low SBP, elevated HR, COPD, non- black race	0.75	In hospital death
EHMRG	HR, creatinine, systolic blood pressure initial oxygen saturation, serum troponin	0.805	7-days death
PROTECT	BUN, respiratory rate, HR, albumin, cholesterol, diabetes, previous HF hospitalization.	0.72	Death or re-hospitalization at 30 days
Post-discharge risk models			
EFFECT	Age, SBP, BUN, sodium concentration, cerebrovascular disease, Dementia, COPD, hepatic cirrhosis, Cancer, Hemoglobin	0.80 (30 days) 0.77 (1-YEAR)	30-days/1-year mortality
OPTIME-CHF	Age, BUN, SBP, Sodium, NYHA class	0.77	60-days mortality
OPTIMIZE – HF	Age, weight, SBP, serum creatinine, History of liver disease, history of depression, history of reactive airway disease	0.72	60-days mortality
ELAN	NT-proBNP at discharge, NT-ProBNP reduction, age, peripheral oedema, SBP, sodium, BUN, NYHA class	0.78	180-days mortality
ADHF/NT-proBNP risk score	COPD, SBP , eGFR, serum sodium, hemoglobin, NT-proBNP; LVEF, tricuspidal regurgitation	0.84	1-year mortality
ESCAPE	Age, BUN, six minute walking test, sodium, CPR/ Mechanical ventilation, diuretic dose at discharge, no betablocker at discharge, BNP	0.76	6-months mortality

CAD Coronary heart disease, *CVA* Cerebral vascular accident, *NT-proBNP* N-terminal brain natriuretic peptide, *BNP* Brain natriuretic peptide. Other abbreviations as in Table 1

systematically followed with standardized assessments of clinical outcomes, which included the primary composite end point of death or hospitalization from any cause and the secondary end point of death alone. A multivariable statistical model for risk stratification was developed from the trial population (O'Connor et al. 2012). The analysed variables were exercise duration on cardiopulmonary exercise test (CPET), quality of life, evaluated by means of the Kansas City Cardiomyopathy Questionnaire (KCCQ), symptom stability, serum urea nitrogen and sex. The strongest baseline predictor of both the primary and the mortality end points was exercise duration on the CPET: for every additional minute of exercise duration, there was an associated 8% reduction in risk for the primary end point and an 18% reduction in risk for mortality. The risk score of the primary end point had a C-index of 0.63. The risk score for mortality had a C-index of 0.70. For this study the investigators used an internal validation while has not been externally validated in an independent cohort of patients with HF because there are

no known similar HF data sets that include peak VO_2, CPET duration, and KCCQ data.

The Meta-analysis Global Group in Chronic Heart Failure (MAGGIC) (Pockok et al. 2013). This study included individual data on 39,372 patients with HF, with both reduced and preserved LVEF, from 30 cohort studies, 6 randomized controlled trials (24,041 patients) and 24 registries (15,331 patients). Using Poisson regression models for survival with forward stepwise variable selection, adjusting for study and follow-up time, 13 independent predictor variables were selected: age, gender, body mass index (BMI), current smoker, systolic blood pressure (SBP), diabetes, NYHA class, LVEF, chronic obstructive pulmonary disease, HF duration, creatinine, beta-blocker, Ace-inhibitor or angiotensin receptor antagonist assumption. Each variable contributes to creating an integer risk score (accessible by the website www.heartfailurerisk.org) that allows calculating the 1-year probability of death and the 3-year probability of death. Two different risk scores have been created for patients with reduced or preserved ejection fraction, respectively. Nearly all predictors display a similar influence on mortality in the two subgroups. Two exceptions are age (HFpEF has a better prognosis in younger patients) and SBP, which have a stronger inverse association with mortality in patients with HFrEF. The authors did not report neither AUC nor C-statistic, making impossible the comparison with other risk models.

Metabolic Exercise Test Data Combined with Cardiac and Kidney Indexes (MECKY Score) Agostoni et al. build a new risk score for patient with HFrEF, integrating measures with potential prognostic value from CPET with established clinical, laboratory and echocardiographic risk factors, in order to identify patients at risk of cardiovascular death and urgent heart transplant (Agostoni et al. 2013). The MECKI score was derived from a cohort of 2716 with HFrEF systolic HF patients followed in 13 Italian centres. Ability to perform a CPET was an inclusion criterion. The prognostic variables used are six: haemoglobin, serum sodium, kidney function, LVEF, peak oxygen consumption and VE/VCO_2 slope. The study end-point was a composite of cardiovascular death and urgent heart transplant.

The MECKI score AUC was 0.804 at 1 year, 0.789 at 2 years, 0.762 at 3, and 0.760 at 4 years.

A major criticism of the MECKI score is that it is only applicable to HF subjects who have performed a maximal CPET. However, at present, MECKI is the long-term prognostic score for HFrEF with the highest AUC. In a comparative analysis of four risk models (HFSS, SHFM, MAGGIC, MECKI), MECKI score showed the best discrimination ability for the composite end-point of all death and urgent transplantation with an AUC of 83%, resulting, furthermore, well calibrated (Freitas et al. 2017).

Predictors of Mortality in 6975 Patients With Chronic Heart Failure in the Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardico-Heart Failure Trial. Proposal for a Nomogram (Barlera et al. 2013). The aim of the present study was to develop a model for predicting mortality in a contemporary cohort of Italian patients recruited in the GISSI-HF trial (Tavazzi et al. 2008), followed for 4 years. The study population consisted of 6975 outpatients with chronic heart failure. 12 independent predictors of mortality, (age, NYHA class, estimate glomerular filtration rate, LVEF, chronic obstructive pulmonary disease, sex, SBP, diabetes mellitus, haemoglobin level, high uric acid level, aortic stenosis, and BMI) entered the model. The authors represented the model with a nomogram that can be used to calculate a prognostic score and to estimate the risk for death for individual patients. The predicted probabilities associated with each factor are mapped into points on a scale from 0 to 100. The presence or the level of each predictive factor is associated with a point system allowing us to sum up the points for all of the factors. The total points accumulated by the various

covariates correspond with the predicted probability of survival at 2 or 4 years. The study revealed that the most significant predictive determinants of mortality were older age, more advanced HF symptoms, and reduced renal function. Then a subset of 1231 patients with cardiac biomarkers (hs-cTnT and NT-proBNP) available at baseline was analysed; the multivariable Cox model for mortality showed that NT-proBNP was the strongest predictor (hazard ratio, 1.51 for 1 unit increase on a log scale, $P < 0.0001$) followed by hscTnT (hazard ratio, 1.50 for each unit increase on a log scale, $P < 0.0001$). The C-statistic of the model was 0.75. A major limitation of this study is the lack of an external validation.

3.2 Acute Heart Failure

Several prognostic models have been developed to predict in-hospital mortality as well as to estimate outcomes between 30 days up to 6 months post-discharge.

3.3 In-Hospital Risk Models

Adehre A risk stratification model to predict in-hospital mortality in patients admitted with acutely decompensated heart failure was derived from data of 33.046 patients from the Acute Decompensated Heart Failure National Registry (ADHERE) (Fonarow et al. 2005). The validity of the model was prospectively tested using data from 32.229 hospitalization. The best single predictor for mortality was blood urea nitrogen (BUN) level of 43 mg/dL or higher. The second best predictor in both the higher and lower BUN nodes was admission SBP, at a discrimination level of <115 mm Hg. Eventually serum creatinine levels of 2.75 mg/dL or higher provided additional prognostic value in patients with BUN levels ≥43 mg/dL and SBP ≤ 115 mm Hg. By the CART method, a risk tree was derived to identify ADHF patients at low, intermediate and high risk for in-hospital mortality in the validation cohort. Mortality in the low and high-risk group was respectively 2.1 and 22%.

The ADHERE algorithm has some strengths: it was derived from a real world population; it was adequately validated in another cohort of patients; it is a parsimonious model requiring the measure only three variables. The ADHERE algorithm may allow immediate and simple triage at admission in the emergency department, not requiring complex calculation. The model has some limitations: the registry entries reflect individual hospitalization, and repeated hospitalizations of the same patient were entered as separated records. Moreover, the mortality of low risk group was too high in comparison with other models.

Acute Heart Failure Index (AHFI) This model was derived by the data of 33.533 patients admitted in the Emergency department (ED) with a diagnosis of heart failure (Auble et al. 2005). Authors derived a prediction rule to identify heart failure patients at low-risk of in-hospital death. The AHFI resulted from the combination of demographic, biochemical and non-invasive diagnostic factors.

The AHFI was validated in 8.383 patients from two cohorts with respect to inpatients death, serious medical complication before hospital discharge, and 30-day death. The performance decreased in the validation cohort: mortality rates in low risk group were almost threefold higher in the validation cohort in comparison with two derivation cohorts (0.7–1.7 vs. 0.3%) (Hsieh et al. 2008; Hsiao et al. 2011).

Organized Program to Initiate Lifesaving Treatment in Hospitalized Patients with Heart Failure (OPTIMIZE-HF) This model derived by the analysis of the national hospital-based registry and quality improvement program OPTIMIZE-HF registry, including data of 48,612 patients (Abraham et al. 2008). The Authors developed a point scoring system to predict in-hospital mortality screening forty-five

potential predictor variables. Multivariable predictors of mortality included age, heart rate, SBP, sodium, creatinine, HF as primary cause of hospitalization, and presence/absence of left ventricular systolic dysfunction. The ability of the logistic regression model to discriminate mortality was tested by a classification and a regression tree (CART) analysis. The final risk-prediction nomogram included age, heart rate, SBP, serum creatinine, serum sodium, primary cause of admission (HF or other), left ventricular systolic dysfunction. For each value of these variables, a score is associated to the probability of in-hospital mortality. The model had a C-statistic of 0.75; however, validation of the score is missing.

Get With the Guidelines-Heart Failure (GWTG-HF) The GWTG-HF program of the American Heart Association provided a risk score that applies to a broad spectrum of heart failure patients, including those with HFpEF (Peterson et al. 2010). 27.850 patients belonged to the derivation sample; 11.933 patients entered the validation sample. The score combined seven clinical factors (older age, low SBP, elevated heart rate, presence of chronic obstructive pulmonary disease, and non-black race). The risk score had good discrimination, with a C-index of 0.75 in both derivation and validation data set. Model calibration evaluated by plots of predicted versus observed mortality and by the Hosmer-Lemeshow test was good. In-hospital mortalities in the lower and higher risk group were 0.4 and 9.7% respectively.

Emergency Heart Failure Mortality Risk Grade (EHMRG) Lee DS et al proposed a multivariate risk index for 7-days death using initial vital signs, clinical, presentation features, and readily available laboratory tests for patients with AHF (Lee et al. 2012). 7433 patients presenting to the emergency department of 86 hospitals composed the derivation cohort. The model was validate in a cohort of 5158 patients. Higher heart rate, creatinine concentration and lower SBP, initial oxygen saturation, no normal serum troponin levels entered the score. Areas under the ROC curves of the multivariate model were 0.805 for the derivation data set and 0.826 for validation data set.

PROTECT This model was derived from 2033 patients enrolled in the clinical trial "Patients Hospitalized with Acute Decompensated Heart Failure and Volume Overload to Assess Treatment Effect on Congestion and Renal Function (PROTECT)" (Massie et al. 2010; Cleland et al. 2014). Patients were hospitalized for AHF; they had mild or moderate impairment of renal function. Outcomes at 30 days were death or rehospitalisation for any reason; death or rehospitalisation for cardiovascular or renal reasons; and, at both 30 and 180 days, all-cause mortality. Authors identified 37 baseline clinical characteristics as candidate predictor variables. Notably no single factor had a C-index >0.70, and few had values >0.60. Eighteen variables had independent prognostic value, but a reduced model using only eight variables (age, previous heart failure hospitalization, peripheral oedema, SBP, serum sodium, urea, creatinine, and albumin) performed similarly: the model C-index was 0.72 for both all variables model and eight items model. C-indices were lower for composite outcomes than for mortality. The model underwent external validation in study population of another clinical trial; C-index in validation population was 0.67.

Patients on inotropic agents, with severe pulmonary disease, recent ischemia and preserved ejection fraction were not included, so the applicability of PROTECT risk score to a wide range of community base population is limited.

4 Post-discharge Risk Models

Enhanced Feedback for Effective Cardiac Treatment (EFFECT) Study Authors of the EFFECT study analysed multiple variables available at hospital presentation of more than 4000

patients (Lee et al. 2003). They developed and validated a model able to predict all cause 30-day and 1-year mortality. Older age, lower SBP, higher respiratory rate, higher urea nitrogen level, hyponatremia, and co-morbidities were multivariable predictors of mortality at both 30 days and 1 year. Mortality rate in the very low risk group was of 0.4% at 30 days and 7.8% at 1 year. Mortality in the very high-risk group was 59% at 30 days and 78.8% at 1 year.

Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure (OPTIME-CHF) Study This model was derived from study population of the OPTIME-CHF (Cuffe et al. 2002); this risk score predicts post-discharge outcomes in 949 patients hospitalized for acute decompensated heart failure for 48 to 72 h of infusion of either milrinone or placebo (Felker et al. 2004). The study population consisted entirely of patients with HFrEF, while patients with significant renal dysfunction or on inotropes were excluded from the study.

The study outcomes were 60-day mortality or the composite of death or rehospitalisation at 60 days. Increased age, lower systolic blood pressure, NYHA class IV symptoms, elevated blood urea nitrogen, and decreased sodium were the variables at presentation predicted death 60 days-mortality. C-index for mortality at 60 days was 0.77 but less for the composite endpoint (C-index 0.69).

Organized Program to Initiate Lifesaving Treatment in Hospitalized Patients with Heart Failure (OPTIMIZE-HF) The data source used to develop this score is comprehensive hospital-based registry. 4402 patients were included in this analysis. Eight variables (age, serum creatinine, reactive airway disease, liver disease, lower SBP, lower serum sodium, lower admission weight, and depression) were used to calculate a score to predict the risk of mortality within 60 days after discharge. The model C-index was 0.72 (O'Connor et al. 2008).

A European coLlaboration on Acute decompeNsated Heart Failure (ELAN-HF) Data from seven prospective cohorts with in total 1301 patient were pooled by Salah et al. to develop a predictive discharge score based on the strongest predicting variables regarding mortality (Salah et al. 2014). Differently from previous studies, the model included natriuretic peptide dosage. The model that incorporated NT-proBNP levels at discharge as well as the changes in NT-proBNP during hospitalisation in addition to age $\geq$75 years, peripheral oedema, SBP $\leq$115 mm Hg, hyponatremia at admission, serum urea of $\geq$15 mmol/L and NYHA class at discharge, had the best C-statistic (AUC 0.78). The addition of NT-proBNP to a reference model significantly improved the net reclassification (62%).

ADHF/NT-proBNP Risk Score Scrutinio confirmed the relevance of natriuretic peptide measurements in patients with acutely decompensated heart failure, studying the improvement in the risk reclassification of 824 patients with acutely decompensated heart failure (453 in the derivation cohort, 371 in the validation cohort) by adding NT-proBNP to other common clinical variables (Scrutinio et al. 2013). The ADHF/NT-proBNP risk score contains eight variables: NT-proBNP chronic obstructive pulmonary disease, estimated glomerular filtration rate, sodium, haemoglobin, LVEF, and moderate to severe tricuspid regurgitation. The score (range 0–22) proved to be effective in predicting one-year mortality. In the derivation cohort, the risk score had a C-index of 0.839 and the Hosmer-Lemeshow statistic was

1.23 ($p = 0.542$), indicating good calibration. In the validation cohort, the risk score had a C-index of 0.768.

The addition of NT-proBNP to the reference model did not improve model discrimination, but resulted in significant risk reclassification.

Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) The ESCAPE trial enrolled 433 patients hospitalized with AHF randomly assigned to receive clinical assessment or pulmonary artery catheter-guided therapy (Binanay et al. 2005). Data from this trial were used to derive a predictive model; the end point was time to death at 6 months (O'Connor et al. 2010). Among the analysed variables, high discharge BNP level showed the strongest association with death. The score proposed included eight variables (Age, BUN, 6-min walk test, sodium, CPR/mechanical ventilation, diuretic dose at discharge, no-betablocker at discharge, BNP) with 1 point possible for each, except for BUN and BNP where additional points were assigned for the highest value with a maximum possible of 13 points. Data from FIRST (Flolan International Randomized Survival Trial) (Califf et al. 1997) were used to externally validate the ESCAPE study. C-index for 6 months mortality was 0.78 in the derivation data set, but decreased to 0.65 in the validation population.

5 Heart Failure Risk Scores: Usefulness and Criticisms

Risk stratification of patients with heart failure is a complex pivotal medical task aimed to improve patient's outcome and efficiency of health care delivery system. To this day, even if a large number of variables has been associated to prognosis, predicting mortality and/or HF hospitalization remains difficult.

Risk score are multivariable predictive models in which each variable is weighted to calculate the probability of the occurrence of an outcome. Risk score should allow an unbiased risk stratification, transferring the result of prognostic studies in the clinical practice.

Nevertheless, despite all the proposed prognostic models, the clinical application is challenging and clinical scores are not yet considered part of the standard of care.

Critical Issues Against the redundancy of models published in the last years, a critical analysis is needed. Only a small percentage of studies qualifies from a methodological point of view.

In their systematic review, Alba et al found out that only 25% of event free survival models in ambulatory patients with HF received validation in some external population (Alba et al. 2013). In other two reviews, 69 of 117 and 41 of 64 models respectively, were not validated (Ouwerkerk et al. 2014; Rahimi et al. 2014). Not validate models generally overestimate the prediction power.

Moreover, when validation is reported, the discrimination, evaluated by the C-index, generally results significantly lower than that found in the derivation model (Alba et al. 2013). Therefore, the generalization and the external applicability of the proposed models remain a main issue. Notably some models may underestimate the mortality risk in elderly patients or at approaching the end of life (Nutter et al. 2010).

Another major limit of risk scores studied at this day is the lacking accuracy in predicting HF hospitalization (a major health problem in western countries): in most studies, the C-index of models predicting HF hospitalization was lower than that of model predicting mortality (Ross et al. 2008; Giamouzis et al. 2011). In a meta-analysis, there was a highly significant difference in C-statistics between models predicting mortality and HF hospitalization (Ouwerkerk et al. 2014). Maybe, some non-medical factors, not included in the risk models, may influence the risk hospitalization. Biomarkers, such as natriuretic peptides, are more promising for this purpose (Jannuzzi et al. 2006, 2010).

Risk scores evaluate the prognosis of a cohort of patients, but prediction of outcome in individual patients is inherently inaccurate. Therefore,

the applicability of a model to the single patient is arguable. It is clear and understandable the meaning of a risk of death of 20% for a cohort (it means that during the follow up about 20 of 100 patients are expected to die). It is less clear the meaning of such a probability for a single patient, for which, the actual survival has only to possible values: 0 or 100%.

Risk scores should improve the process of care. However, there are few evidences (none in acute heart failure) that clinical decision making guided by risk score could allocate correctly patients to different therapies.

In a previous study, the HFSS was able to identify patient who get the best benefit from heart transplant (Lim et al. 2005). More recently, Bilchick et al. reported the successful use of the SHFM to predict implantable Cardioverter defibrillator benefit in a large cohort of patients (Bilchick et al. 2017).

A further limit of risk score is their time horizon, ranging from one to 5 years, which may not be an adequate period in younger patients.

Eventually, risk score may predict death or (less well) hospitalizations, but do not account for quality of life changes, that in some subgroups of patients, (like in the elderly) may be the most relevant outcome. Study using the trade-off utility has shown that patients with decompensated heart failure will trade more than 30% of their predicted life expectancy in order to have a better quality of life (Howlett 2013).

Risk Scores and Guidelines Recommendations According to 2013 ACCF/AHA heart failure guidelines (Yancy et al. 2013), "validate" multivariable risk scores have a class IIa recommendation (it is reasonable to perform procedure/administer treatment, but additional studies with focused objectives needed) to estimate subsequent risk of mortality in heart failure patients.

It is worth noting that in the same guidelines a class I recommendation (Procedure/treatment should be performed/administered) is given to the dosage of natriuretic peptides for establishing prognosis in acutely decompensated HF. The following risk scores have been selected and cited by the guidelines 's authors: SHFM, HFSS, Charme risk score, Corona risk score for chronic heart failure; I-preserve score for heart failure with preserved ejection fraction; ADHERE model, GWTG-HF, EFFECT risk score, ESCAPE risk score, OPTMIZE risk score for acutely decompensated heart failure. Oddly guidelines' authors have cited some models that have not been adequately validated.

The guidelines of European Society of Cardiology highlight the limitations of clinical scores, remembering that their clinical applicability is limited and precise risk stratification in HF remains challenging (Ponikowski et al. 2016).

The 2016 International Society for Heart and Lung Transplantation listing criteria for heart transplantation recommend the use of prognosis scores along with CPET to guide listing for transplantation for ambulatory patients in circumstances of ambiguity (e.g. peak $VO_2 > 12$ and < 14 ml/kg per min). An estimate 1-year survival as calculated by the SHFM of $<$ 80% or an HFSS in the medium/high risk range should be considered as reasonable cut points for listing (Class IIb). According to these guidelines, listing patients solely on the criteria of risk score is not indicated (class III) (Mehra et al. 2016). On the contrary, CPET to guide transplant listing has a class I recommendation.

What Risk Model Should Be Used? First, physician involved in the care of patients with heart failure should evaluate the quality of research that produced the model.

Risk scores derived by registries and population studies have a better external validity in comparison with models derived from clinical trial, and, generally, a better accuracy (Alba et al. 2013). Clinical trial populations are usually younger, more carefully characterized, and may be better managed. Only models with a good discrimination in validation cohort are recommended. No single model fits for all heart

failure patients, because some variables may have a different relevance in specific subgroups.

For estimating prognosis in older patients, models focused on comorbidities are perhaps advisable, while, for heart transplant listing of ambulatory younger patients, models including exercise capacity, (i.e. maximum oxygen consumption), should be preferred.

In the setting of AHF, when quickness of decision is a crucial factor, it is advisable to stratify risk by a simple model, with few easily, measurable variables (like ADHERE Tree).

Predictors of Prognosis More than 200 variables have been used in different models; a few common and strong markers of risk, however, emerged the most frequent factors: age, sex, blood urea nitrogen, sodium, renal function, SBP, natriuretic peptides, LVEF, and NYHA class. In a meta-analysis blood urea nitrogen and sodium had the highest predictive value (Ouwerkerk et al. 2014). These variables should always be considered in the clinical practice and in the development of new models.

Future Direction Two of the most popular risk scores, HFSS and SHFM, were derived from 286 and 1125 patients respectively. Today, these figures result infinitesimal if compared to what we are going to manage: the rapid adoption of electronic health records (EHRs) is changing the world of clinical research. The growth of EHRs will make it possible to access unprecedented amounts of clinical data and offers the potential for collecting accurate information about millions of patients. Even if ethical and legal issues have to be resolved, and big data analyses are not immune to some limitations, in the next future it will be possible to derivate and validate in real time risk scores from hundreds of thousands patients. Big data approach needs new methods for analysis in the field of artificial intelligence (AI). Machine learning, deep learning and cognitive computing are the AI techniques involved in the analysis of big data (Krittanawong et al. 2017). System biology approach, that incorporate data from biomarker, genomic, metabolomics and proteomic, is promising. The acquisition of these techniques should lead up to a precision cardiovascular medicine, an approach for disease treatment and prevention that takes into account individual variability in genes, environment, and lifestyle for each person.

6 Conclusions

Many risk scores have been proposed in the previous years, however, these models have not been widely implemented in clinical practice. In populations different from that from which the risk models were derived, their discrimination capability is far from optimal. Validate models, however, could be a useful tool to help, not substitute, medical judgment, to guide clinical decision making, especially in borderline patients, or in the grey zone of single validates predictors of prognosis. The research of new more accurate models should carry on, benefitting from the availability of big data analyses and system biology approach.

Names: Herzog, Eyal, editor.
Title: Herzog's CCU book / [edited by] Eyal Herzog.
Other titles: CCU book | Cardiac care unit book
Description: Philadelphia: Wolters Kluwer Health, [2018] | Includes bibliographical references and index.
Identifiers: LCCN 2017044559 | eISBN 9781496362681
Subjects: | MESH: Heart Diseases | Critical Care
Classification: LCC RC682 | NLM WG 210 | DDC 616.1/2—dc23 LC record available at https://lccn.loc.gov/2017044559

This work is provided "as is," and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon health care professionals' examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data, and other factors unique to the patient. The publisher does not provide medical advice or guidance, and this work is merely a reference tool. Health care professionals, and not the publisher, are solely responsible for the use of this work, including all medical judgments, and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and health care professionals should consult a variety of sources. When prescribing medication, health care professionals are advised to consult the product information sheet (the manufacturer's package insert) accompanying each drug to verify, among other things, conditions of use, warnings, and side effects and identify any changes in dosage schedule or contraindications, particularly if

the medication to be administered is new, infrequently used, or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

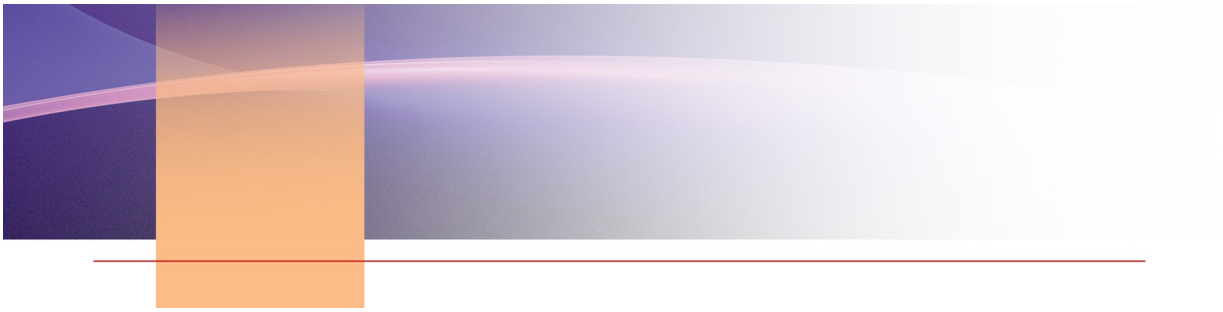
† Deceased. His untimely passing at the end of 2016 has left a void in our hearts and minds.



Preface

Heart disease is the leading cause of death in the world. Advances in the treatment of heart disease are considered among the greatest achievements of modern medicine. Physicians, nurses, and all health care providers who care for patients with heart disease consider the cardiac care unit (CCU) the most exciting place in the hospital.

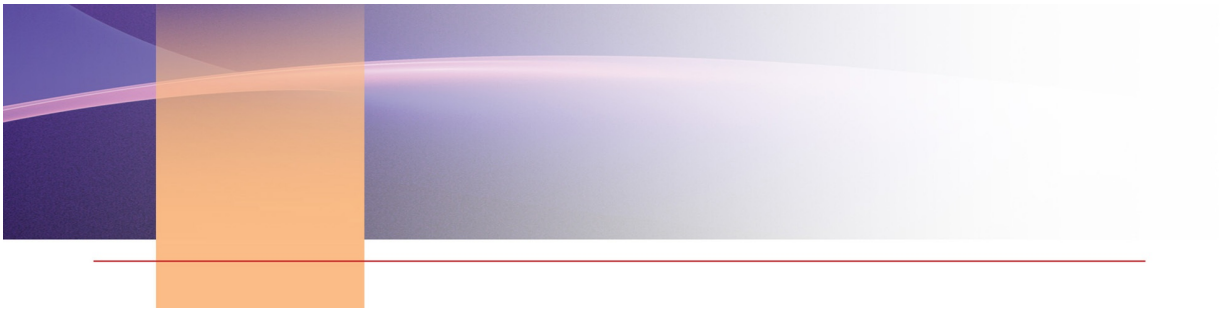
The *CCU Book* is essentially two books combined into one. Most chapters have two sections: the first is for physicians and other health care providers, and the second is for patients and their families.

The first section of each chapter is aimed toward physicians (interns, residents, fellows, and attendings), medical students, nurses, physician assistants, and other health care providers who rotate or practice in the CCU. It is organized such that readers will not need to consult any textbooks regarding the topics discussed and will be able to understand the simplified pathophysiology and management of the disease. This includes diagnostic modalities, initial critical care management in the CCU, follow-up care in a step-down unit, and plans for discharge. Algorithms and pathways for management are provided for easy implementation in any health care system.

The second part of each chapter covers the same topics previously discussed but is directed toward the patients and their families. The language and the medical terminology are simpler and geared toward the general public.

It is my hope that this book will serve as a teaching tool to save the lives of patients with heart disease in the CCU.

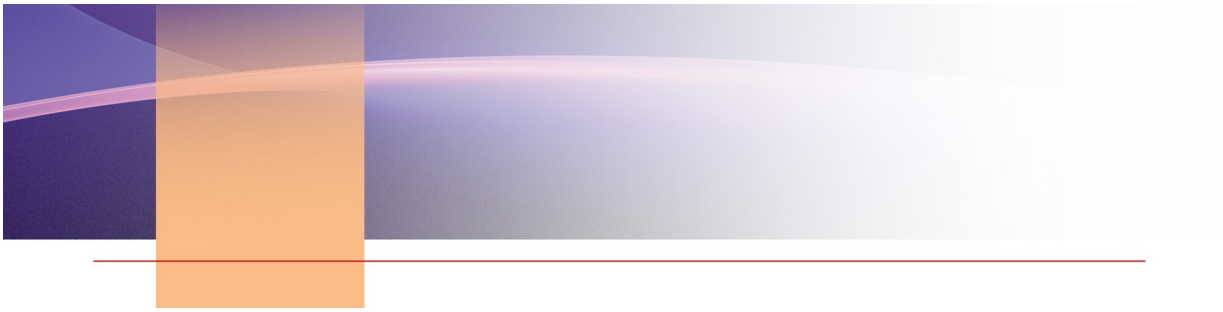
Eyal Herzog



Acknowledgments

I would like to acknowledge the extraordinary work of LaToya Selby and Candice Francis from my office at Mount Sinai St. Luke’s Hospital in New York; they are my right hand in assisting my trainees and patients in the hospital and are also the editing coordinators for this book.

Thank you,
Eyal Herzog



Contents

Section I

ACUTE CORONARY SYNDROME

1 Pathway for the Management of Acute Coronary Syndrome
Eyal Herzog, Jacqueline E. Tamis-Holland, Emad F. Aziz

2 ST-Segment Elevation Myocardial Infarction
Chirag Bavishi, Eyal Herzog, Jacqueline E. Tamis-Holland

PATIENT AND FAMILY INFORMATION FOR: ST-ELEVATION MYOCARDIAL INFARCTION

3 Non–ST-Elevation Acute Coronary Syndromes
Ronen Jaffe, Eyal Herzog, Moshe Flugelman

PATIENT AND FAMILY INFORMATION FOR: NON–ST-ELEVATION ACUTE CORONARY SYNDROMES

4 Echocardiography in Acute Coronary Syndrome
Eyal Herzog, Indra Warren

PATIENT AND FAMILY INFORMATION FOR: ECHOCARDIOGRAPHY IN ACUTE CORONARY SYNDROME

5 Use of Radionuclide Imaging in Acute Coronary Syndrome

Jacqueline E. Tamis-Holland
Emad F. Aziz

Pathway for the Management of Acute Coronary Syndrome

The practice of medicine is changing at unprecedented speed. Today's reasonable assumption is outlined by tomorrow's evidence. We face a deluge of data as we confront the onslaught of acute coronary syndrome (ACS). ACS subsumes a spectrum of clinical entities, ranging from unstable angina (UA) to ST-elevation myocardial infarction (STEMI). The management of ACS is deservedly scrutinized because it accounts for about 2 million hospitalizations and a remarkable 30% of all deaths in the United States each year. Clinical guidelines on the management of ACS, which are based on clinical trials, have been updated and published.[1–3]

In this chapter, we describe a novel pathway for the management of ACS in our health care system.[4, 5]

The pathway has been designated with the acronym PAIN (***P***riority risk, ***A***dvanced risk, ***I***ntermediate risk, and ***N***egative/Low risk), which reflects the patient's most immediate risk stratification upon admission (**Figure 1.1**). This risk stratification reflects the patient's 30-day risks for death and myocardial infarction (MI) following the initial ACS event.

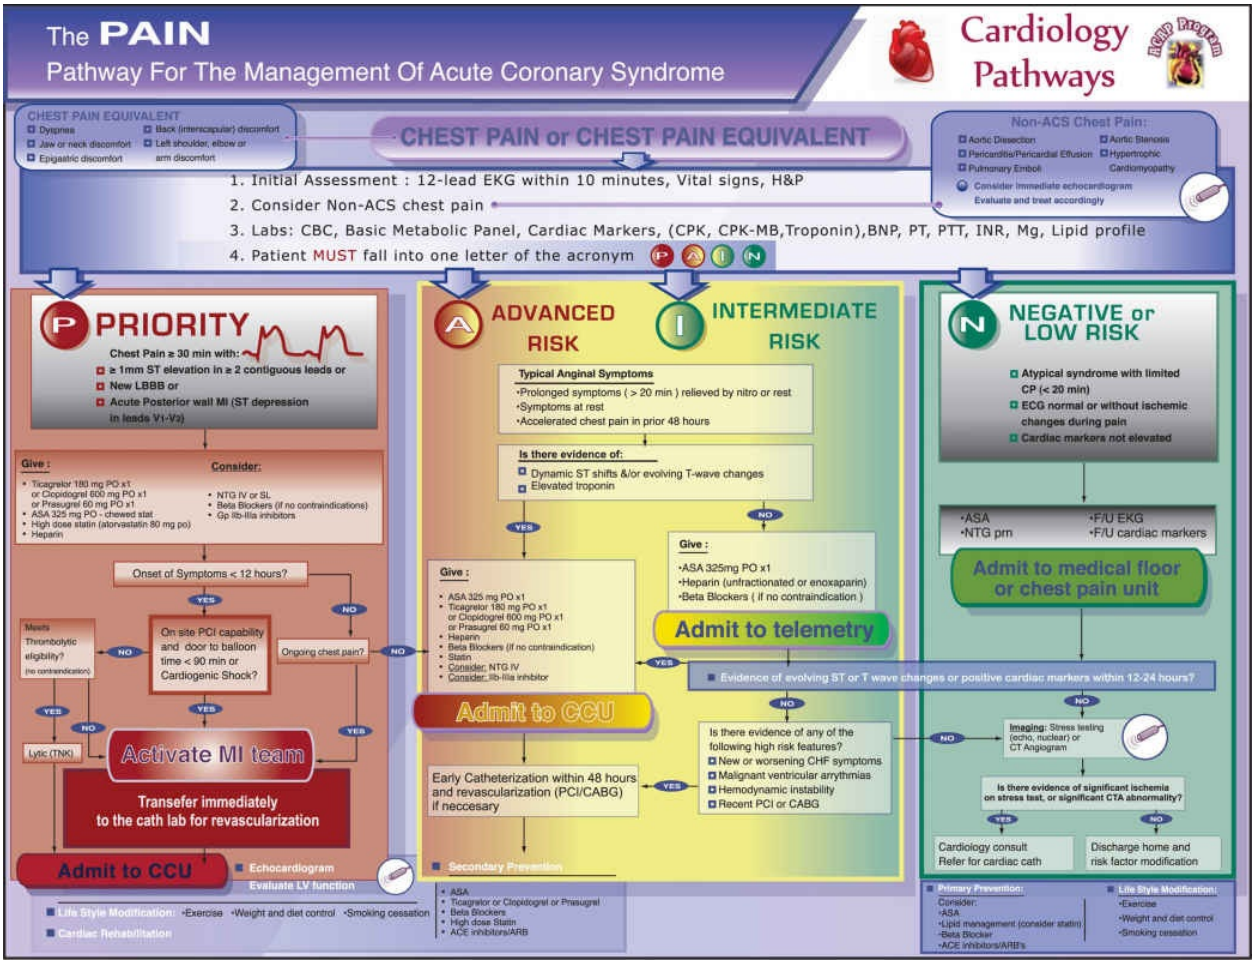

FIGURE 1.1 The PAIN pathway for the management of acute coronary syndrome. ACE, angiotensin converting enzyme; ACS, acute coronary syndrome; ARB, angiotensin receptor blocker; BNP, brain natriuretic peptide; CABG, coronary artery bypass surgery; CHF, congestive heart failure; CCU, coronary care unit; CPK, creatine phosphokinase; CPK-MB, CPK-muscle and brain; ECG, electrocardiogram; INR, international normalized ratio; LBBB, left bundle branch block; MI, myocardial infarction; PCI, percutaneous coronary intervention; PT, prothrombin time; PTT, partial thromboplastin time.

The pathway is color coded with the “PAIN” acronym (P—red, A—yellow, I—yellow, N—green), which guides patient management according to the patient’s risk stratification. These colors—similar to the traffic light code—have been chosen as an easy reference for the provider about the sequential risk level of patients with ACS.[6]

In comparison with the North American and European guidelines for ACS,[1–3] in the proposed PAIN algorithm, P (priority) is equivalent to STEMI or STE (ST-elevation)-ACS; A (advanced) and I (intermediate) are equivalent to non–STE-ACS; and N (negative) means that there is no evidence of ACS.

INITIAL ASSESSMENT OF PATIENTS WITH CHEST PAIN OR CHEST PAIN EQUIVALENT

Patients who present to emergency departments with chest pain or chest pain equivalent will be enrolled into this pathway.

Figure 1.2 shows the chest pain equivalent symptoms. The initial assessment is seen in **Figure 1.3**. All patients should have an electrocardiogram (ECG) performed within 10 minutes as well as a detailed history and physical examination.

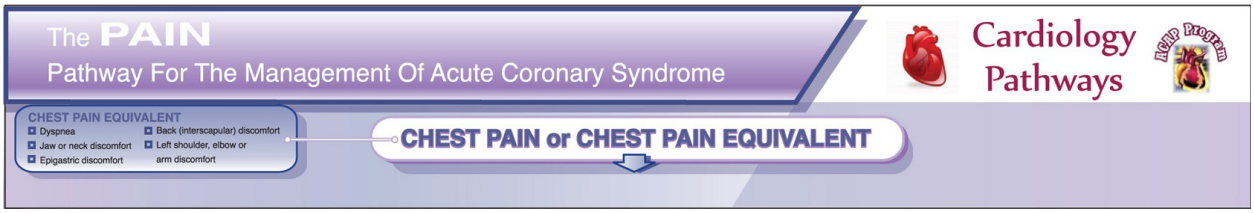

FIGURE 1.2 Chest pain and chest pain equivalent symptoms.

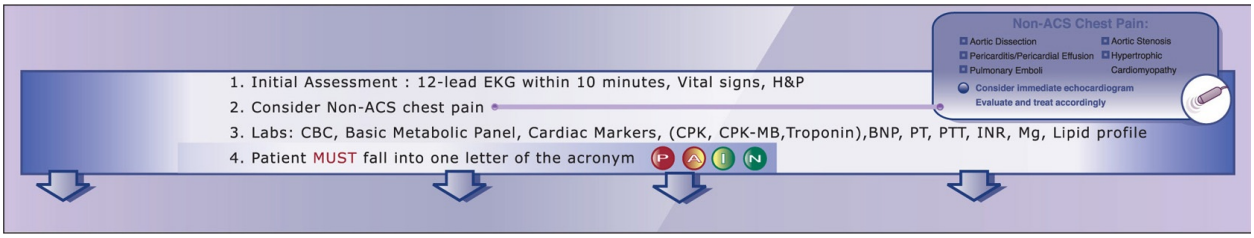

FIGURE 1.3 Initial assessment of patients with chest pain. ACS, acute coronary syndrome; CBC, complete blood count; CPK, creatine phosphokinase; CPK-MB, CPK-muscle and brain; BNP, brain natriuretic peptide; ECG, electrocardiogram; INR, international normalized ratio; PT, prothrombin time; PTT, partial thromboplastin time.

Non-ACS chest pain should be excluded urgently. These conditions include aortic dissection, pericarditis and pericardial effusion, pulmonary emboli, aortic stenosis, and hypertrophic cardiomyopathy. If any of these emergency conditions is suspected, we recommend immediately obtaining an echocardiogram or a computed tomography (CT) scan and treating accordingly.

Our recommended initial laboratory tests include complete blood count, basic metabolic panel, cardiac markers (to include creatine phosphokinase [CPK], CPK-muscle and brain [CPK-MB], and troponin), brain natriuretic peptide (BNP), prothrombin time, partial thromboplastin time, international normalized

ratio, magnesium level, and a lipid profile.

INITIAL MANAGEMENT OF PRIORITY PATIENTS

Priority patients are those with symptoms of chest pain or chest pain equivalent lasting longer than 30 minutes with one of the following ECG criteria for acute MI:

1. Group (1): New ST-elevation at the J point in at least two contiguous leads: ≥2 mm (0.2 mV) in men or ≥1.5 mm (0.15 mV) in women in leads V2–V3 and/or ≥1 mm (0.1 mV) in other contiguous chest leads or the limb leads
2. Group (2): New left bundle branch block (LBBB) or
3. Group (3): Acute posterior wall MI (ST-segment depression in leads V1–V3)

The initial treatment of these patients includes obtaining an intravenous line; providing oxygen; treating patients with oral aspirin (chewable 325 mg stat) and a loading dose of one of the following agents: ticagrelor (180 mg), clopidogrel (600 mg), or prasugrel (60 mg); and giving high-dose statin (atorvastatin 80 mg po). We also recommend considering a bolus of IV heparin (1 mg/kg to a maximum dose of 4000 units) and nitroglycerin if it will not delay the transfer of the patient to the Cardiac Catheterization Laboratory (**Figure 1.4**).

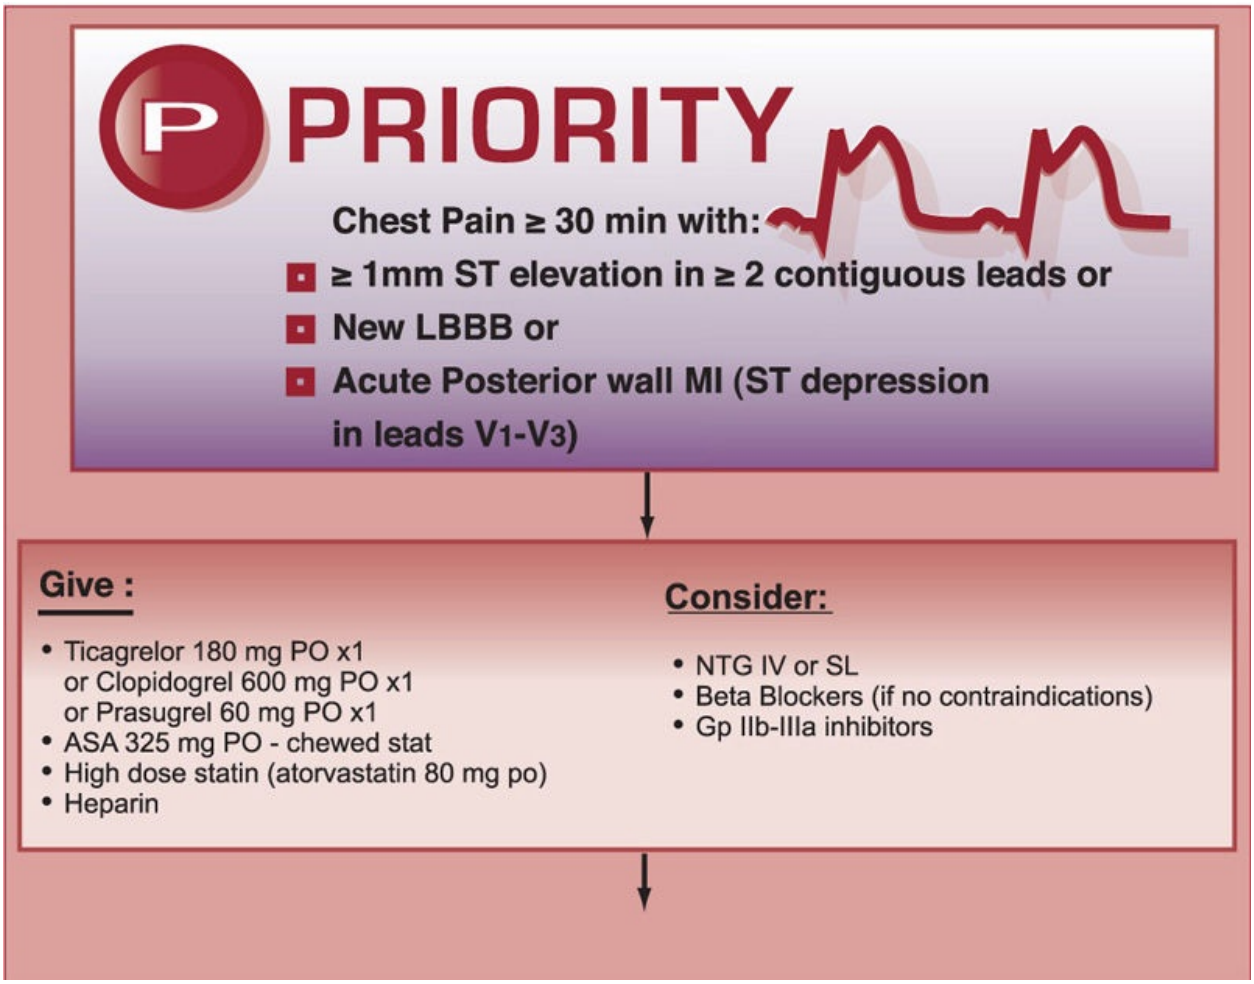

FIGURE 1.4 The initial management of priority patients (those with ST-elevation myocardial infarction). LBBB, left bundle branch block; MI, myocardial infarction.

The key question for further management of these patients is the duration of the patients' symptoms. For patients whose symptoms exceed 12 hours, presence of persistent or residual chest pain determines the next strategy. If there is no evidence of continued symptoms, these patients will generally be treated as though they had been risk stratified with the advanced risk group.

For patients whose symptoms are less than 12 hours or with ongoing chest pain, the decision for further management is based on the availability of on-site angioplasty (percutaneous coronary intervention [PCI]) capability or the ability to transfer the patient to a PCI-capable hospital for immediate PCI within 120 minutes, and the clinical condition of the patient. Patients presenting to a PCI-capable hospital or patients presenting to a non–PCI-capable hospital but who can be transferred to a PCI-capable hospital with an expected "first door to balloon" time of less than 120 minutes should be transferred immediately to the

cardiac catheterization laboratory for revascularization. The MI team is activated for this group of patients (**Figure 1.5**). Furthermore, patients with cardiogenic shock should be transferred immediately to the cardiac catheterization laboratory even if they present to a non–PCI-capable hospital and anticipated time to transfer is more than 120 minutes.

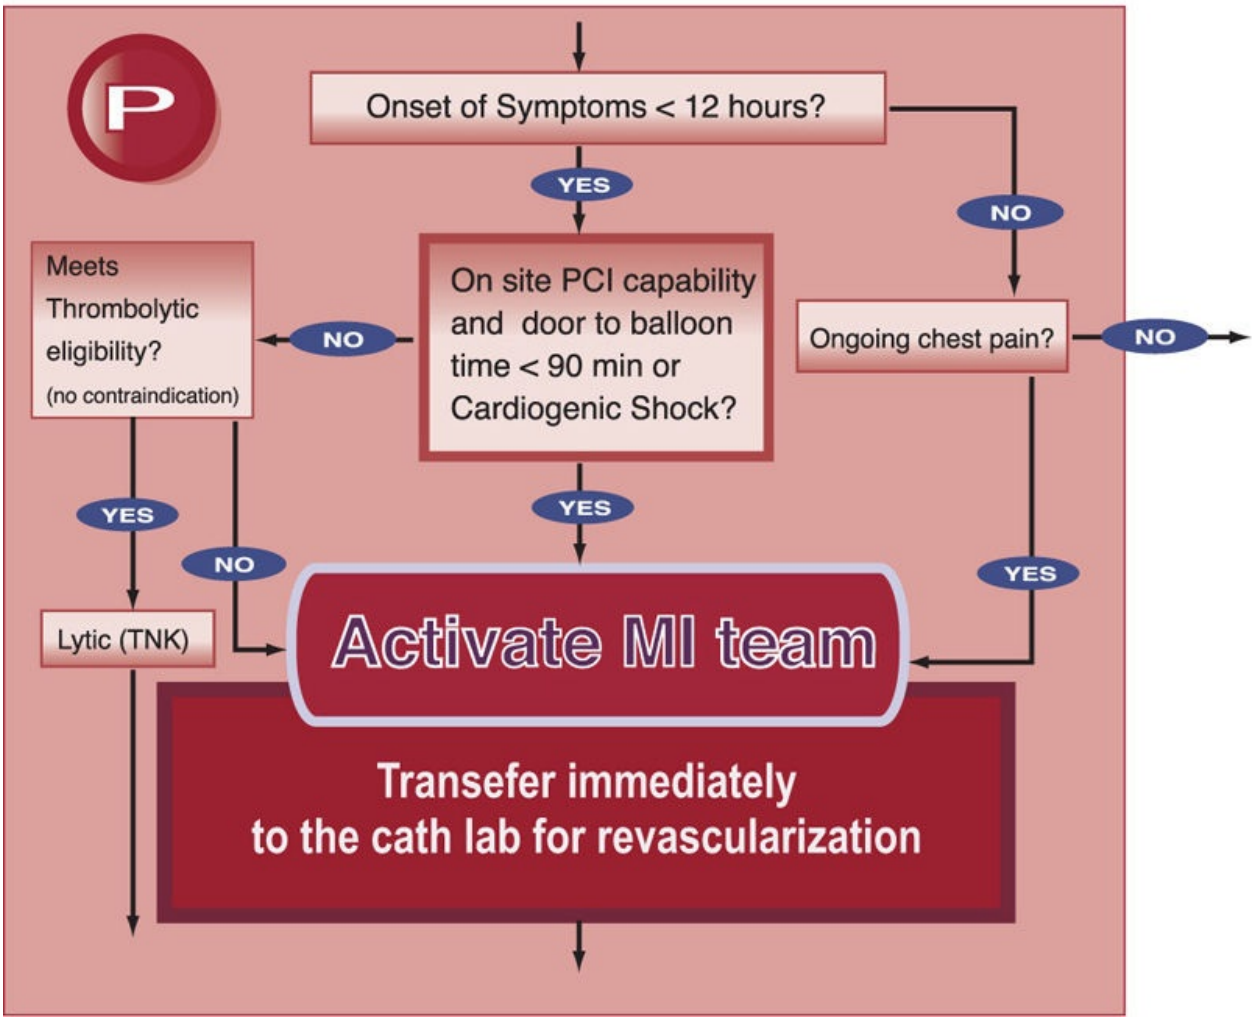

FIGURE 1.5 Advanced management of priority myocardial infarction patients. MI, myocardial infarction; PCI, percutaneous coronary intervention.

In our health care system, a single call made by the emergency department physician to the page operator activates the MI team, which includes the following healthcare providers:

1. The interventional cardiologist on call (who is considered the team leader
2. The director of the Coronary Care Unit (CCU)

3. The cardiology fellow on call
4. The interventional cardiology fellow on call
5. The catheterization laboratory (cath lab) nurse on call
6. The cath lab technologist on call
7. The CCU nursing manager on call
8. The senior internal medicine resident on call

Activating these groups of people has been extremely successful in our institution and has reduced markedly our door to balloon time as well as our first medical contact to device time.

For hospitals without PCI capability and with expected first door-balloon time of more than 120 minutes, we recommend thrombolytic therapy if there are no contraindications.

CORONARY CARE UNIT MANAGEMENT AND SECONDARY PREVENTION FOR PATIENTS WITH PRIORITY MYOCARDIAL INFARCTION

Patients with priority MI should be admitted to the CCU (**Figure 1.6**). All patients should have an echocardiogram to evaluate left ventricle systolic and diastolic function and to exclude valvular abnormality and pericardial involvement. We recommend a CCU stay of 24 to 48 hours to exclude arrhythmia or mechanical complications. For patients with no evidence of mechanical complications or significant arrhythmia, secondary prevention drugs should be started, including aspirin, one of the additional antiplatelet drugs (ticagrelor, clopidogrel, or prasugrel) a high-dose statin, a beta-blocker, and an angiotensin converting enzyme (ACE) inhibitor, or an angiotensin receptor blocker (ARB). Aldosterone blocking agents should be considered for patients with diabetes or LV ejection fraction less than 40%.

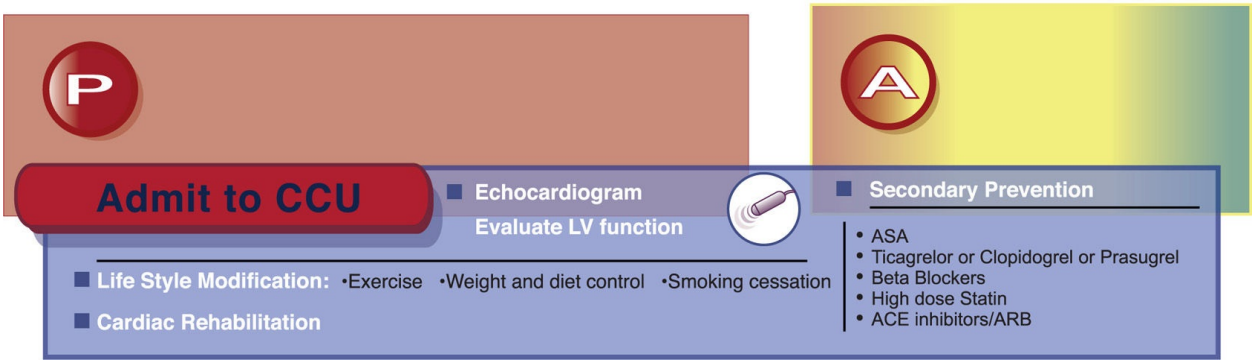

FIGURE 1.6 Coronary care unit management and secondary prevention for patients with priority myocardial infarction. ACE, angiotensin converting enzyme; ARB, angiotensin receptor blocker; CCU, coronary care unit.

Most patients can be discharged within 48 hours with recommendation for lifestyle modification, including exercise, weight and diet control, smoking cessation, and cardiac rehabilitation. Secondary prevention drugs should be continued on discharge.

MANAGEMENT OF ADVANCED RISK ACUTE CORONARY SYNDROME

Typical anginal symptoms are required to be present in patients who will be enrolled into the advanced or intermediate risk groups.

These symptoms include the following:

1. Prolonged chest pain (>20 minutes) relieved by nitroglycerine or rest
2. Chest pain at rest or
3. Accelerated chest pain within 48 hours

To qualify for the advanced risk group, patients must have dynamic ST changes on the ECG (>0.5 mm), dynamic ischemic T-wave changes, or elevated cardiac biomarkers (troponin >0.2 ng/mL) (**Figure 1.7**).

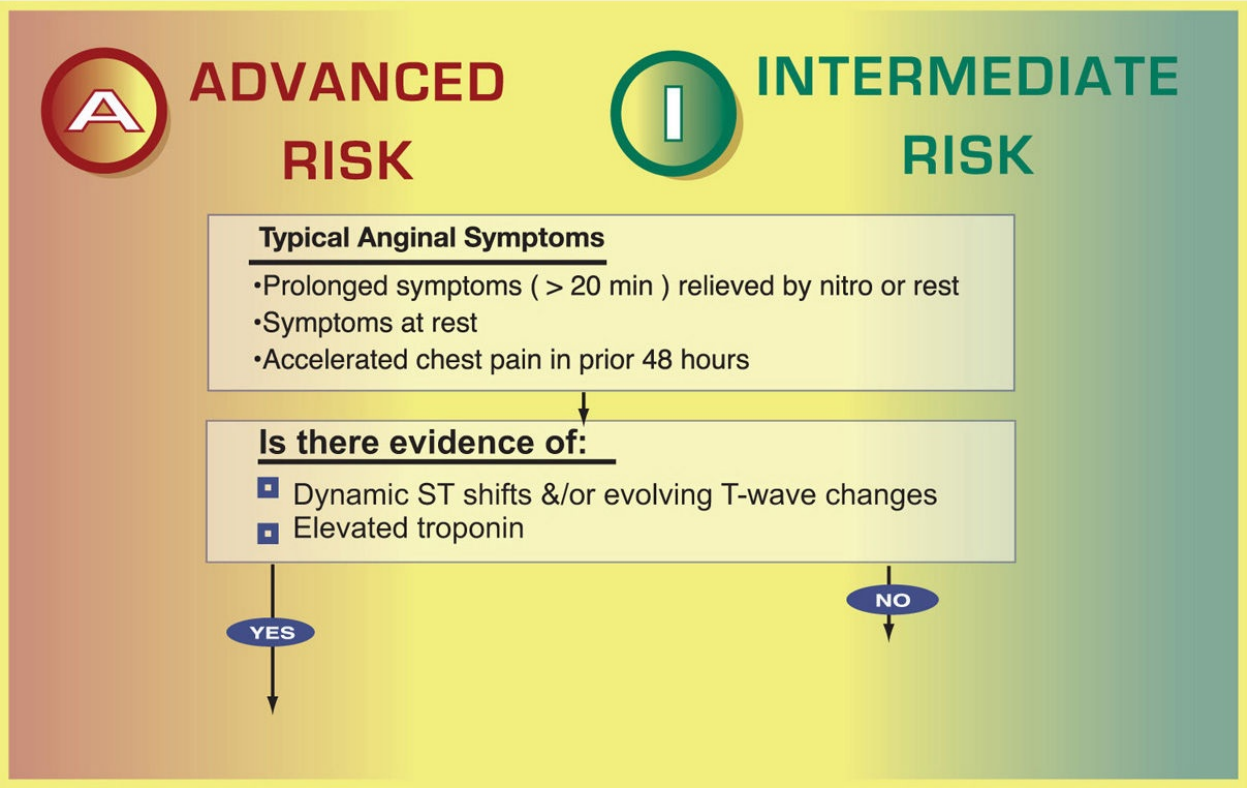

FIGURE 1.7 Risk stratification as advanced risk acute coronary syndrome.

We recommend that patients be admitted to the CCU and be treated with aspirin; ticagrelor or clopidogrel; anticoagulation, including either intravenous heparin or low molecular weight heparin; a beta-blocker; and a statin; consider glycoprotein IIb–IIIa inhibitor or nitroglycerin if there are no contraindications (**Figure 1.8**).

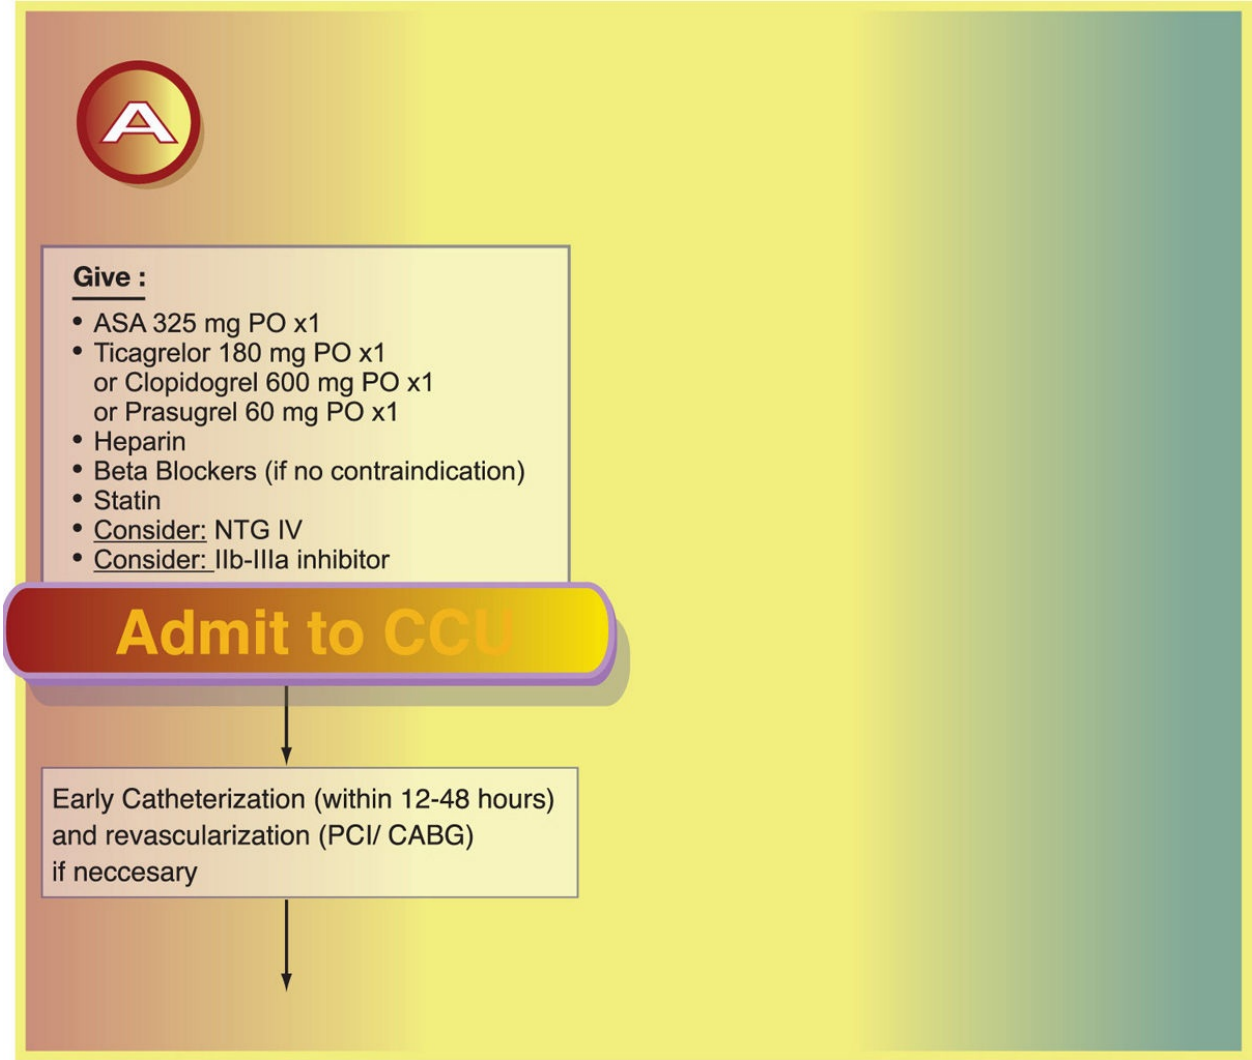

FIGURE 1.8 Management of patients with advanced risk acute coronary syndrome. CCU, coronary care unit; CABG, coronary artery bypass surgery; PCI, percutaneous coronary intervention.

These patients should have early cardiac catheterization within 48 hours and revascularization by PCI or coronary artery bypass surgery (CABG) if there is obstructive coronary artery disease noted on coronary angiography. All patients should have an echocardiogram to evaluate left ventricular (LV) function. Recommendation for secondary prevention medication, lifestyle modification, and cardiac rehabilitation should be provided as in the case of patients in the priority risk group (**Figure 1.6**).

MANAGEMENT OF INTERMEDIATE RISK GROUP

Both the intermediate risk group and the advanced risk patients present to the hospital with typical anginal symptoms. Compared with the advanced risk patients, the immediate risk patients *do not* have evidence of dynamic ST changes or ischemic T-wave changes on the ECG or evidence of positive cardiac markers. These patients should be admitted to the telemetry floor and be given aspirin, heparin, and a beta-blocker if there is no contraindication (**Figure 1.9**). We recommend a minimum telemetry stay of 12 to 24 hours. During this period of time, if there is evidence of dynamic ST changes or ischemic T-wave changes on the ECG or evidence for positive cardiac markers, the patients should be treated as if they had been stratified to the advanced group.

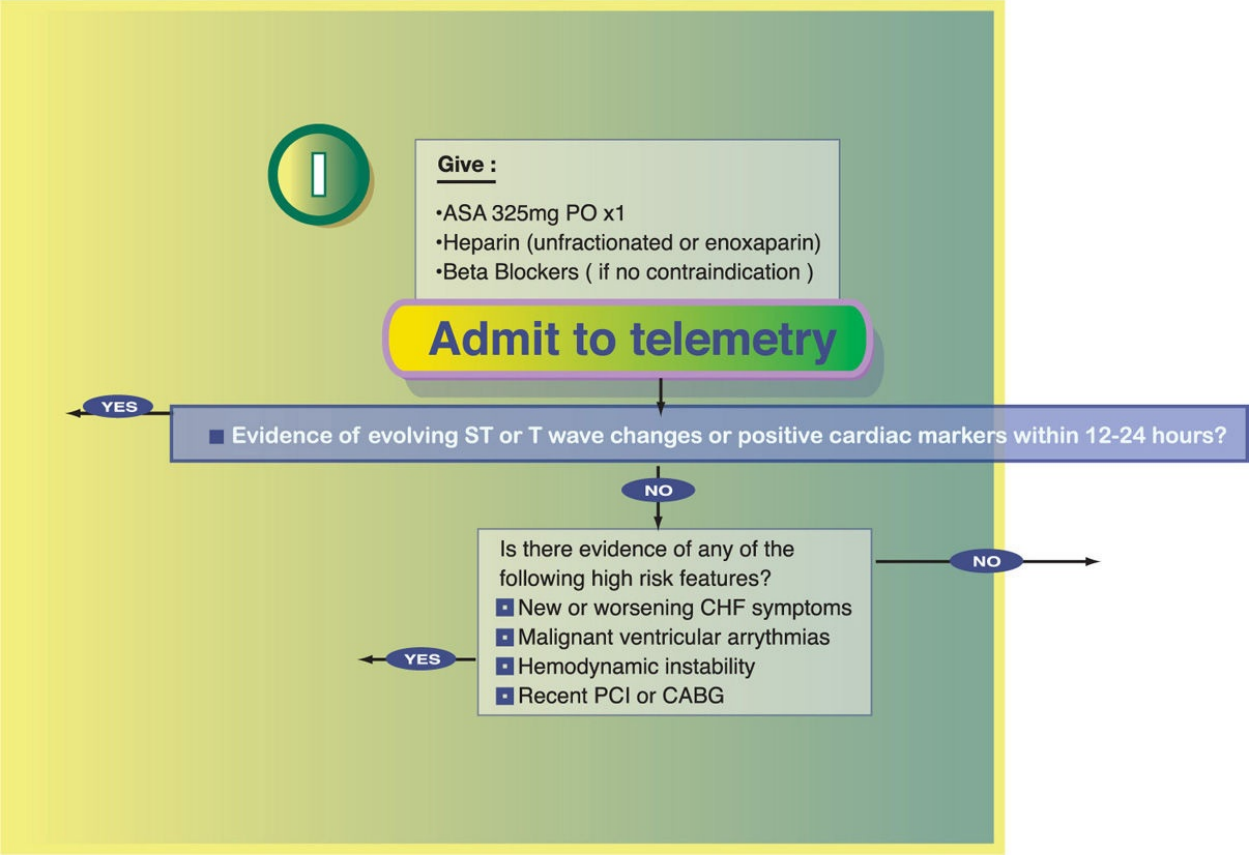

FIGURE 1.9 Management of patients with intermediate risk acute coronary syndrome. CHF, congestive heart failure; CABG, coronary artery bypass surgery; PCI, percutaneous coronary intervention.

The intermediate risk group patients are assessed again for the following high-risk features:

1. New or worsening heart failure symptoms

2. Malignant ventricular arrhythmias
3. Hemodynamic instability
4. Recent PCI or CABG

If there is evidence of any of these high-risk features, we recommend cardiac catheterization within 48 hours and revascularization by PCI or CABG if necessary. Patients with no evidence of high-risk features should be referred for cardiac imaging and stress testing (stress echocardiography or stress nuclear test) or for CT angiography.

MANAGEMENT OF NEGATIVE- OR LOW-RISK GROUP PATIENTS

These groups of patients have atypical symptoms, do not have significant ischemic ECG changes during pain, and do not have elevated cardiac biomarkers.

These patients should be treated only with aspirin and given sublingual nitroglycerin if needed. If a decision is made to admit them to the hospital, they should be admitted to a chest pain unit or to a regular medical floor. They should be followed up for 12 to 24 hours with repeated ECG and cardiac biomarkers (**Figure 1.10**). If there is evidence of evolving ST changes or ischemic T-wave changes on the ECG or any evidence of positive cardiac markers, the patients should be treated aggressively, as for the advanced risk group patients.

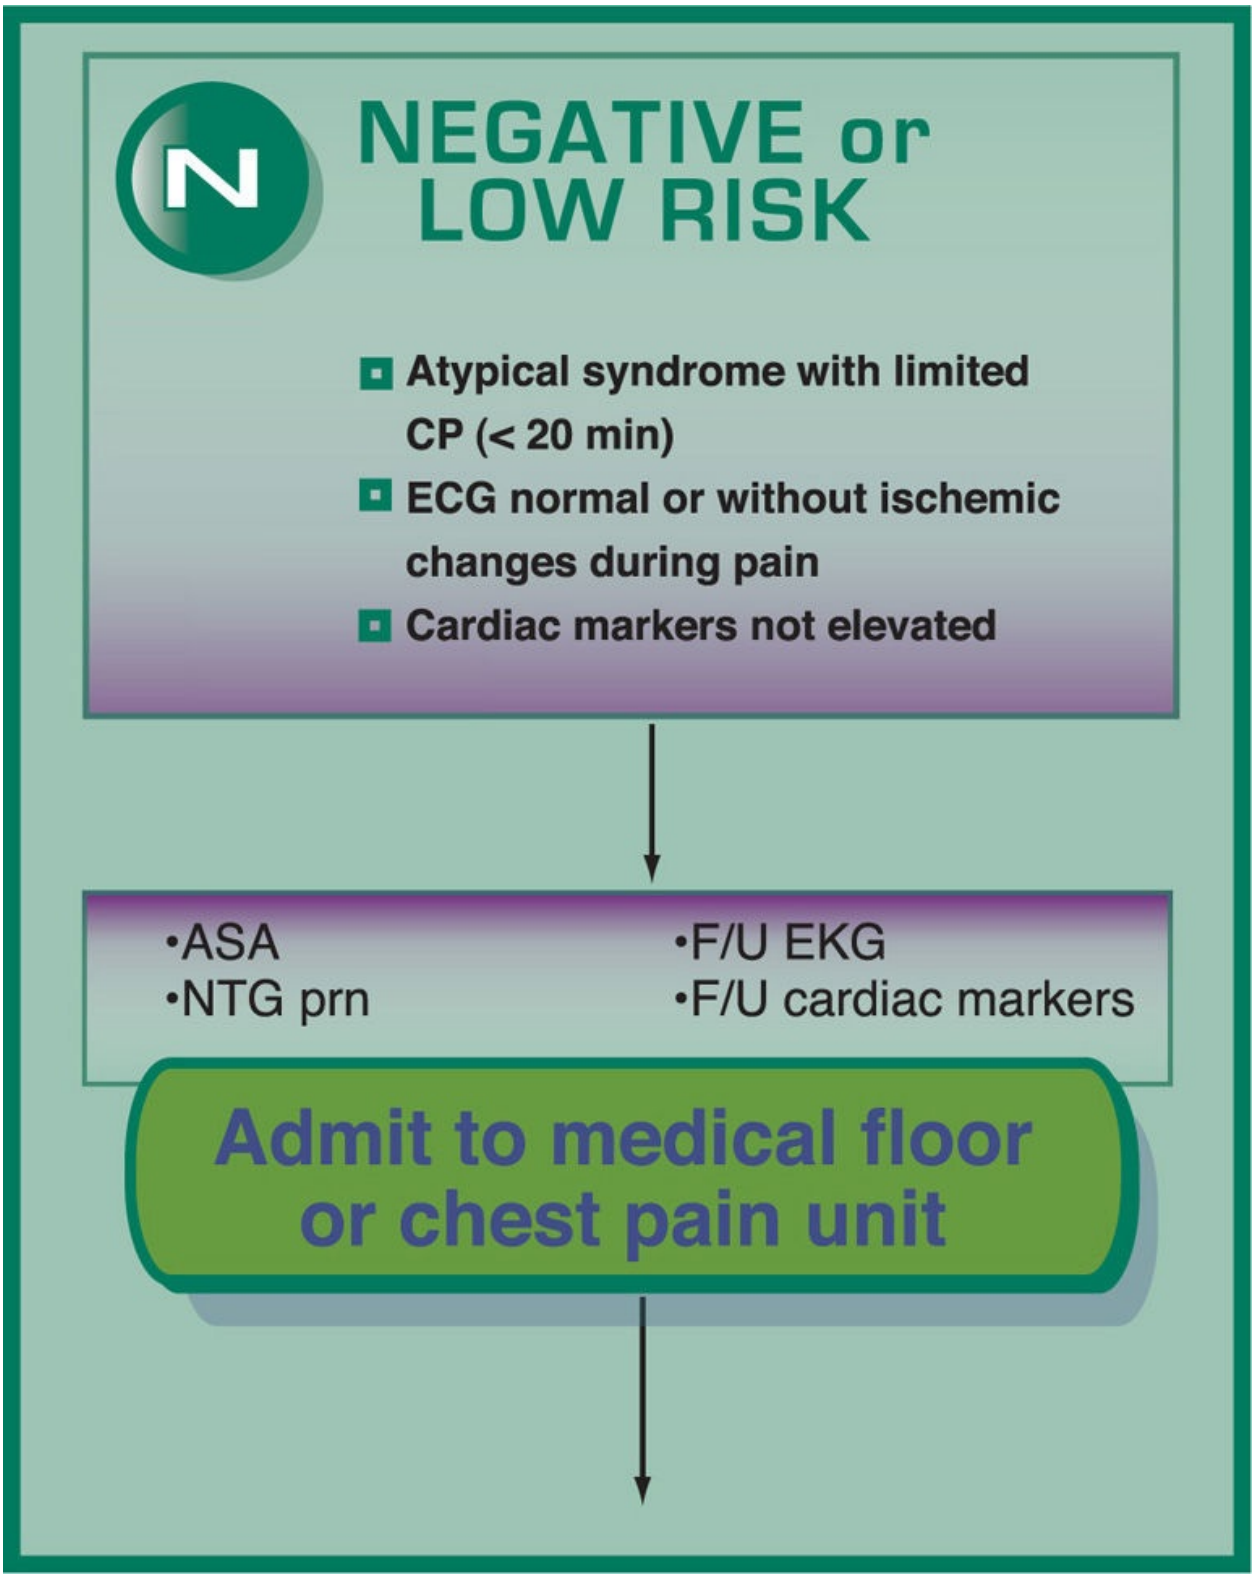

FIGURE 1.10 Initial management of patients with negative- or low-risk acute coronary syndrome; ASA, acetylsalicylic acid; CP, chest pain; ECG, electrocardiogram; NTG, nitroglycerin.

If there are no significant ECG changes and all cardiac markers are negative, we recommend cardiac imaging and stress testing by stress echocardiography or stress nuclear test or a CT angiography (**Figure 1.11**).

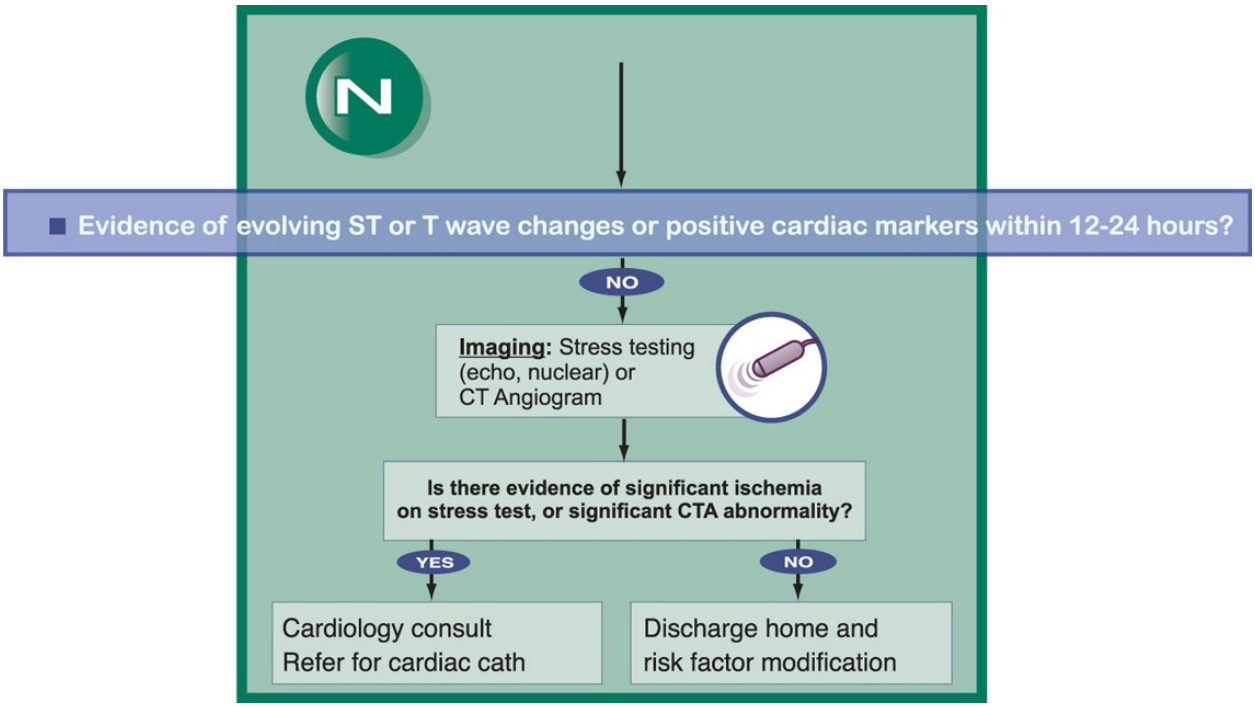

FIGURE 1.11 Risk stratification of low-risk patients by using cardiac imaging stress testing.

Evidence of significant ischemia on any of these stress imaging modalities will be followed by a referral for cardiac catheterization. If there is no evidence of significant ischemia on stress testing, the patients will be discharged home with a recommendation for risk factor modification, to include primary prevention medication and lifestyle modification (**Figure 1.12**).

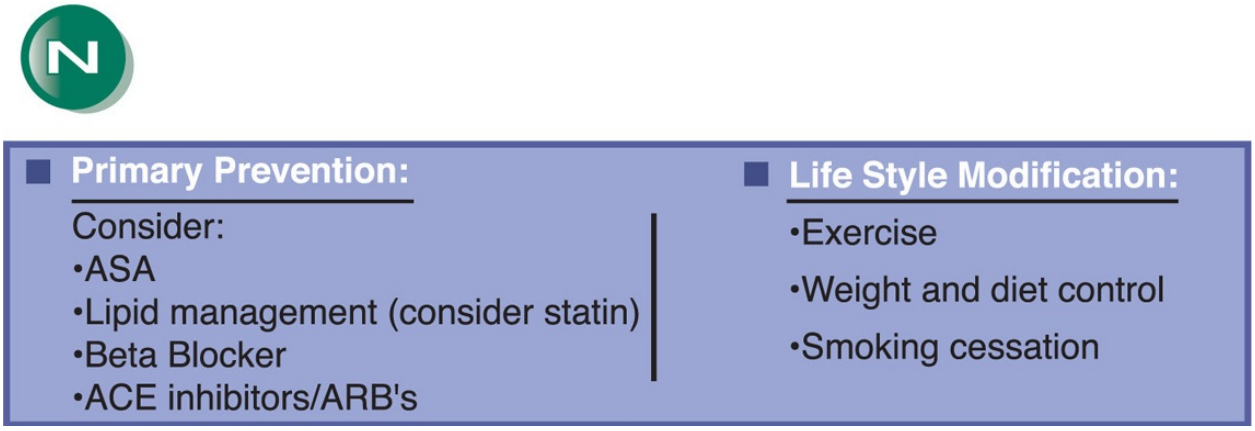

FIGURE 1.12 Primary prevention for low-risk patients. ACE, angiotensin converting enzyme; ARB, angiotensin receptor blocker; ASA, acetylsalicylic acid.

ST-Segment Elevation Myocardial Infarction

INTRODUCTION

ST-segment elevation myocardial infarction (STEMI) represents the most urgent form of acute coronary syndromes (ACS). Pathophysiologically, it is characterized by occlusive intracoronary thrombus formation, resulting in the total cessation of coronary artery blood flow, and the characteristic pattern of ST-segment elevation on the electrocardiogram (ECG), indicative of an acute current of injury from transmural ischemia. Prompt recognition is the key step in the management of such patients to ensure early revascularization, thus limiting the extent of ischemic myocardium and minimizing early and late morbidity and mortality associated with STEMI.

EPIDEMIOLOGY

STEMI remains a major public health problem in both developed and developing nations. In the United States, there are approximately 1 million hospitalizations each year for ACS, and STEMI comprises 25% to 40% of these cases.[1, 2] Approximately one-third of the patients with STEMI are women. In the

past decade, there has been a marked decline in the incidence of STEMI, presumably as a result of the widespread institution of aggressive preventive therapies. In-hospital mortality for patients with STEMI ranges from 5% to 6%, whereas 1-year mortality is variable and estimated to range from 7% to 18%.[1] However, important age-related, sex-related, and geographic differences exist.

PATHOPHYSIOLOGY

The occlusive intracoronary thrombus is usually the result of rupture, ulceration, or erosion of an atherosclerotic plaque. Plaque rupture accounts for the majority of the cases. This leads to either partial obstruction, which generally causes myocardial ischemia in the absence of ST-segment elevation (non–ST-segment elevation ACS), or complete occlusion and STEMI. The myocardium supplied by the culprit artery loses its contractile ability, which leads to the following abnormal contractile patterns: dyssynchrony, hypokinesis, akinesis, and dyskinesis. The remaining noninfarcted myocardium usually manifests hyperkinesis unless there is underlying coronary artery disease affecting the territory supplied by these arteries. If a large area of myocardium is jeopardized, left ventricular pump function becomes depressed. Diastolic dysfunction is invariably associated with systolic dysfunction. Severely reduced systolic function leads to a decrease in left ventricular stroke volume, which lowers systemic pressures and coronary perfusion pressure, potentiating myocardial ischemia and leading to a vicious cycle. In extreme cases of severe myocardial damage, this will eventually lead to cardiogenic shock.

CLINICAL DIAGNOSIS AND ASSESSMENT

The diagnosis of STEMI generally requires symptoms suggestive of myocardial ischemia associated with persistent ST-segment elevation on ECG and evidence of myocardial necrosis, which is typically supported by an elevation in cardiac enzymes.

SYMPTOMS

The sudden onset of chest discomfort is the most common presenting symptom. The chest discomfort is usually retrosternal, with a mid- to left-sided

predisposition. The pain is usually described as “pressure-like,” “crushing,” “squeezing,” or “compressing.” The pain may sometimes radiate to the left arm, left shoulder, neck, or jaw. These symptoms may be associated with shortness of breath, diaphoresis, nausea, or vomiting. These typical clinical symptoms are present in many, but not all, patients with STEMI. Women, elderly patients, and patients with diabetes may present with atypical symptoms. Such symptoms can include epigastric pain, shortness of breath, back pain, or nausea and diaphoresis alone. In some patients, the presentation of STEMI is manifested by symptoms of ventricular tachycardia or symptoms of left ventricular failure. Occasionally, patients with STEMI may present with cardiac arrest. A focused history and physical exam should be performed on all patients with suspected STEMI, to aid in making the diagnosis and identifying high-risk patients.

ELECTROCARDIOGRAM

A 12-lead ECG should be acquired and interpreted promptly (within 10 minutes) in all suspected cases of acute myocardial infarction (MI). In the presence of a strong clinical suspicion, if the initial ECG is nondiagnostic, a repeat ECG should be performed 5 to 10 minutes later to assess for evolving ST elevation. Hyperacute T waves are the earliest ECG manifestations of a STEMI and may precede the characteristic ST-segment elevation. On the other hand, up to 15% of patients with STEMI can have a normal ECG. In these circumstances, the left circumflex artery is often the culprit vessel.

The European Society of Cardiology/ACCF/AHA/World Heart Federation Task Force for the Universal Definition of MI and the ACCF/AHA/SCAI Guidelines for the Management of ST Elevation Myocardial Infarction include the following criteria for the ECG definition of ST elevation infarction[1, 3]:

1. New ST elevation at the J point in at least two contiguous leads of ≥2 mm (0.2 mV) in men or ≥1.5 mm (0.15 mV) in women in leads V2–V3 and/or of ≥1 mm (0.1 mV) in other contiguous chest leads or the limb leads.
2. New ST depressions in ≥2 precordial leads (V1–V4) are indicative of a transmural posterior infarction.
3. New or presumably new left bundle branch block (LBBB). (While this may be a STEMI equivalent, the diagnostic accuracy of this finding has recently been questioned.[1] There are algorithms that may help to further differentiate a true STEMI in the setting of LBBB.)

In patients with suspected right ventricular infarction, right precordial leads (V3R and V4R) could further aid in the diagnosis. In addition, in cases of a suspected posterior infarction, recording of posterior leads is strongly recommended (V7 lead should be recorded at the left posterior axillary line, V8 lead should be recorded at the left midscapular line, and V9 lead should be recorded at the left paraspinal border).[3] The presence of "reciprocal changes" in the form of ST-segment depression in the leads that are opposite to the location of the ST elevations is a characteristic finding that greatly increases the specificity of the diagnosis of STEMI. Multilead ST-segment depression with coexistent ST elevation in lead aVR alone has been described in patients with left main or proximal left anterior descending artery occlusion.

It is important to recognize that the ECG changes that are depicted in a patient with suspected STEMI are a dynamic finding. The ST-segment changes will evolve throughout the patient's postinfarction course and will often reflect the extent to which the patient has achieved restoration of myocardial blood flow at the tissue level. **Figure 2.1** outlines the evolution of ECG changes in a patient with a large anterior infarction who received prompt reperfusion therapy.

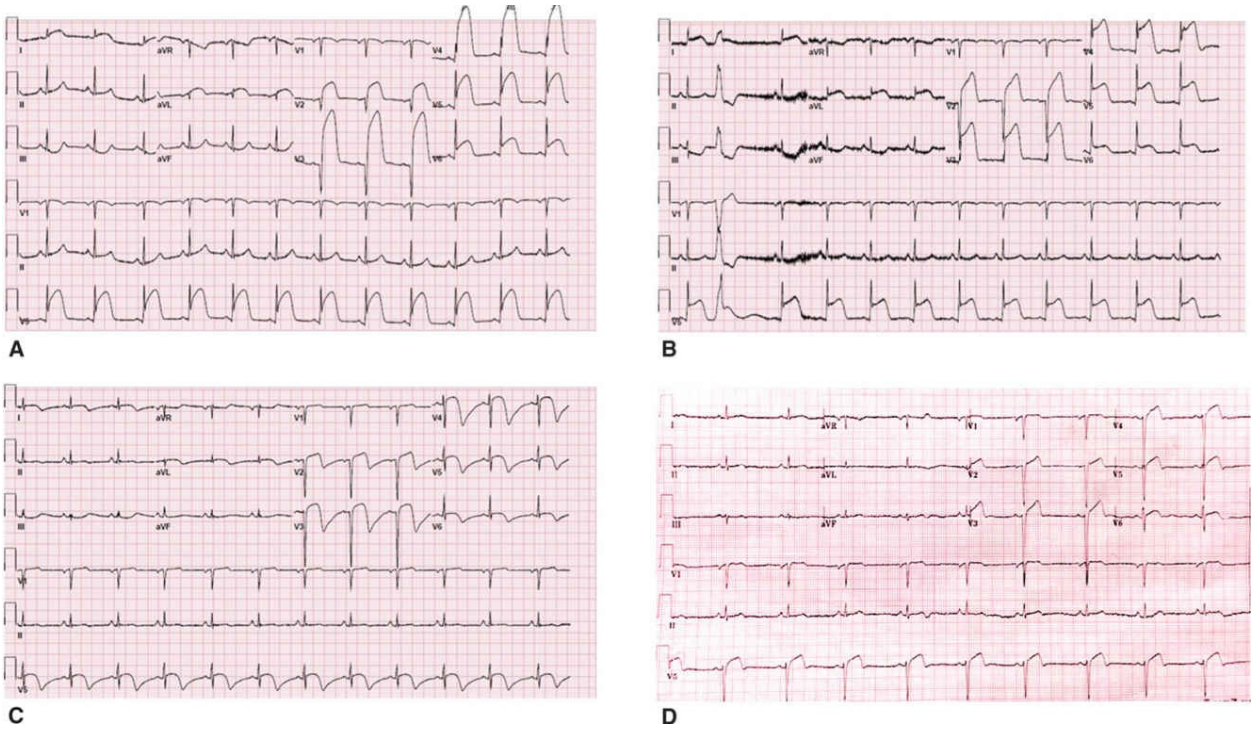

FIGURE 2.1 The evolution of the ECG during an acute infarction. A, The ECG of a 54-year-old male presenting 2 hours after the onset of severe chest pain demonstrating a large anterolateral infarction. B, The ECG in this same patient immediately after reperfusion therapy with primary PCI. Despite restoration of

TIMI III flow in the infarct artery and complete relief of chest pain, there remains moderate ST-segment elevation. Note, however, that the ST-segment elevation has been reduced by more than 50% in the lead with the greatest degree of ST elevation on initial ECG. This usually indicates achievement of tissue-level reperfusion. C, The ECG 48 hours after the acute infarction. The patient was asymptomatic at the time the ECG was performed, and his cardiac enzymes were downtrending. Note the marked ST and T wave changes and the prolongation of the QT interval. This finding is not uncommon postinfarction even in patients treated successfully with reperfusion therapy. D, The ECG was performed 2 weeks after the infarction. Note the marked improvement in the ST and T wave abnormalities. ECG, electrocardiogram; PCI, percutaneous coronary intervention; STEMI, ST-segment elevation myocardial infarction; TIMI, thrombolysis in myocardial infarction.

BIOMARKERS

Serum biomarkers can be detected when they are released from damaged myocardial cells. Because this is a time-bound process, serum biomarkers are not useful for early detection of STEMI but can confirm myocardial injury if a patient is presenting late after symptom onset. Established cardiac biomarkers used to detect acute MI are cardiac-specific troponins (troponin I and troponin T), creatine kinase (CK) and CK isoenzymes (CK-MB fraction), and myoglobin. **Figure 2.2** depicts the Kinetic profiles of the various biomarkers used in the diagnosis of acute STEMI. Myoglobin elevations peak early but are not cardiac-specific. Cardiac troponin is the preferred biomarker for the diagnosis of MI because of its high specificity and sensitivity. The biomarkers of myocardial injury, however, do not provide any information on the cause of injury. Elevated levels should always be correlated clinically because it could be secondary to nonischemic insults. In STEMI, clinicians should not wait for the results of cardiac biomarkers to initiate treatment. Clinical presentation and 12-lead ECG should serve as the initial diagnostic tools. CK and CK-MB are the tests of choice to define a recurrent MI in the early days after STEMI.

RISK ASSESSMENT

It is important to perform a risk assessment for all patents with STEMI. This assessment should be done on initial presentation, and repeat assessments should be performed throughout the hospital stay. A risk assessment provides the physician with important estimates of the patient's overall prognosis and guides the health care team on the most appropriate therapies on the basis of this risk. For example, in a post hoc analysis of the DANish trial in Acute Myocardial Infarction-2 (DANAMI-2),[4] primary percutaneous coronary intervention (PCI) was associated with a significant reduction in 3-year mortality compared with fibrinolysis (25% vs 36%) in high-risk patients with a thrombolysis in myocardial infarction (TIMI) risk score ≥5. Risk assessments also allow the physician to provide realistic information to patients and their families regarding a patient's prognosis. A risk assessment is often based on the historical and clinical information that is available to the health care team when the patient first presents to the hospital, and is further modified by the patient's subsequent

hospital course.

Scoring systems such as the TIMI risk score[5] or the Global Registry of Acute Coronary Events (GRACE) score[6] are tools that provide a qualitative assessment of risk and the likelihood that the patient will suffer a subsequent ischemic or terminal event in the short term. The TIMI risk score is an easy to use risk score for patients with STEMI. The TIMI score was derived from a dataset of patients enrolled in the TIMI-II trial and validated using information from those patients enrolled in the TIMI-9 trial. The score comprises eight variables, each of which is assigned a certain number of points. The variables include the following: (1) Age: 65 to 74 years = 2 points; and ≥75 years = 3 points; (2) Systolic blood pressure < 100 mm Hg = 3 points; (3) Heart rate > 100 beats/min = 2 points; (4) Kilip class II–IV = 2 points; (5) History of diabetes or hypertension or angina = 1 point; (6) Weight < 67 kg = 1 point; (7) Anterior infarct or LBBB = 1 point; and (8) Time to treatment > 4 hours = 1 point. Across the spectrum of risk, mortality at 30 days varies from less than 1% for low-risk patients (those with a TIMI score of 1) to over 35% for high-risk patient (those with a TIMI score of 8).

The GRACE risk score assesses the likelihood of in-hospital and 6-month mortality among patients with ACS, including STEMI, non–ST-elevation MI, or unstable angina. The score was derived using variables from an unselected population of patients enrolled in the GRACE Registry, an international clinical registry of all patients with ACS admitted to selected hospitals. The GRACE risk score gives a broader range of weighted values for each particular risk factor. Because the GRACE score was derived from an unselected population of patients (rather than data from patients enrolled in clinical trials), it incorporates a larger range of clinical variables than the TIMI risk score. Eight factors are used in this score: (1) Age, (2) Heart rate, (3) Systolic blood pressure, (4) serum creatinine, (5) Cardiac arrest on presentation, (6) ST-segment deviation, (7) Elevated/abnormal cardiac enzymes, and (8) Rales or jugular venous distension versus pulmonary edema versus shock. The GRACE score calculator is available as a web-based tool for easy use (http://www.outcomes-umassmed.org/grace/). The GRACE score was validated using the clinical data of the patients enrolled in the Global Use of Strategies to Open Occluded Arteries IIb (GUSTO IIb) study. The predicted mortality for the patients in the GUSTO IIb study calculated with the GRACE scoring system was strongly correlated with the observed mortality (*c*-statistic = 0.791), thus emphasizing the strong predictive accuracy of this scoring system.

REPERFUSION THERAPY

The management of STEMI involves an integrated strategy that begins with early recognition of symptoms and diagnosis, contact with emergency medical services, time-efficient practices in emergency departments to shorten door-to-balloon times or door-to-needle times, and a skilled heart team to ensure timely revascularization. To achieve these goals, the American Heart Association recommends that each community develops a STEMI system of care, which includes[1, 7]:

1. A process for prehospital identification of STEMI and prehospital activation of the cardiac catheterization laboratory, with destination protocols in place to bypass non-PCI hospitals and direct patients with suspected STEMI diagnosed in the field to PCI-capable hospitals.
2. Protocols enabling the rapid diagnosis and treatment of STEMI at non–PCI-capable hospitals, including the facilitation of transfer of such patients to PCI-capable hospitals and/or the rapid and early use of fibrinolytic therapy for those patients who present to hospitals without PCI capability and who cannot be transferred to PCI-capable hospitals in a timely manner.
3. Ongoing multidisciplinary team meetings (including emergency medical services, non-PCI hospitals, and PCI centers) to evaluate outcomes and quality improvement metrics.

PRIMARY PERCUTANEOUS CORONARY INTERVENTION

Current guidelines recommend that reperfusion with either fibrinolysis or primary PCI be performed as soon as possible after arrival at the hospital.[1] In general, primary PCI is the preferred reperfusion therapy. Several randomized controlled trials (RCTs) and observational studies have shown the superiority of primary PCI compared with fibrinolytic therapy.[8, 9] In a meta-analysis of 23 randomized trials, primary PCI was associated with a reduction in short-term and long-term major adverse cardiovascular events, including death, nonfatal Recurrent MI, and stroke.[8] The benefits of PCI over fibrinolytic therapy were seen irrespective of the type of fibrinolytic agent used, and even when reperfusion was delayed because of transfer for primary PCI. Restoration of TIMI-3 flow has a major impact on short- and long-term mortality. Primary PCI can achieve TIMI-3 flow in the infarct artery in >85% of patients,[9, 10] compared

with only about 60% to 63% of patients using thrombolytic therapy.[11] Conceivably, PCI has been shown to limit infarct size and salvage greater myocardium compared with fibrinolysis.[12] Primary PCI also reduces recurrent ischemia, resulting in fewer revascularization procedures and a shorter length of stay compared with fibrinolysis.[13] Primary PCI should be performed in patients with ischemic symptoms of <12 hours' duration presenting to PCI-capable hospitals, and for patients presenting to non–PCI-capable hospitals only if PCI can be performed within 120 minutes of first hospital arrival (see below). For patients with a delayed presentation of 12 to 24 hours after symptom onset, PCI can still be considered. Patients who present to hospitals without PCI capabilities should be transferred for primary PCI if they have contraindications to fibrinolytic therapy or cardiogenic shock, irrespective of the time delay from first medical contact.[1]

Transfer for Primary Percutaneous Coronary Intervention

Several trials have shown benefits in transferring patients with STEMI for primary PCI from a non–PCI-capable hospital to a PCI-capable hospital. The DANAMI-2 trial[14] conducted in Denmark was the largest of such studies, involving 1572 patients. The trial found that the transfer of patients with STEMI from a non–PCI-capable hospital to a PCI-capable hospital for primary PCI was superior to the use of fibrinolytic therapy at the referring hospital. The median transfer time was 67 minutes, and average first door-to-device time was approximately 110 minutes. Most of these transfer studies were performed in European centers where transfer times are generally relatively short, and efficient systems with protocols for transport are already in place. Data from the recent AHA Mission: Lifeline Program of 14,518 patients transferred from non–PCI-capable hospitals for primary PCI between 2008 and 2012 in the United States showed that more than one-third of the patients with STEMI who were transferred for primary PCI failed to achieve a first door-to-device time ≤120 minutes, despite estimated transfer times of less than 60 minutes.[15] If the time to treatment with primary PCI falls beyond the window of 120 minutes, it is possible that the relative benefit from primary PCI as compared with fibrinolytic therapy may be lost. These findings suggest that ongoing efforts to optimize STEMI systems across the country are still needed to achieve primary PCI care for transfer patients as mandated by the guidelines.

FIBRINOLYTIC THERAPY

When it is anticipated that primary PCI cannot be performed within 120 minutes of first medical contact and the onset of ischemic symptoms is within 12 hours, then fibrinolytic therapy should be given. As stated earlier, myocardial salvage is a time-dependent process, and successful epicardial perfusion can be achieved if fibrinolytic therapy is administered early after symptom onset. In fact, studies have demonstrated the superiority of fibrinolysis over primary PCI when therapy is administered within 1 to 2 hours of symptom onset (concept of the "golden hour").[16] The efficacy and utility of fibrinolytic agents diminish with time, and their benefit in patients who present >12 hours after symptom onset is uncertain; however, the guidelines still provide a window of use within 12 to 24 hours of symptom onset for large infarct or patients with ongoing symptoms. It is recommended that when fibrinolytic therapy is indicated or chosen as the primary reperfusion strategy, it should be administered within 30 minutes of arrival at the hospital. Unfortunately, not all patients are candidates for fibrinolytic therapy because of possible contraindications, but should instead be considered for transfer for primary PCI.[1] **Table 2.1** outlines the absolute and relative contraindications to fibrinolytic therapy. Major complications of fibrinolytic therapy include bleeding, particularly intracranial hemorrhage (<1%) and other serious bleeding (<2%). Approximately 20% to 25% of patients have failure of reperfusion,[17] and an additional 25% to 30% have reocclusion,[18] which is associated with increased in-hospital mortality and significant impairment in left ventricular function.[19]

TABLE 2.1 Contraindications to Fibrinolytic Therapy

ABSOLUTE	RELATIVE
Any prior intracranial hemorrhage	History of chronic, severe poorly controlled hypertension
Known structural cerebral vascular lesion (ie, arteriovenous malformation)	Severe hypertension (systolic blood pressure > 180 mm Hg or diastolic blood pressure > 110 mm Hg)
Malignant cerebral neoplasm (primary or metastatic)	History of prior ischemic stroke >3 mo
Ischemic stroke within 3 mo	Dementia
Active bleeding or bleeding diathesis (excluding menses)	Other known intracranial pathology

Important closed-head or facial trauma within 3 mo	Traumatic or prolonged (>10 min) cardiopulmonary resuscitation
Intracranial or intraspinal surgery within 3 mo	Major surgery (<3 wk)
Severe and uncontrolled hypertension unresponsive to therapies	Recent (within 2–4 wk) internal bleeding
For planned streptokinase use: streptokinase within 6 mo	Noncompressible vascular punctures
	Pregnancy
	Active peptic ulcer

MEDICAL MANAGEMENT

GENERAL MEASURES

Oxygen is provided to treat hypoxia. In a randomized study evaluating the benefits of oxygen therapy administered routinely to patients at 8 L/min (in the absence of clinical hypoxia), oxygen therapy was associated with increased rates of recurrent MI and ventricular arrhythmias and increased infarct size.[20] For this reason, oxygen should be reserved for those patients with signs of hypoxia, including an oxygen saturation of <95% on room air. In patients with severe pulmonary edema compromising the respiratory status, endotracheal intubation and mechanical ventilation may be necessary. Morphine or nitrates should be given to control pain and associated increased sympathetic activity, but these therapies have little effect on overall clinical outcome. Nitrates are contraindicated in patients with suspected right ventricular infarction, hypotension, or recent use of 5′ phosphodiesterase inhibitors.

ANTIPLATELET THERAPY

A cascade of thrombotic processes follow rupture, fissure, or erosion of an atherosclerotic plaque. Circulating platelets become activated on contact with the lipid-filled core, collagen, and other thrombogenic contents. Activated platelets release adenosine diphosphate (ADP) and thromboxane A_2 and cause expression of the glycoprotein IIb/IIIa receptors, which bind to adhesive proteins such as von Willebrand factor and fibrinogen and amplify the thrombotic process at the

ruptured plaque. Of the various receptors involved in the process, the P2Y12 receptors activated by ADP play a key role in platelet activation, adhesion, and aggregation. A thrombus rich in platelets promotes reocclusion after successful fibrinolysis[21] and even after primary PCI.[22] Antiplatelet agents thus play a central role in the treatment of patients with STEMI. **Figure 2.3** illustrates the various receptors seen on the surface of the platelet and the interaction of the platelet receptor inhibitors with these receptors.

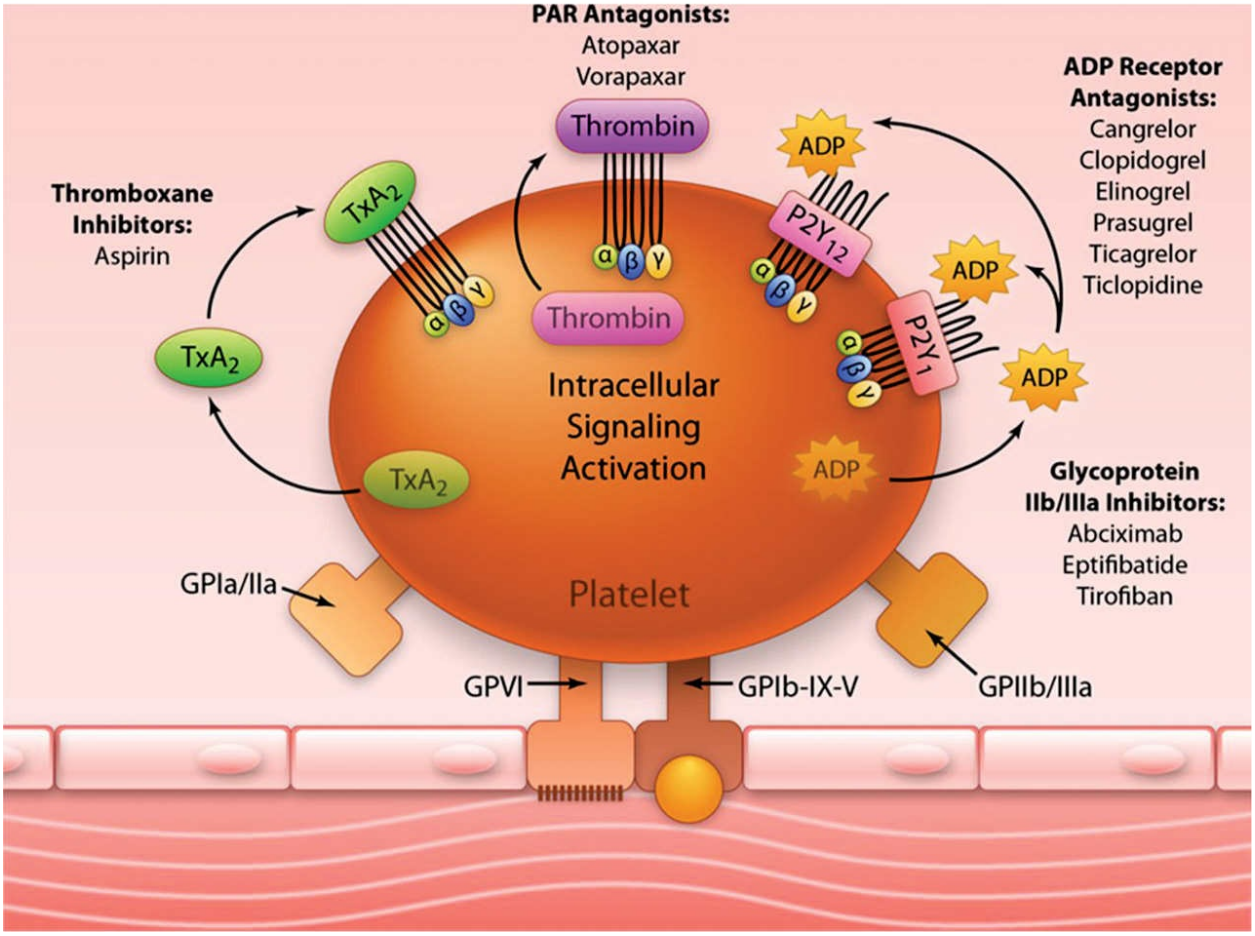

FIGURE 2.3 Schematic diagram of the interplay of platelet receptors and platelet receptor inhibitors. There are various targets of action for antiplatelet therapies. ADP, adenosine diphosphate; GP, glycoprotein; PAR, protease-activated receptor; Tx, Thromboxane. (Reproduced from Bhatt DL, Hulot J-S, Moliterno DJ, et al. Antiplatelet and anticoagulation therapy for acute coronary syndromes. *Circ Res*. 2014;114:1929-1943, with permission of the publisher. Copyright 2016, American Heart Association.)

Aspirin

Aspirin irreversibly inhibits the cyclooxygenase enzyme, which is the mediator of the initial step in the synthesis of thromboxane A_2 and arachidonic acid. Non–enteric-coated aspirin in doses of 162 to 325 mg should be given to patients to "chew" immediately on initial presentation. After primary PCI or fibrinolysis, the preferred maintenance dose is 81 mg. In the CURRENT-OASIS 7 trial,[23] there were no differences in the efficacy and safety end points between aspirin 325 mg and aspirin 81 mg in patients with ACS undergoing invasive treatment. Observational studies, however, have suggested increased bleeding in follow-up with higher doses of maintenance aspirin,[24] and hence the lower dose is generally advised.

P2Y12 Inhibitors

The P2Y12 inhibitors include oral (clopidogrel, prasugrel, and ticagrelor) and intravenous (cangrelor) agents. These medications block the binding of ADP to the P2Y12 receptor, thus inhibiting the P2Y12 receptor–mediated activation of the glycoprotein IIb/IIIa receptor and subsequent platelet aggregation. Adding P2Y12 inhibitors to aspirin offers added benefit in patients with MI, and benefits have been noted in medically treated patients as well. **Table 2.2** outlines the properties of the currently available oral P2Y12 inhibitors.

TABLE 2.2 Comparison of P2Y12 Inhibitors

P2Y12 INHIBITOR	CLOPIDOGREL	PRASUGREL	TICAGRELOR
Class	Thienopyridine	Thienopyridine	Cyclopentyl-triazolopyrimidine
Prodrug	Yes	Yes	No
Receptor binding	Irreversible	Irreversible	Reversible
Onset of effect	2–4 h	30 min	30 min
Duration of effect	3–10 d	5–10 d	3–4 d
Metabolism	Hepatic	Hepatic	Hepatic
Clearance	Renal 50%, fecal 46%	Renal 68%, fecal 27%	Renal 26%, fecal 58%
Loading dose	300–600 mg	60 mg	180 mg
Maintenance dose	75 mg daily	10 mg daily	90 mg twice daily
Withdrawal before surgery	5 d	7 d	5 d

Clopidogrel

Clopidogrel, a prodrug, converts to active metabolite and binds irreversibly to the P2Y12 receptor on platelets. Numerous RCTs have demonstrated that pretreatment with clopidogrel reduces cardiovascular mortality and ischemic events post-PCI.[25] Clopidogrel administered at a loading dose of 600 mg (as compared with 300 mg) is associated with a 42% relative reduction in the rates of definite stent thrombosis.[23] The AHA/ACC guidelines recommend a loading dose of 600 mg to be given as early as possible for those patients planned for

primary PCI.[1] The Clopidogrel and Metoprolol in Myocardial Infarction Trial/Second Chinese Cardiac Study (COMMIT/CCS-2) study[26] showed that the use of clopidogrel for medically treated STEMI benefited patients through a 9% reduction in the composite end point of death, recurrent MI, and stroke; further, a 7% reduction in all-cause death was noted among patients randomized to clopidogrel treatment. A 300 mg loading dose of clopidogrel is advised for medically treated patients (fibrinolytic-treated patients or patients who did not receive reperfusion therapy), followed by a maintenance dose of 75 mg daily. A loading dose is not recommended for medically treated patients over 75 years old.

Prasugrel

As with clopidogrel, prasugrel is a prodrug that, on converting to active metabolite, irreversibly blocks the P2Y12 receptor. As compared with clopidogrel, prasugrel achieves faster and more potent platelet inhibition. In a prespecified subgroup analysis of patients with STEMI enrolled in the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-TIMI (TRITON-TIMI 38),[27] prasugrel, as compared with clopidogrel, was associated with a 32% reduction in the primary composite end point of cardiovascular death, MI, or stroke without any increase in non–coronary artery bypass graft (CABG) bleeding. Prasugrel was also associated with a 52% reduction in stent thrombosis in follow-up. It is important to note that despite the absence of an increase in bleeding events in the patients with STEMI enrolled in the TRITON-TIMI 38 trial, a higher rate of non-CABG major bleeding was noted in the overall trial. Therefore, prasugrel should be used with caution in patients who are ≥75 years of age or whose body weight ≤60 kg. Prasugrel is contraindicated in those patients with a history of prior stroke or transient ischemic attack. The recommended loading dose of prasugrel is 60 mg, followed by a maintenance dose of 10 mg daily.

Ticagrelor

Ticagrelor is a direct acting selective antagonist that binds reversibly to the P2Y12 receptor. In a subgroup analysis of patients with STEMI enrolled in the Platelet Inhibition and Patient Outcomes (PLATO) trial,[28] ticagrelor showed a 13% reduction in the combined end point of cardiovascular death, MI, or stroke with no increase in the risk of any bleeding, compared with clopidogrel.

Mortality was also significantly reduced with ticagrelor. The recommended loading dose of ticagrelor is 180 mg, and the recommended maintenance dose is 90 mg twice a day. When ticagrelor is used, the maintenance dose of aspirin is 81 mg daily. Dyspnea is one of the frequently reported side effects of ticagrelor, with about 14% of patients reporting dyspnea in the main PLATO trial; however, drug discontinuation caused by dyspnea was less than 1%.[29]

Cangrelor

Cangrelor is an intravenous, nonthienopyridine, direct P2Y12 receptor blocker that has rapid onset and rapid offset (within minutes) of its effects. Pooled analysis of the Cangrelor versus Standard Therapy to Achieve Optimal Management of Platelet Inhibition (CHAMPION) trials[30] showed that cangrelor decreased periprocedural outcomes of all-cause death, MI, ischemia-driven revascularization, or stent thrombosis. An increase in minor bleeding, but not major bleeding, was noted. Although these trials came under scrutiny because of their designs and timing of administration of clopidogrel, the results of the trials collectively support the use of cangrelor in those patients who are "inadequately" pretreated with clopidogrel before PCI.

Glycoprotein IIb/IIIa Receptor Inhibitors

Glycoprotein IIb/IIIa receptor inhibitors (GPI) block the binding of the glycoprotein IIb/IIIa receptors to fibrinogen, thereby inhibiting fibrinogen-platelet bridging. They are potent parenteral platelet inhibitors. Three agents are available—abciximab, eptifibatide, and tirofiban. In the setting of primary PCI, abciximab has been studied the most. Compared with unfractionated heparin (UFH) or low-molecular-weight heparin alone, GPIs are associated with a significant reduction in cardiovascular events, largely driven by a reduction in periprocedural MI.[31] An increased risk for bleeding was also observed in the trials studying GPI use. Studies supporting the use of these agents during PCI were largely performed before the widespread use of dual antiplatelet therapy, and the role of GPI in the current era is less well defined. Furthermore, data on the benefits of these agents in the setting of STEMI have shown variable results.[32, 33] Per guidelines, it is reasonable to begin treatment with GPI at the time of primary PCI in selected patients (large thrombus burden or inadequate P2Y12 receptor antagonist loading) with STEMI who are receiving UFH.

ANTICOAGULATION THERAPY

Anticoagulant therapy is used in the acute setting of STEMI in preparation for primary PCI. It is also used in medically treated patients following fibrinolysis, or in those patients who are not otherwise eligible for reperfusion therapy. The choice of anticoagulation depends on the patient's risk of bleeding and the treatment strategy.

Unfractionated Heparin or Bivalirudin in Primary Percutaneous Coronary Intervention

UFH titrated to an appropriate activated clotting time (approximately 250 seconds) and bivalirudin are the most commonly used therapies for primary PCI. UFH can be used with or without planned GPI, whereas bivalirudin is typically administered with provisional use of GPI. Many studies have compared the use of bivalirudin with UFH in patients with STEMI. These studies consistently demonstrated a lower rate of major bleeding with bivalirudin and lower net adverse cardiac events but a higher risk of stent thrombosis. A meta-analysis of randomized trials comparing these two anticoagulants in patients undergoing primary PCI demonstrated a 19% reduction in all-cause mortality, a 32% reduction in cardiac mortality, and a 38% reduction in major bleeding with bivalirudin.[34] Bivalirudin, however, was associated with a 3-fold higher rate of stent thrombosis. Prolonged bivalirudin infusion post-PCI may help to mitigate this early risk of stent thrombosis in patients with STEMI; in those with higher risk for bleeding, bivalirudin is preferred.

Unfractionated Heparin, Enoxaparin, or Fondaparinux with Fibrinolytic Therapy

Patients undergoing fibrinolysis should receive anticoagulant therapy for a minimum of 48 hours, and preferably for the duration of the index hospitalization, or until revascularization is performed.[1] Based on age, weight, and renal function, either UFH, enoxaparin, or fondaparinux can be used. The Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Treatment (ExTRACT)- TIMI 25 study[35] demonstrated a 17% reduction in the rates of death or recurrent MI at 30 days with the use of enoxaparin as compared with UFH following fibrinolytic therapy, but a higher rate of major bleeding was observed. Despite the higher rates of major bleeding, net adverse events, including a composite of death, nonfatal recurrent MI, and nonfatal intracerebral

hemorrhage, was lower with enoxaparin. If anticoagulation therapy is extended beyond 48 hours, enoxaparin is preferred. In patients undergoing PCI post–fibrinolytic therapy, heparin is a reasonable alternative. Finally limited data have shown some benefit to fondaparinux for medically treated and fibrinolytic-treated patients with STEMI.[36] It should be noted, however, that if PCI is planned, fondaparinux should not be used as the sole anticoagulant to support the PCI because of the risk of catheter-related thrombosis.[36]

β-BLOCKERS

β-Blockers decrease the risk for ventricular arrhythmias, reduce remodeling, improve left ventricular hemodynamics, and may reduce infarct size.[37] Oral β-blockers should be initiated within the first 24 hours in all patients with STEMI, in the absence of any contraindication. Patients with initial contraindications to β-blockers should be reevaluated after 24 hours for β-blocker therapy. Intravenous β-blockers can be given at the time of presentation in patients who are hypertensive or have ongoing ischemia, but the routine use of IV β-Blockers has not been proven beneficial. β-Blockers are contraindicated in patients with signs of heart failure, evidence of a low output state, increased risk for cardiogenic shock, or other contraindications to use (PR interval >0.24 seconds, second- or third-degree heart block, active asthma, or reactive airways disease).

STATIN THERAPY

In stabilized patients, a fasting lipid panel should be obtained, and high-intensity statin therapy (atorvastatin or rosuvastatin) should be initiated or continued if there are no contraindications. Numerous studies have demonstrated that statins lower the risk of future cardiovascular events and the need for coronary revascularization in patients with ACS.[38] Statin therapy is beneficial even in patients with baseline low-density lipoprotein cholesterol levels <70 mg/dL.[39]

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS OR ANGIOTENSIN RECEPTOR BLOCKERS

In a meta-analysis of four RCTs and >98,000 patients in which angiotensin-converting enzyme (ACE) inhibitors were started within 36 hours of MI, compared with placebo, ACE inhibitors significantly reduced 30-day mortality and heart failure.[40] Although data have shown a benefit of ACE inhibitors in all

patients with STEMI, the benefits appear most pronounced in patients with large areas of myocardium involved or in patients with congestive heart failure. Therefore, ACE inhibitors should be administered within the first 24 hours to all patients with STEMI with anterior location, heart failure, or ejection fraction ≤40%, unless contraindicated. ACE inhibitors can also be given to otherwise stable and low-risk patients with STEMI as well. The major contraindications of ACE inhibitors/ARBs (angiotensin receptor blockers) are hypotension, worsening renal function, or drug allergy. ARBs are indicated for patients who are ACE inhibitor–intolerant.

ALDOSTERONE ANTAGONISTS

Spironolactone and eplerenone are aldosterone antagonists. The AHA/ACC guidelines recommend initiation of an aldosterone antagonist in patients with STEMI and no contraindications in those who are already receiving an ACE inhibitor and β-blocker and who have an ejection fraction ≤0.40 and either symptomatic congestive heart failure or diabetes mellitus.[1] This recommendation is supported by the results from the Eplerenone Post–Acute Myocardial Infarction Heart Failure Efficacy and Survival trial,[41] which studied the effect of eplerenone in addition to standard therapy in patients with acute MI and an ejection fraction ≤40% and signs of heart failure. Eplerenone resulted in a 15% reduction in total mortality and a 17% reduction in cardiovascular mortality mainly because of a reduction in sudden cardiac death. Aldosterone antagonists should not be given to patients with renal failure (creatinine ≥ 2.5 mg/dL in men and ≥2.0 mg/dL in women) and hyperkalemia (potassium ≥5.0 mEq/L).

ADDITIONAL MANAGEMENT

ECHOCARDIOGRAPHY

An echocardiogram is a simple tool to assess post-MI ejection fraction and can provide useful information regarding a patient's overall prognosis. All patients with STEMI should receive an echocardiogram before hospital discharge and ideally within the first 24 hours of presentation. Echocardiography can also aid in identifying stunned or jeopardized myocardium, evaluate ejection fraction following reperfusion, and can help detect mechanical complications of STEMI such as free wall rupture, acute ventricular septal defect, and mitral regurgitation (see section on Mechanical Complications). Finally, in patients with ST

elevation of uncertain etiology, echocardiography performed on initial presentation can help distinguish myocardial ischemia from common nonischemic causes of chest pain such as perimyocarditis, valvular heart disease, pulmonary embolism, or aortic dissection.

CORONARY ANGIOGRAPHY

Although the majority of patients with STEMI will be treated with primary PCI, a substantial minority of patients will present to hospitals without timely access to primary PCI and will therefore be treated with fibrinolytic therapy; these patients should be considered for coronary angiography at some point during the hospital course. In general, patients with severe heart failure or cardiogenic shock should be transferred for immediate coronary angiography following fibrinolytic therapy. It is also recommended that patients who do not demonstrate evidence for restoration of myocardial blood flow following fibrinolytic therapy be considered for immediate transfer for coronary angiography.

Over the last decade, numerous studies have supported a strategy of early coronary angiography (within 3 to 24 hours) following fibrinolytic therapy even in seemingly stable patients.[42, 43] The Trial of Routine Angioplasty and Stenting after Fibrinolysis to Enhance Reperfusion in Acute Myocardial Infarction (TRANSFER-AMI) study[42] was the largest of all such trials evaluating the benefit of routine early angiography following fibrinolytic therapy, and reported a 36% reduction in clinical events, including 30-day death, recurrent MI, worsening heart failure, or shock in the group of patients assigned to early catheterization. A meta-analysis of all such trials reported a 64% reduction in the rate of death or recurrent infarction at 30 days with early coronary angiography following fibrinolytic therapy, which was particularly pronounced among the trials enrolling high-risk patients.[43] As a result of these data, routine early coronary angiography (within 3 to 24 hours of fibrinolytic therapy) should be considered for all stable patients. For the remaining patients who may not have been referred for early angiography, the AHA/ACC guidelines give a class I recommendation for coronary angiography in cases of spontaneous or inducible ischemia.[1] In the absence of these findings, routine coronary angiography before hospital discharge (to define the anatomy) may still be considered.

STRESS TESTING

For those medically treated patients who do not undergo initial coronary

angiography, noninvasive stress testing should be performed. This allows the clinician to assess for residual ischemia post-MI (both in the infarct-related artery and to assess ischemia in areas remote from the infarct which might be indicative of multivessel disease). After the first 48 to 72 hours, pharmacologic stress testing may be performed and has been shown to be safe and effective. Alternatively, a submaximal exercise stress test might also be considered to help guide recommendations for postdischarge exercise plans but should be followed with a maximal stress test within 6 weeks once the patient is fully recovered.

PERCUTANEOUS CORONARY INTERVENTION OF THE NONCULPRIT ARTERY

In patients with STEMI, approximately 50% will have multivessel disease.[44] There are three options for the treatment of multivessel disease in STEMI. These include: (1) Treatment of the culprit artery only with ischemia-guided management of nonculprit arteries; (2) performing multivessel PCI at the time of primary PCI; or (3) treatment of the culprit artery only during the primary PCI followed by staged PCI of nonculprit arteries at a later date. Several randomized trials evaluating these strategies have reported benefits from PCI of the nonculprit artery (done either at the time of primary PCI or as a staged procedure).[45, 46] The Preventive Angioplasty in Acute Myocardial Infarction trial[45] randomized 465 patients to a strategy of multivessel PCI performed at the time of the primary PCI or usual care. This study demonstrated a 65% reduction in major cardiovascular events with multivessel PCI, including a composite of death from cardiac causes, nonfatal MI, and refractory angina. Although the study was not powered to show a reduction in the individual components of the composite end points, the benefits reported in this study were consistent across all of the individual components of the composite end point. In the Third Danish Study of Optimal Acute Treatment of Patients with ST-Segment Elevation Myocardial Infarction (DANAMI 3-PRIMULTI) trial,[46] the patients were randomized to a strategy of fractional flow reserve (FFR)–guided staged PCI or conservative care. In this study of 607 patients, FFR-guided staged PCI was associated with a 44% reduction in the composite of death, nonfatal MI, or ischemia-driven revascularization. This appeared to be entirely driven by a lower rate of ischemia-driven revascularization. It is important to note that all of the trials to date examining PCI strategies for patients with STEMI and multivessel disease have been small or moderate in size and none of the trials were powered

to evaluate the individual components of the composite end point. The Complete versus Culprit-only Revascularization to Treat Multi-vessel Disease After Primary PCI for STEMI (COMPLETE) trial[47] will randomize 3900 patients to a strategy of staged multivessel PCI or culprit artery only revascularization and should provide us with important information regarding staged PCI for patients with STEMI and multivessel disease. Until we have a larger data set of results, it is important to remember that the management of multivessel disease in STEMI should be individualized. Factors that might influence the decision to proceed with additional revascularization include patient-related factors (the presence of severe left ventricular dysfunction, recurrent angina, or arrhythmias might favor complete revascularization; on the other hand, older patients or patients with chronic kidney disease might benefit from a more conservative approach to care), coronary anatomy (patients with relatively discrete lesions with a low complexity might be appropriate for multivessel PCI performed at the time of primary PCI), and patient preferences.

COMPLICATIONS ARISING AFTER STEMI

BLEEDING

Bleeding after MI is associated with increased mortality, recurrent MI, longer hospital stay, and increased cost.[48] Major bleeding may occur in up to 5% to 10% of patients undergoing PCI; however, the incidence rates vary depending on patient population, antithrombotic combinations, and bleeding definition.[49] Various definitions and risk scores have been developed to assess the severity and prognosis of bleeding.[50] Access-site bleeding accounts for the majority of bleeding; however, gastrointestinal and intracerebral bleeding may occur (in particular in fibrinolytic-treated patients) and could be life-threatening. Bleeding risk increases with age and is particularly notable in patients with low body weight, female sex, femoral access, or those receiving fibrinolytic therapy or GPI. There is an exponential increase in the risk of bleeding when triple therapy is required during or after hospitalization. Every effort should be made to minimize bleeding complications. Bleeding risk can be mitigated with the use of bivalirudin anticoagulant therapy during PCI or through radial access PCI. In addition, when triple therapy is indicated, careful titration of the international normalized ratio with a narrower goal of 2.0 to 2.5 is recommended.

LEFT VENTRICULAR RUPTURE

Left ventricular rupture is a rare complication of acute MI occurring in 0.17% to 0.31% of cases.[51] Rupture develops after a large STEMI usually at the junction of infarcted and normal myocardium and is often lethal. Rupture typical occurs about 2 to 5 days following acute infarction but has been shown to occur as early as day 1 post-MI. Risk factors for rupture include delayed time to reperfusion, advanced age, and female sex. Rupture can occur at the free wall, resulting in immediate death, or present subacutely with signs of shock because of contained rupture and cardiac tamponade. Frank free wall rupture is often immediately fatal, whereas survival in a contained rupture will depend on the timing to the recognition of the rupture, hemodynamic stabilization and, most importantly, surgical repair. A telltale sign of a contained rupture is the sudden onset of hypotension or shock with clear lungs and elevated jugular venous pressure. Another form of left ventricular wall rupture includes ventricular septal rupture. Anterior infarctions are associated with rupture of the septum in an apical location, whereas ruptures associated with inferior infarctions usual involve the basal septum. In these cases, patients typically present with hemodynamic instability, heart failure, and development of a loud, holosystolic murmur. Echocardiography is instrumental in the diagnosis of any of these forms of rupture. Definitive management for all forms of rupture is surgical repair; however, the feasibility of surgical repair and timing of surgery are controversial and vary with clinical presentation.

ACUTE MITRAL REGURGITATION

Significant mitral regurgitation is noted in approximately 3% of cases of acute MI.[52] The etiology of acute mitral regurgitation includes ischemic papillary muscle displacement/rupture, left ventricular dilatation, or true aneurysm. Papillary muscle rupture, partial or complete, is a life-threatening complication. This usually occurs 2 to 7 days after the infarct. Clinical manifestation includes hypotension, pulmonary edema, and a mid- to late systolic murmur in the mitral area. Diagnosis is confirmed by echocardiography (with color flow Doppler). The management includes prompt diagnosis, afterload reduction with nitrates, diuretics, intra-aortic balloon pump, and emergent surgery. Nevertheless, mortality remains high.

LEFT VENTRICULAR ANEURYSM

True aneurysms consist of a discrete, dyskinetic area of thin left ventricular wall with a broad neck. Rupture of these aneurysms is uncommon. This should be differentiated from a *pseudoaneurysm,* which is a contained ventricular rupture (see above). Aneurysms are most often noted in patients who are not treated with reperfusion therapy or who have lack of evidence of tissue level reperfusion following fibrinolytic therapy or PCI (persistent ST-segment elevation noted on the ECG in the immediate hours and days after treatment). Diagnosis is made by noninvasive imaging modalities. Possible sequelae of left ventricular aneurysm include congestive heart failure, ventricular arrhythmias, and left ventricular thrombus. Because of the risk for mural thrombosis and systemic embolization, oral anticoagulation therapy should be considered in patients with aneurysms, especially in the first 3 months post-MI. Surgical aneurysmectomy is reserved for select cases of patients who are severely symptomatic.

LEFT VENTRICULAR THROMBUS

Although the incidence of left ventricular thrombus has decreased with the use of primary PCI and the use of potent antithrombotic therapies, it is not an uncommon complication after STEMI, occurring in 4% to 8% of cases and usually associated with anterior wall infarctions.[53] Systemic embolization is always a potential risk. High-risk features for embolization on echocardiography include increased mobility, protrusion into the ventricular chamber, and contiguous zones of akinesis and hyperkinesis. Cardiac MRI can also be helpful to aid in diagnosis. Treatment requires anticoagulation with warfarin for at least 3 to 6 months.

ATRIOVENTRICULAR BLOCK

Ischemic injury can produce a variety of conduction blocks. Complete atrioventricular block is more common in inferior than in anterior infarct. It is usually transient and improves with revascularization. Some patients may require temporary pacing, but permanent complete heart block associated with an inferior infarction is generally rare.

VENTRICULAR ARRHYTHMIAS

Ventricular tachycardia and ventricular fibrillation are the most dreaded complications. Nonsustained ventricular tachycardia in the first 24 hours postinfarct is generally benign and not associated with a worse prognosis.[54]

Correction of electrolyte abnormalities, including hypokalemia, hypomagnesemia, and institution of β-blockers serve as prophylaxis for occurrence of malignant arrhythmias. Occasionally, postinfarction arrhythmias can indicate reocclusion and may necessitate additional coronary angiography even in the absence of other signs or symptoms of reocclusion. Treatment of unstable ventricular tachycardia/ventricular fibrillation consists of electrical defibrillation, administration of antiarrhythmic agents such as amiodarone or lidocaine, and repeat coronary angiography if clinically warranted. Generally, the presence of sustained ventricular arrhythmias beyond 48 to 72 hours in the absence of evidence of reocclusion is associated with a poor prognosis, and consideration should be given to the placement of a cardiac defibrillator.

CARDIOGENIC SHOCK

Cardiogenic shock is the most common cause of death in patients with STEMI, occurring in 5% to 15% of all acute infarctions.[55] Cardiogenic shock can either be a manifestation of severe pump failure in the setting of a large infarct or a sequela of mechanical complications of MI. It is characterized by a constellation of findings reflecting systemic hypotension, low cardiac output, and evidence of vital organ hypoperfusion (eg clouded sensorium, cool extremities, oliguria, acidosis). The formal diagnostic criteria for cardiogenic shock will vary depending on the dataset examined, but, in general, cardiogenic shock requires refractory (not transient) hypotension in the absence of any other underlying causes with evidence of a low output state. **Table 2.3** outlines the diagnostic criteria for shock taken from the Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock (SHOCK) trial.[56] The diagnosis of shock can be confirmed through the use of right heart catheterization measurements; however, the clinical presentation and use of Doppler and 2D echocardiography provide similar information to right heart catheterization, and therefore right heart catheterization is not always indicated. Early revascularization with PCI or CABG is the recommended reperfusion strategy for patients with STEMI and shock, irrespective of the time delay.[56] For patients who are unsuitable candidates for PCI or CABG, fibrinolysis can be given if there are no contraindications. Inotropes and vasopressor agents can be used to maintain hemodynamic stability and organ perfusion. Norepinephrine, dopamine, or dobutamine are used for the initial pharmacologic management. However, in patients with elevated systemic vascular resistance, vasopressor agents and high-

dose inotropes may be counterproductive, and these patients should be evaluated for mechanical circulatory support devices.

TABLE 2.3 Criteria for Cardiogenic Shock

CLINICAL CRITERIA
Persistent hypotension (a systolic blood pressure of <90 mm Hg for at least 30 min or the need for supportive measures to maintain a systolic blood pressure of ≥90 mm Hg)
End-organ hypoperfusion Altered mental status Cool extremities Urine output of <30 mL/h Elevated serum lactate levels
Heart rate of ≥60 beats/min
HEMODYNAMIC CRITERIA
Cardiac index (<1.8 L/min/m^2 without support or <2.0 to 2.2 L/min/m^2 with support)
Adequate or elevated filling pressure (left ventricular end-diastolic pressure >18 mm Hg or right ventricular end-diastolic pressure >10 to 15 mm Hg or pulmonary capillary wedge pressure of ≥15 mm Hg)

Intra-aortic balloon pumps (IABP) can be used in patients with cardiogenic shock who do not stabilize with pharmacologic therapies. Although observational data support the use of IABP in patients with cardiogenic shock demonstrating improved outcomes,[57] the Intra-aortic Balloon Pump in Cardiogenic Shock II (IABP-SHOCK II) trial[58] failed to show any benefit from the use of IABP in patients with acute MI complicated by cardiogenic shock. The study examined patients presenting with acute MI and shock who were planned for early revascularization. The primary end point, 30-day all-cause mortality, was not significantly reduced with the use of IABP in shock. The study, however, did not address the optimal management of patients who develop shock later in the hospital course following revascularization. Fewer data are available to guide the use of IABP in cases of shock that develop after reperfusion, and most physicians would try to support these patients with mechanical circulatory support devices as a bridge to recovery, or as a bridge to additional revascularization and/or surgical repair of complications. Other temporary mechanical circulatory support devices such as Impella 2.5 or Impella CP, Tandem Heart, and percutaneous extracorporeal membrane oxygenator, may

be helpful in severe cases of shock, but randomized data are not available. There are advantages and limitations to each of the support devices, and the decision to initiate hemodynamic support should be individualized.

DISCHARGE PLANNING

TIMING OF DISCHARGE

The timing of discharge is highly variable and often influenced by the clinical and Socio-demographic variables of the patient. There are no recommendations as to what constitutes appropriate duration of hospitalization for patients with STEMI. In low-risk patients with single vessel disease, who undergo successful primary PCI and are free of early sustained ventricular tachyarrhythmias, hypotension, heart failure, or any bleeding episodes, discharge home at 48 hours is generally reasonable.

PATIENT EDUCATION AND COUNSELING

One of the critical aspects of discharge planning is education of patients and their families. The plan of care for the patients should include the following domains of care:

1. Review of medications, including the importance of adherence
2. Follow-up appointments and testing
3. Dietary counseling
4. Physical and sexual activities counseling
5. Smoking cessation (if applicable)
6. Secondary prevention
7. Cardiac rehabilitation

CARDIAC REHABILITATION

Cardiac rehab is a medically supervised exercise program that has been shown to improve the cardiovascular health of patients with acute MI. The goals of exercise-based cardiac rehabilitation after STEMI are to increase functional capacity, improve symptoms, decrease potential disability, improve the quality of life, help the patient to modify coronary risk factors and thereby reduce morbidity and mortality.[1, 59] Core components include a baseline and follow-up patient assessment, exercise counseling, nutritional counseling, smoking

cessation counseling, psychosocial counseling, and management of blood pressure, lipids, and diabetes mellitus with pharmacologic treatment, as appropriate.[59] In spite of the proven benefits of cardiac rehabilitation, it is underutilized because of several hospital-level factors and insurance issues.[60] Efforts must be concentrated on ensuring timely access to cardiac rehabilitation in patients with STEMI.

FUTURE DIRECTIONS

There remains a strong need to improve public awareness and educate the general population about symptoms of heart attacks and the importance of timely care, to improve the time from symptom onset to presentation for medical evaluation. Multicultural and multilingual efforts should be made, especially in those for whom English is not the first language. Research into newer therapies should continue. Research into treatments to minimize or reverse ventricular remodeling, and novel therapies involving stem cell or bone marrow precursor cells, stent technology, antiplatelets, and anticoagulants are ongoing.

Patient and Family Information for: ST-ELEVATION MYOCARDIAL INFARCTION

WHAT IS A STEMI?

ST-elevation myocardial infarction (STEMI) or “heart attack” is a life-threatening emergency condition that occurs when one of the arteries supplying blood to the heart muscle suddenly becomes completely blocked. This is more commonly referred to as a heart attack and is one of the leading causes of death in the United States. A STEMI heart attack is considered an emergency because within a very short period of time, a part of the heart muscle can become permanently damaged because of the absence of blood flow from the blocked artery; therefore, urgent medical attention and treatment is required. Studies have shown that the major delay in treatment of a patient with a STEMI is often related to the patient’s ability to recognize the symptoms and call for help. This is why all patients with chest pain or discomfort lasting more than 10 minutes are encouraged to call 911 for immediate evaluation.

WHAT CAUSES A STEMI?

Patients at risk for a heart attack often have mild or intermediate blockages caused by plaque buildup in the arteries of the heart (coronary arteries). Normally, these blockages do not cause any symptoms because the blood flow to the heart muscle is not usually compromised. However, if these plaques rupture (or crack), the blood in the artery is then exposed to the sticky material inside of the plaque, and this will lead to the formation of a large blood clot that will

completely block the flow of blood down the artery. Some conditions may increase a patient's risk of developing a heart attack. These are referred to as risk factors. It is important to understand that the presence of risk factors increases a patient's chance of developing a heart attack. However, even if a patient has a lot of risk factors, it does not mean that he or she will definitely have a heart attack. On the contrary, some patients without any risk factors may still have a heart attack. The major risk factors that have been identified to cause coronary artery disease and heart attacks include a family history of heart attacks or coronary artery disease, a history of diabetes, high blood pressure, or high cholesterol levels, smoking cigarettes or other types of tobacco products, being overweight, not being physically active, and male gender. Some of these conditions can be changed or controlled by living a healthier lifestyle and/or taking medications to control the condition.

HOW DO DOCTORS DIAGNOSE A STEMI?

The presentation of heart attacks can be variable, but most commonly patients experience profound chest discomfort or chest pain. Patients may describe this chest pain as a chest "squeezing," "tightness," or "heaviness," and sometimes a patient may have shortness of breath, cold sweats, and nausea. The chest pain is typically located in the center of the chest and often described as radiating to the left shoulder, arm, or jaw. The patient may instead have symptoms of upper belly pain, shoulder or back pain, or shortness of breath in the absence of chest pain. Older patients, female patients, and patients with diabetes are more likely to have these less typical symptoms. When an individual presents with these complaints, medical personnel use a chest pain protocol to allow a rapid evaluation in order to quickly confirm the patient's diagnosis so as to allow for immediate treatment.

The mainstay of diagnosis of a STEMI is the electrocardiogram (ECG). During an ECG, electrodes are attached to the outside of the chest wall with a sticky material, and these electrodes measure the electrical conduction through the heart. If the patient is having a "STEMI" the ECG will have a characteristic appearance, known as ST segment elevation. This characteristic appearance helps to distinguish a STEMI heart attack from other heart conditions or other non–heart-related conditions. It is essential to perform and interpret an ECG early after a patient presents for evaluation. Doctors may also order blood tests

called cardiac enzymes (cardiac troponin or creatinine kinase CPK-MB). These enzymes are normally contained within the heart cells; When the heart cells die during a heart attack, the heart cells are destroyed and the enzymes are released into the bloodstream. If the health care team strongly suspects, on the basis of symptoms and the abnormalities seen on ECG, that a patient is having a heart attack, then treatment will be given even before the results of the blood tests are reported.

There are two options doctors may use to reopen blocked arteries. The first treatment is the administration of fibrinolytic medications. These medications dissolve the blood clot in the artery of the heart. The second treatment is a procedure called an angioplasty or stent, commonly referred to as primary percutaneous coronary intervention (PCI). During primary PCI, a balloon and/or stents are used by a cardiologist to physically open up the blocked artery. Extensive research involving multiple studies have shown that primary PCI is the best treatment to restore blood flow for a patient with STEMI. However, not all hospitals have the ability to perform emergency primary PCI. If a patient lives in a region in which there are no nearby hospitals that can provide emergency angioplasty or stent, the doctor may first treat the patient with fibrinolytic medications and later transfer him or her to a hospital for possible angioplasty or stent. Regardless of the type of treatment a patient receives, the goal is to rapidly provide the therapy to open the blocked arteries: Fibrinolytic therapy should be administered within 30 minutes; Primary PCI should be performed within 90 minutes of presentation.

WHAT OTHER TREATMENTS DO PATIENTS WITH STEMI RECEIVE?

Once a patient is diagnosed with a STEMI, doctors will begin therapy with medications that thin the blood and decrease its stickiness. Blood thinners are referred to as anticoagulants. Agents that decrease the stickiness of the blood are referred to as antiplatelet agents. All patients with a STEMI will also be placed on a cardiac monitor, and their vitals signs (blood pressure, heart rate, and breathing rates) will be closely monitored. The next step for treating patients with STEMI is to open the blocked artery. As previously mentioned, if a patient is admitted to a hospital that offers emergency primary PCI, the blocked artery will be opened by inflating a balloon in the artery and placing a stent. If a patient

is admitted to a hospital that does not have the capability of performing emergency stenting, the patient will be transferred to another hospital that can perform primary PCI. If there are no nearby hospitals that have the capability of performing primary PCI, the patient might first receive fibrinolytic therapy and later be transferred to another hospital as needed. On most occasions, when an angioplasty is performed a stent is placed in the coronary artery to prevent reocclusion. The two types of stents that are used are bare-metal stents and drug-eluting stents. Drug-eluting or "coated" stents are less likely to narrow again compared with bare-metal stents, but they require a more prolonged duration of treatment with antiplatelet medications. In some cases, the best way to treat the blocked arteries is open-heart surgery. In addition to antiplatelets therapy, other medications may be given. These include angiotensin-converting enzyme inhibitors and beta-blockers. These medications decrease the work required by the heart, and they help the heart to recover and get stronger after a heart attack. Cholesterol lowering medications, called statins, are an important medication used to treat patients with a heart attack. They help to prevent the occurrence of another heart attack.

PREVENTION AND FOLLOW-UP

There are two types of heart attack prevention. Primary prevention is aimed at decreasing a patient's chance of having a "first" heart attack. The goal of secondary prevention is to prevent the occurrence of another heart attack (a "second heart attack"). In patients with STEMI, the focus is on secondary prevention so that the patient will be less likely to suffer from another heart attack. This requires rigorous efforts and attention to living a good lifestyle and taking medications on a regular basis. It is important that patients eat a heart-healthy diet. Heart-healthy diets are diets that are rich in fruits and vegetables and whole grains, and low in saturated fats, trans fats, sweetened drinks, and processed foods. If possible, patients should begin a regular exercise plan (with a doctor's guidance). Although individual recommendations may vary, the goal is to do at least 30 minutes of moderate-intensity exercise most days of the week. Weight loss, avoidance of excess alcohol, and cessation of smoking are also important components of a healthy lifestyle. It is critical that patients also adhere to taking all of their prescribed medications on a regular basis and discuss any concerns about their medications with their doctor before stopping a prescribed

medication. Patients should closely follow up with their cardiologist for regular monitoring to ensure compliance with lifestyle measures and medications so as to prevent the complications from the heart attack and lower the risk of recurrences. From a public health perspective, CPR could save the lives of patients who suffer heart attack and sudden death, and everyone should ideally be certified in CPR.

Non–ST-Elevation Acute Coronary Syndromes

NON–ST-ELEVATION MYOCARDIAL INFARCTION: DEFINITION AND CLINICAL SPECTRUM

The term non–ST-elevation myocardial infarction (NSTEMI) refers to acute coronary syndrome (ACS) in which myocardial ischemia results in tissue necrosis in the absence of ST-segment elevation on the electrocardiogram (ECG). By definition, NSTEMI is accompanied by elevated levels of cardiac biomarkers, signifying loss of myocardial tissue and differentiating NSTEMI from unstable angina. The clinical spectrum of NSTEMI ranges from mild ischemic insults with preserved left ventricular function to life-threatening ischemic events associated with global myocardial ischemia and hemodynamic compromise as well as cardiac arrest. Detailed practice guidelines have been published by the European Society of Cardiology in 2016,[1] the American Heart Association (AHA), and American Society of Cardiology (ACC) in 2014.[2] A comparison between the two documents has also been published.[3]

PATHOPHYSIOLOGY

Myocardial infarction typically results from formation of a coronary thrombus at the site of an existing atherosclerotic plaque.[4] The degree of coronary stenosis at the culprit site before the acute ischemic event is frequently mild or moderate. Coronary thrombosis is caused by disruption of the fibrous cap that forms a barrier between the blood and procoagulant constituents within the plaque. Postmortem studies as well as intravascular imaging studies indicate that most events are triggered by rupture of a thin-cap fibrous atheroma overlying a lipid-rich necrotic core. Superficial plaque erosions are responsible for most of the remainder of cases. In contrast to ST-elevation myocardial infarction (STEMI), the culprit coronary lesion in most NSTEMI cases is not totally occlusive. Embolization of particulate matter from the thrombus within the epicardial coronary artery to the distal microvasculature, as well as intermittent coronary occlusion, leads to myocardial necrosis in these cases. Rarely, NSTEMI is caused by total occlusion of a major coronary artery without associated elevation of the ST-segment in the ECG.

EPIDEMIOLOGY

Currently, NSTEMI outnumbers STEMI by a ratio of 3:1, with an estimated annual US incidence of around 500,000.[5] Patients with NSTEMI have more comorbidities than those with STEMI. In-hospital mortality is similar for patients with NSTEMI and STEMI (9.5% vs 9.7%); however, 1-year postdischarge mortality is higher in patients with NSTEMI (18.7% vs 11.4%).[6, 7]

DIAGNOSIS

HISTORY

Precordial chest pain is a frequent presenting symptom in patients with NSTEMI. Typical angina involves a sensation of retrosternal heaviness or pressure radiating to the left arm. Chest pain may be atypical, may radiate to any anatomic location between the umbilicus and the mandible, and in some cases may be absent. Alternatively, patients may complain of angina equivalents such as dyspnea, palpitations, and generalized weakness. Atypical presentation is more common in females, diabetics, patients with renal failure, and the elderly. Presence of risk factors for atherosclerosis such as diabetes mellitus,

hypertension, hyperlipidemia, renal failure, a family history of coronary disease, a history of smoking, advanced age, and a previous diagnosis of coronary or peripheral vascular disease are common in patients with NSTEMI. It is important to document current medications the patient is receiving (which may interact with medications to be administered) and to inquire about use of illicit drugs such as cocaine, which may trigger myocardial ischemia. In a patient with ACS, it is crucial to rule out a history of bleeding before initiating antithrombotic and anticoagulant therapy. Allergy to intravascular contrast media should be ruled out and renal function assessed before referring the patient for cardiac catheterization.

PHYSICAL EXAMINATION

Examination may be normal in patients with NSTEMI. It is important to detect signs of hemodynamic compromise if present (reduced blood pressure, accelerated heart rate, signs of peripheral hypoperfusion, jugular venous distention, pulmonary congestion) because these patients may benefit from intensive care and an early invasive strategy. A hypertensive crisis may trigger myocardial ischemia and should be diagnosed and treated rapidly. A systolic murmur may signify a mechanical complication such as acute ischemic mitral regurgitation. A detailed physical examination is crucial for detecting findings, which may point to an alternative diagnosis such as pericarditis (friction rub and pulsus paradoxus), aortic stenosis (systolic murmur), aortic dissection (differences in blood pressure between limbs), musculoskeletal disorders (sensitivity to palpation of the chest wall), and so on. Irregular heart rhythm may also be present in NSTEMI with premature beats and atrial fibrillation. Rapid rate may play a role in the pathophysiology of NSTEMI and should be documented and referred to in the therapeutic strategy.

ELECTROCARDIOGRAM

The ECG may show a variety of anomalies such as ST-segment depression, transient ST-segment elevation, T wave inversion, as well as tachyarrhythmias and bradyarrhythmias. In more than 30% of patients, the ECG is normal. It is important not to misdiagnose a true posterior-wall STEMI (ST-depression and tall R waves in leads V1–V3) and new-onset left bundle branch block (LBBB), which warrant emergency coronary reperfusion.

CARDIAC BIOMARKERS

Measurement of cardiac troponin (cTn) serum levels using regular assays or high-sensitivity assays (hs-cTn) is an effective quantitative method for identifying myocardial necrosis in patients suspected of having NSTEMI. Many hospitals still use regular troponin assays. cTn is a more sensitive and specific marker for myocardial injury than creatine kinase and its muscle–brain isoenzyme. Whereas elevations up to 3-fold the upper reference limit are a nonspecific finding with limited positive predictive value for diagnosis of acute myocardial infarction (MI), elevations beyond 5-fold the upper reference limit have high (>90%) positive predictive value. High-sensitivity troponin assays detect myocardial necrosis within 1 hour of onset of symptoms and typically remain elevated for several days. A variety of conditions other than MI may be accompanied by troponin elevations including critical illness (e.g. burns), nonischemic cardiac injury (e.g. myocarditis, infiltrative disease), aortic dissection, pulmonary embolism, and renal failure. Renal failure can modify the pathognomonic levels of troponin, but dynamic changes in troponin are indicative of myocardial necrosis.

ANCILLARY TESTING

A variety of functional and anatomic imaging modalities may be used to noninvasively detect and quantify myocardial ischemia, to assess prognosis, and to identify high-risk patients. Chest X-ray may demonstrate noncardiac causes of chest discomfort such as pneumonia, pneumothorax, and rib fracture and should be performed in all patients in whom the diagnosis of an ACS is deemed unlikely. Echocardiography assesses left ventricular ejection fraction, reveals regional wall motion abnormalities suggestive of acute or chronic coronary disease, and is crucial for assessment of patients who are hemodynamically unstable. Echocardiography may assist in diagnosing alternative causes of chest pain such as aortic stenosis, pericarditis (pericardial effusion), pulmonary embolism (pulmonary hypertension and right ventricular dilatation), Takotsubo cardiomyopathy, and aortic dissection. Stress echocardiography (during exercise or administration of dipyridamole or dobutamine) may diagnose and quantify degree of myocardial ischemia and offers superior prognostic information compared with a regular exercise test. Contrast echocardiography may be used to assess myocardial perfusion. Cardiac magnetic resonance may be used to assess myocardial perfusion and wall motion and to diagnose myocardial scar

formation (late gadolinium hyperenhancement). Nuclear myocardial perfusion imaging detects myocardial ischemia and may be used to assess myocardial viability and ejection fraction. Multidetector computed tomography enables noninvasive detection of coronary disease; however, efficacy may be limited in patients with severe coronary calcification, prior stent implantation, and irregular and fast heart rhythms.

DIFFERENTIAL DIAGNOSIS

A majority of patients presenting to the emergency department with chest pain have a noncardiac etiology for their complaints. The differential diagnosis of NSTEMI in individuals presenting with chest pain includes STEMI (diagnostic ECG); unstable angina (lack of biomarker elevation); thoracic emergencies such as acute aortic syndromes (e.g. aortic dissection) and pulmonary embolism; infectious or inflammatory conditions such as pneumonia, myocarditis, and pericarditis; gastrointestinal disorders; and musculoskeletal disorders of the chest wall. A detailed history and physical examination are crucial for diagnosing these conditions and should be complemented by judicious use of imaging studies.

DIAGNOSTIC ALGORITHM

In patients presenting with chest pain who are suspected of having an ACS, a key priority is to identify those with indications for emergency coronary reperfusion (eg, STEMI, new-onset LBBB, ongoing ischemia, hemodynamic instability) (**Figure 3.1**). Life-threatening conditions that can mimic NSTEMI such as acute aortic syndromes and pulmonary embolism should be rapidly excluded on the basis of the history, examination, and appropriate imaging studies (e.g. “triple rule out” CT angiography). The remainder should undergo a diagnostic protocol, which is designed to rapidly rule-in or rule-out myocardial ischemia as the underlying cause of their symptoms. cTn assays, preferably hs-cTn assays, are crucial for rapid triage of these patients because serum levels increase rapidly in patients with myocardial damage. A dynamic rise in serum cTn levels above the 99th percentile in patients with a compatible clinical presentation is diagnostic of MI. A typical 0 h/3 h algorithm in patients suspected to have sustained an NSTEMI is based on testing of hs-cTn serum levels on admission to the emergency department. Levels below the upper limit of normal in patients in whom chest pain began more than 6 hours previously

effectively rules out the diagnosis. Repeat testing of hs-cTn levels is performed 3 hours later in those who developed chest pain less than 6 hours before presentation, when initial levels were not elevated. Patients in whom hs-cTn levels are not elevated may be discharged or referred for further noninvasive evaluation. In those with elevated hs-cTn levels on admission, a dynamic rise in levels is required to confirm the diagnosis of NSTEMI. Patients with a diagnosis of NSTEMI are referred for invasive management unless contraindicated. An alternative 0 h/1 h algorithm may be used; however, it is less well validated.

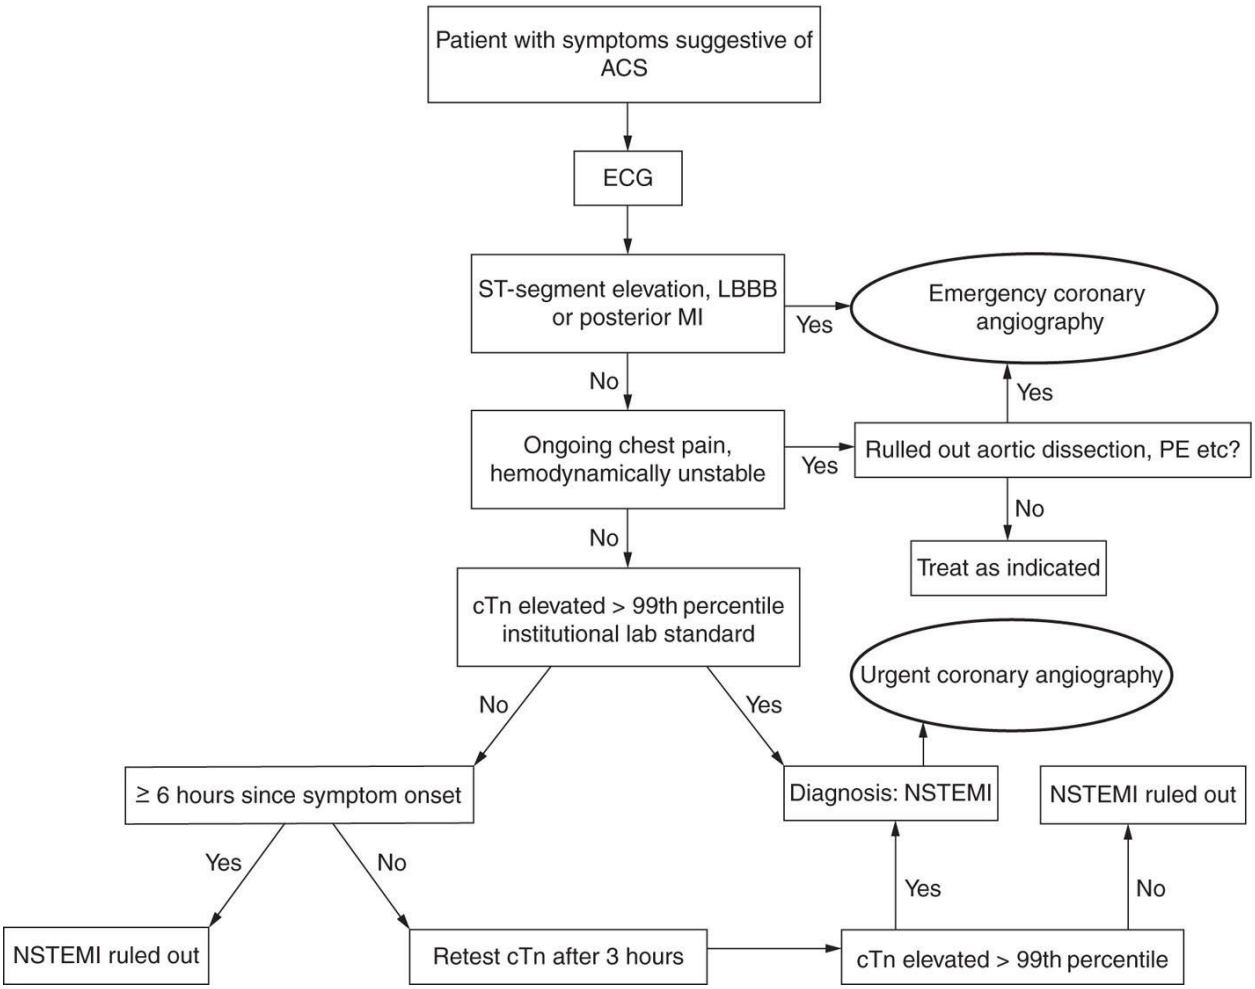

FIGURE 3.1 Diagnostic algorithm in patients with suspected NSTEMI. ACS, acute coronary syndrome; cTn, cardiac troponin; ECG, electrocardiogram; LBBB, left bundle branch block; MI, myocardial infarction; NSTEMI, non–ST-elevation myocardial infarction; PE, pulmonary embolism.

RISK STRATIFICATION

Early triage of patients with NSTEMI is crucial in order to identify individuals who are at high risk for development of further myocardial damage. Ongoing chest pain, dynamic ST-changes on the ECG, and hemodynamic instability suggest need for emergency revascularization. Assessment of the risk for life-threatening cardiac arrhythmias is crucial for selecting the appropriate hospital environment and degree of monitoring required for these patients. Predictors of serious arrhythmias include hemodynamic instability, documented major arrhythmias, ejection fraction ≤40%, untreated significant coronary lesions on angiography, and complications related to coronary intervention. Patients with

NSTEMI and risk factors for serious arrhythmias should be kept in cardiac care unit.

Several scores provide quantitative assessment of ischemic risk and prognostication up to 3 years. The thrombolysis in myocardial infarction (TIMI) risk score (online calculator: http://www.timi.org/index.php?page=calculators) uses seven metrics to assess prognosis. The variables included in the risk score are: age ≥65 years, presence of ≥3 risk factors for coronary disease, known coronary disease, recent aspirin use (within the past week), severe angina (≥2 episodes within the past 24 hours), ST deviation ≥0.5 mm on the ECG, and elevated cardiac biomarkers. The Global Registry of Acute Coronary Events (GRACE) 2.0 risk score (online calculator: http://www.gracescore.org/WebSite/default.aspx?ReturnUrl=%2f) has been shown to provide superior prognostication compared with the TIMI risk score. Variables included in the GRACE 2.0 risk score are: age, blood pressure, heart rate, renal function, cardiac arrest, Killip class, elevated cardiac biomarkers, and ST-segment deviation.

Assessment of risk for bleeding is crucial before administration of anticoagulant and antiplatelet drugs. Current risk scores are relevant mainly for predicting bleeding in patients with NSTEMI undergoing coronary angiography; however, their relevance to patients selected for noninvasive treatment or those receiving oral anticoagulants is unclear. The ***C***an ***R***apid risk stratification of ***U***nstable angina patients ***S***uppress ***AD***verse outcomes with ***E***arly implementation of the ACC/AHA guidelines (CRUSADE) bleeding risk score (online calculator: http://www.crusadebleedingscore.org) uses the following variables: female sex, diabetes, peripheral vascular or cerebrovascular disease, heart rate, blood pressure, heart failure, hematocrit, and creatinine clearance. The Acute Catheterization and Urgent Intervention Triage strategy (ACUITY) bleeding risk score takes into account the following variables: female sex, advanced age, elevated serum creatinine, white blood cell count, anemia, and presentation as NSTEMI or STEMI. These scores may require updating in view of recent changes in clinical practice, which include increasing use of transradial vascular access, diminishing popularity of glycoprotein IIb/IIIa inhibitors, substitution of clopidogrel for more potent oral antiplatelet drugs, and shift in anticoagulant regimens from heparin to bivalirudin.

MEDICAL TREATMENT

ANTI-ISCHEMIC AGENTS

The objective of medical therapy is to correct the imbalance between myocardial supply and demand and to reduce thrombus-related events (**Figure 3.2**). Some of the research relating to pharmacologic treatment of NSTEMI dates back to the era before the advent of current antiplatelet and anticoagulant medications and preceded modern invasive treatment strategies.

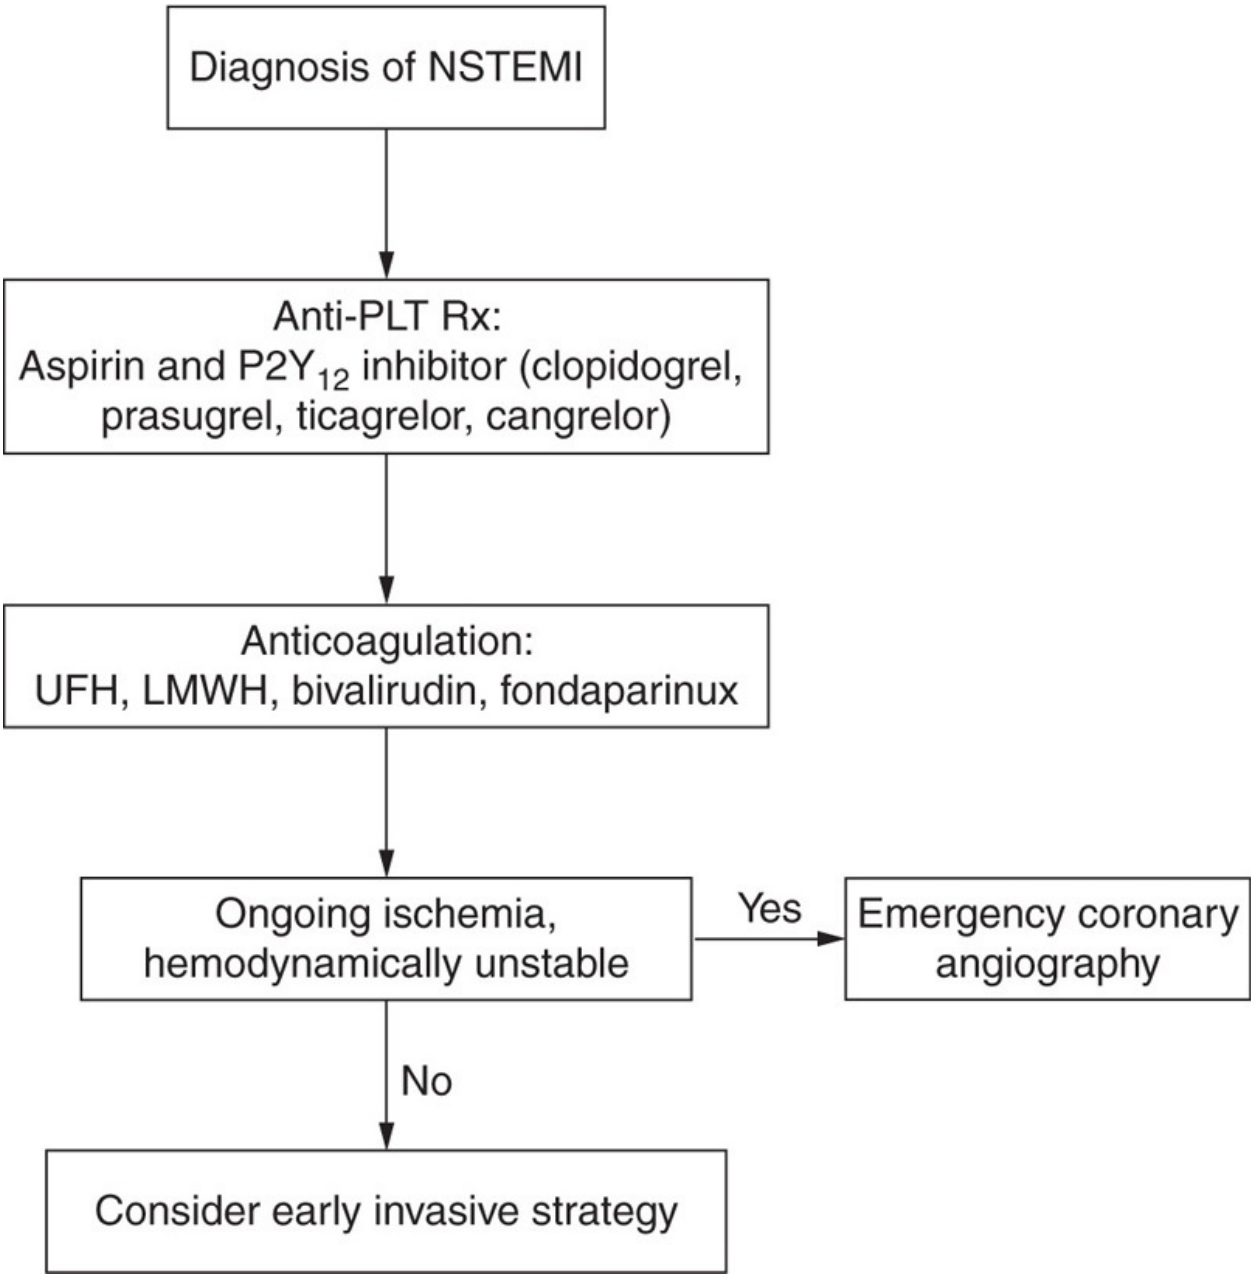

FIGURE 3.2 Treatment algorithm in patients with diagnosis of NSTEMI. Anti-PLT Rx, antiplatelet therapy; LMWH, low-molecular-weight heparin; NSTEMI, non–ST-elevation myocardial infarction; UFH,

unfractionated heparin.

General Measures

Bed rest minimizes physical activity, reduces myocardial oxygen demand, and enables effective patient monitoring. Oxygen should not be administered universally, but only to hypoxic patients with arterial oxygen saturation <90%. Opiates reduce chest pain and anxiety and therefore myocardial oxygen demand; however, they may reduce intestinal absorption of oral antiplatelet medications and may lower blood pressure in hypotensive patients—especially in those given concomitant nitrates. Nitrates may lower blood pressure in hypertensive patients and facilitate regression of ST-segment depression on the ECG. Their role is symptom relief with no proven impact on patient outcome. Nitrates should be given cautiously to hemodynamically unstable patients and are contraindicated in patients who have received phosphodiesterase type 5 inhibitors (sildenafil, tadalafil) within the past 24 to 48 hours.

β-Adrenergic-Blocking Agents

β-Blockers reduce myocardial oxygen demand (reduced contractility, heart rate, and blood pressure). Early studies found a mortality benefit for administration of β-blockers; however, they should be given cautiously to hypotensive and bradycardic patients because they may increase the incidence of cardiogenic shock. β-Blockers may worsen coronary spasm in patients who have used cocaine.

ANTIPLATELET THERAPY

Combined antiplatelet therapy with aspirin and an inhibitor of the $P2Y_{12}$ receptor decreases the occurrence of recurrent ischemic event and improves clinical outcomes in patients with NSTEMI compared with aspirin monotherapy. Dual therapy also increases the risk of bleeding, especially if ticagrelor or prasugrel is substituted for clopidogrel. This bleeding risk is especially relevant to the estimated 10% of NSTEMI patients who are referred for coronary artery bypass surgery (CABG). Prasugrel administration should be withheld until coronary angiography has been performed and need for CABG has been excluded.

Aspirin

Aspirin suppresses platelet thromboxane A_2 production by irreversibly inactivating cyclooxygenase-1. Pivotal trials of aspirin in ACS, performed before the recognition of the importance of an early invasive strategy, found a reduction in occurrence of MI and death. High-dose (300 to 325 mg/d) and low-dose (75 to 100 mg/d) aspirin are equally effective and should be given following a loading dose of 150 to 300 mg of a nonenteric-coated formulation.

$P2Y_{12}$ Receptor Blockers

Clopidogrel

Clopidogrel irreversibly inactivates platelet $P2Y_{12}$ receptors and inhibits adenosine diphosphate (ADP)-induced platelet aggregation. Clopidogrel is a pro-drug that undergoes hepatic metabolism via the cytochrome p450 to release an active metabolite. In patients with ACS, combined treatment of aspirin and clopidogrel decreases ischemic events. Some patients have inadequate response to clopidogrel and may be at risk for increased ischemic events and stent thrombosis. Individual responsiveness to clopidogrel may be related to gene polymorphisms; however, the role of screening for platelet responsiveness to clopidogrel in clinical practice is unclear. The loading dose of clopidogrel is 300 to 600 mg and maintenance dose is 75 mg/d. In the Clopidogrel and Aspirin Optimal Dose Usage to Reduce Recurrent Events−Seventh Organization to Assess Strategies in Ischemic Syndromes (CURRENT-OASIS7) study, doubling the maintenance dose during the first week reduced the risk of ischemic events.[8]

Prasugrel

Prasugrel irreversibly inactivates platelet $P2Y_{12}$ receptors and inhibits ADP-induced platelet aggregation with faster onset and greater inhibitory effect than clopidogrel. In the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-TIMI (TRITON-TIMI 38) study, prasugrel reduced the risk of MI and stent thrombosis compared with clopidogrel but increased the risk of bleeding.[9] Prasugrel is contraindicated in patients with known cerebrovascular disease, elderly patients (>75 years old) and those with low body weight (<60 kg). Loading dose is 60 mg and the maintenance dose is 10 mg/d.

Ticagrelor

Ticagrelor reversibly inhibits platelet $P2Y_{12}$ receptors with onset of action and efficacy similar to prasugrel. The half-life of 6 to 12 hours mandates that ticagrelor is taken twice daily. In the Platelet Inhibition and Patient Outcomes (PLATO) study, ticagrelor decreased death, MI, and stroke as well as stent thrombosis compared with clopidogrel but increased the risk of nonfatal bleeding.[10] Side effects include dyspnea. Loading dose is 180 mg, and maintenance does is 90 mg twice daily.

Cangrelor

Cangrelor is administered intravenously and induces short-term (1 to 2 hours) inhibition of platelet $P2Y_{12}$ receptors. Cangrelor reduces thrombotic events and stent thrombosis compared with clopidogrel but increases the risk of bleeding.[11]

Glycoprotein IIb/IIIa Receptor Inhibitors

Glycoprotein IIb/IIIa receptor inhibitors effectively prevent platelet aggregation; however, their use is associated with an increased risk of bleeding. Studies performed before the era of oral $P2Y_{12}$ antagonists suggested a clinical benefit; however, the safety of administering these drugs concomitantly with ticagrelor and prasurel is unknown. Currently, administration of these agents is recommended only in the setting of thrombotic complications of PCI.

ANTICOAGULATION

Anticoagulants target thrombin generation and fibrin formation and act in synergy with antiplatelet agents. A challenge in treating these patients is to achieve the optimal balance between the need to safely and effectively prevent thrombus-related events and the desire to reduce bleeding complications.

Unfractionated Heparin

Unfractionated heparin (UFH) is composed of an assortment of molecules of variable size that generate a conformational change in antithrombin and inactivate factors II (thrombin) and X. UFH is administered intravenously, the dose–response of UFH is unpredictable, the therapeutic window narrow, and the treatment predisposes patients to development of heparin-induced thrombocytopenia (HIT). Anticoagulation can be reversed by administration of protamine sulfate, and the degree of anticoagulation can be assessed by

measuring the activated Partial Thromboplastin Time (aPTT).

Low-Molecular-Weight Heparin

Low-molecular-weight heparin (LMWH) is administered subcutaneously and achieves more predictable anticoagulant effect compared with UFH. Protamine achieves partial reversal of LMWH-induced anticoagulation. LMWH causes HIT less often than UFH, and the LMWH dose should be reduced in patients with renal failure.

Fondaparinux

Fondaparinux is a reversible selective inhibitor of factor X. Fondaparinux is administered subcutaneously and does not induce HIT. Fondaparinux lowers rates of bleeding and mortality compared with LMWH without increasing ischemic events; however, UFH should be added during PCI to avoid catheter thrombosis.[12, 13]

Bivalirudin

Bivalirudin is an intravenously administered direct thrombin inhibitor. Bivalirudin with bailout administration of glycoprotein IIb/IIIa inhibitors achieves an anti-ischemic effect comparable to UFH or LMWH with routine co-administration of glycoprotein IIb/IIIa inhibitors, but with reduced bleeding complications.

INITIAL CONSERVATIVE VERSUS INITIAL INVASIVE APPROACH

Routine coronary angiography in patients with NSTEMI enables rapid confirmation of the diagnosis of ACS by identification of the culprit lesion in an epicardial coronary artery, risk assessment based on the coronary anatomy and performance of early coronary revascularization. Randomized trials have shown that an invasive strategy achieved superior clinical outcomes (reduced mortality and rehospitalization) compared with a strategy of selective angiography based on positive findings in noninvasive tests.[14, 15] Selection of patients for an early invasive strategy should be individualized and should take into consideration the presence of comorbidities, cognitive impairment, renal failure, frailty, etc. An

early invasive strategy (angiography with 12 to 48 hours of hospital admission) reduced the risk of adverse cardiac events compared with a delayed invasive strategy, especially in high-risk patients (GRACE risk score > 140).[16] Coronary angiography and intervention via transradial vascular access decreases mortality and vascular complications compared with transfemoral access[17] and complete revascularization is associated with superior clinical outcomes compared with culprit-only revascularization.[18] Revascularization should be performed after demonstration of a hemodynamically significant flow-limiting coronary stenosis. Stenting is generally performed in discrete coronary lesions, whereas patients with diffuse coronary disease (SYNTAX score > 23 to 33) should be considered for CABG.

DISCHARGE PLANNING

Secondary prevention of coronary events is crucial in patients being discharged after hospitalization for NSTEMI. Patients should be educated about the importance of modifying their risk profile and instructed regarding the importance of a healthy lifestyle, smoking cessation, weight reduction, routine aerobic exercise, optimal blood pressure control, and consumption of a Mediterranean diet low in saturated fats and rich in vegetable products. Enrollment in a cardiac rehabilitation program may enhance patient compliance, reduce cardiac mortality and hospital admissions, and improve quality of life.[19]

STATINS

High-intensity statin therapy is recommended to reduce low-density lipoprotein (LDL)-cholesterol levels to below 70 mg/dL or as low as possible, depending on the specific hospital's protocol. Ezetimibe treatment may be considered in patients who are intolerant to high-dose statins and those who fail to reach the desired LDL levels.

BETA BLOCKERS AND ACE INHIBITORS

Beta Blockers and ACE Inhibitors are indicated in patients with a reduced left ventricular ejection fraction (<40%); however, their efficacy in patients with preserved left ventricular ejection fraction in the current era of routine coronary revascularization is unproven.

ANTIPLATELET THERAPY

Dual antiplatelet therapy (DAPT) with aspirin and a $P2Y_{12}$ inhibitor is mandatory after coronary stenting and also in patients who did not undergo coronary revascularization. Tailoring the duration of DAPT involves a tradeoff between reductions in stent thrombosis and MI and increases in major hemorrhage.[20] DAPT should be continued for at least 1 year, and continuation of DAPT beyond that time frame has been suggested to reduce ischemic events[21]; however, duration of DAPT should be individualized according to the estimated patient's risk of future ischemic events as well as bleeding risk.[22]

Patient and Family Information for: NON–ST-ELEVATION ACUTE CORONARY SYNDROMES

WHAT IS CORONARY ARTERY DISEASE, AND WHAT IS A HEART ATTACK?

Coronary disease results from blockages in the arteries that supply oxygenated blood to the heart muscle. Coronary disease results from atherosclerosis, which is a process in which cholesterol accumulates in cells within the vessel wall. Atherosclerosis is very common in the general population and is linked to several risk factors such as smoking, obesity, high blood pressure, diabetes, and a family history of coronary disease. A heart attack results from sudden development of a blood clot on top of an atherosclerotic plaque, which occludes the coronary artery and prevents blood flow to the heart muscle. Because the pumping heart needs a constant blood supply, occlusion of a coronary artery may cause irreversible damage and replacement of the normal muscle cells with scar tissue. The typical symptom during a heart attack is crushing chest pain radiating to the left arm; however, the presenting symptoms of a heart attack may be atypical, and many other diseases may be associated with symptoms that mimic a heart attack.

HOW IS A HEART ATTACK DIAGNOSED?

Diagnosis of a heart attack is based on assessment of the patient’s complaints, physical examination, the ECG, and various blood tests and ancillary tests.

ELECTROCARDIOGRAM

The ECG in a patient with a heart attack may show a finding called ST-elevation, which usually signifies complete blockage of a coronary artery. Heart attack patients with ST-elevation on the ECG are usually referred for emergency coronary catheterization in order to open the blocked artery immediately and prevent further damage to the heart muscle. More often, the ECG in patients with a heart attack does not show ST-elevation. These patients usually do not require emergency catheterization, but are typically referred for catheterization within 1 to 2 days in order to evaluate the patency of the coronary arteries and select the best treatment approach.

BLOOD TESTS

Even minimal damage to the heart muscle may lead to secretion of a protein called troponin into the blood stream. Measurement of blood troponin levels enables accurate diagnosis of a heart attack.

ADDITIONAL TESTS

- Echocardiography uses ultrasound to evaluate the structure and functioning of the heart. This noninvasive test is very useful for detecting damage to the heart muscle following a heart attack.
- Exercise testing: During physical exercise, the workload on the heart increases in order to supply larger volumes of oxygenated blood to the skeletal muscles. This increased cardiac workload means that the heart muscle itself requires increased blood supply through the coronary arteries. Obstruction to blood flow in the coronaries during exercise may cause an imbalance between oxygen supply and demand in the heart muscle, which is called myocardial ischemia. ECG changes during exercise may reflect ischemia and signify that catheterization should be performed in order to accurately analyze the anatomy of the coronary arteries.
- Myocardial perfusion scans measure the uptake of radioactive substances in the heart muscle at rest and during exercise to detect ischemia.
- Cardiac CT is a noninvasive test that enables accurate mapping of the coronary anatomy and detection of blockages within these arteries.

TREATMENT

MEDICATIONS

Various medications have proven benefit in patients with coronary artery disease. Aspirin is a blood thinner, which is used to prevent development of blood clots within the coronaries. In patients with a heart attack, an additional oral blood thinner is usually given to enhance the effect of aspirin. Three commonly used blood thinners are clopidogrel (Plavix), prasugrel (Effient), and ticagrelor (Brilinta). Statins are cholesterol-lowering drugs that may prevent heart attacks and death in patients with coronary disease. β-Blockers are drugs that lower the heart rate and blood pressure and therefore decrease the workload on the heart. Nitrates are drugs that improve blood supply to the heart muscle in patients with coronary disease.

CARDIAC CATHETERIZATION

During catheterization, a thin tube (catheter) is inserted via an artery in the groin or in the wrist to the heart. The procedure is performed in a special room, which is called a catheterization laboratory where X-ray is used to study the heart and coronary arteries. Injection of a fluid called contrast media enables accurate mapping of the course and patency of the coronary arteries and detection of blockages within them.

CORONARY ANGIOPLASTY

Angioplasty is a technique that enables opening of blockages within the coronary arteries through a catheter. A small balloon is used to open the blockages. A stent is a metallic cylinder that is placed within the blockage to keep it open. Modern stents (drug-eluting stents) have special drugs attached to them that prevent renarrowing of the arteries.

CORONARY BYPASS SURGERY

Bypass surgery is open-heart surgery in which alternative blood vessels (bypass grafts) are connected to the diseased coronary arteries beyond the point at which they are blocked. This is done in order to renew blood supply to the heart muscle. Bypass surgery is usually performed in patients with multiple blockages in the coronary arteries who are not considered good candidates for angioplasty, especially in diabetics.

RECOVERY

- Diet: Patients with coronary disease should use a “Mediterranean” diet with a high consumption of vegetables and fruit and low in saturated fats and red meat. Patients should lower their calorie consumption in order to achieve an ideal body weight.
- Exercise: Aerobic exercise has proven benefit in preventing future heart attacks, lowering blood pressure, and achieving weight loss. A typical exercise regimen entails walking an hour a day at a speed of 3 mph.
- Smoking: Continued smoking after a heart attack significantly increases the risk of repeated heart attacks, stroke, and death. Smoking cessation is crucial in patients with coronary disease and may be assisted by special counseling.
- Medications: Patients with coronary disease require life-long aspirin to prevent future heart attacks and statins to lower the blood cholesterol. Patients who have received coronary stents require an additional blood thinner (clopidogrel, prasugrel, ticagrelor) for a period ranging between several months and 1 year. Some patients require additional medications to control high blood pressure and diabetes, to treat heart failure or rhythm disturbances, and to reduce chest pain (angina).

Echocardiography in Acute Coronary Syndrome

INTRODUCTION

The past few decades have witnessed remarkable progress in the understanding of the pathophysiology of acute coronary syndrome (ACS). This, in turn, has led to advances in various imaging techniques for diagnosis and therapeutic options. Developments in the field of echocardiography have paralleled the progress made in ACS. The initial use of echocardiography was to detect pericardial effusions and cardiac tumors. However, the current applications of various forms of echocardiography include an extended list of pathologic and therapeutic indications. Advances in echocardiographic techniques and instrumentation have rivaled those in management of ACS.[1] This chapter is focused on the role of echocardiography in ACS.

ASSESSMENT OF REGIONAL SYSTOLIC FUNCTION IN ACUTE CORONARY SYNDROME

Occlusion of an epicardial coronary artery at the time of ACS may lead to a loss of contractile function in the myocardial segments subtended by that vessel. The magnitude and duration of wall motion abnormalities depend on the severity,

extent, and duration of the coronary occlusion.

In unstable angina, left and right ventricular wall motion may be normal unless transthoracic echocardiography happens to be performed during an episode of chest pain.

Non–ST-elevation myocardial infarction (NSTEMI) usually results from an occlusion of a coronary branch vessel often in an elderly patient with pre-existing collateral coronary circulation. Typically, the loss of contractile function is restricted to the subendocardial layer, which is most vulnerable to ischemia. However, on standard echocardiography, the contractility loss may be observed in the entire thickness of the affected myocardial segment. This overestimation of contractile loss is attributed to tethering (an apparent passive loss of contractility in normal segments because of contractile loss in an adjacent area).

ST-elevation myocardial infarction (STEMI) often results from an acute occlusion of a major coronary vessel and tends to occur in a younger age group compared with NSTEMI. If the total session of coronary flow lasts for more than 3 to 6 hours, myocardial necrosis will occur and the myocardium in the affected segments will be replaced with a fibrous tissue over the ensuing weeks.[2]

The magnitude of regional contractile loss in ACS is usually assessed semiquantitatively. It is usually interpreted clinically as follows[2]:

1. Interpretation of wall motion abnormalities:
   Normal: Contractility preserved
   Hypokinesis: Partial loss of contractility
   Akinesis: Complete loss of contractility
   Dyskinesis: Paradoxical movement of the affected segment away from the center of the ventricle during systole
   Aneurysmal: Outward movement of the affected segment during both systole and diastole
2. Extent and location of affected segments
3. Suspected coronary artery distribution (left anterior descending artery [LAD] vs right coronary artery vs left circumflex artery).

ASSESSMENT OF GLOBAL SYSTOLIC FUNCTION IN ACUTE CORONARY SYNDROME

Global ventricular systolic function in ACS is assessed through both wall motion scoring and global ventricular ejection fraction (EF).

Wall Motion Scoring

Wall motion scoring analysis assigns a numeric value to the degree of contractile dysfunction in each segment. The most common scoring criteria are seen in **Table 4.1**.[3]

TABLE 4.1 Left Ventricular Wall Motion Scoring

	Score
Normal or hyperkinetic	1
Hypokinetic (reduced thickening)	2
Akinetic (absent or negligible thickening)	3
Dyskinetic (systolic thinning or stretching, aneurysmal)	4

Wall Motion Score Index = Sum of Individual Segment Scores/Number of Evaluated Segments.

Once all segments are assigned individual scores, a total score is calculated as a sum of individual scores. A Wall Motion Score Index (WMSI) is then calculated as a ratio between the total score over the number of evaluated segments. The WMSI is a dimensionless index.

A 17-segment model is commonly used to allow for standardized communication within echocardiography and with other imaging modalities. In this 17-segment model, the apex is divided into five segments (septal, anterior, inferior, lateral, and an "apical cap" defined as the myocardium beyond the end of the left ventricular [LV] cavity).[3] For a fully visualized normal ventricle, the total score is 17 (all segments have normal contractility). Because all 17 segments are evaluated, the WMSI of a normal heart is 17/17 = 1. For abnormal ventricles, the higher the WMSI, the more significant the wall motion abnormally is. A score above 1.7 represents significant wall motion abnormality.

Assessment of Ventricular Ejection Fraction

Numerous studies have consistently shown left ventricular ejection fraction (LVEF) as one of the most powerful predictors of future mortality and morbidity in patients with heart disease.[4] LVEF is the single most powerful predictor of mortality and the risk for developing life-threatening ventricular arrhythmias after myocardial infarction.[5] Furthermore, once the ACS resolves, the residual

LVEF is important for treatment options as LVEF cutoff values are built into recommendations for both medical and electrical device therapies. Even with treatment and clinical stabilization of heart failure, there is an inverse, almost linear, relationship between LVEF and survival in patients whose LVEF is less than 45% (**Figure 4.1**).[6]

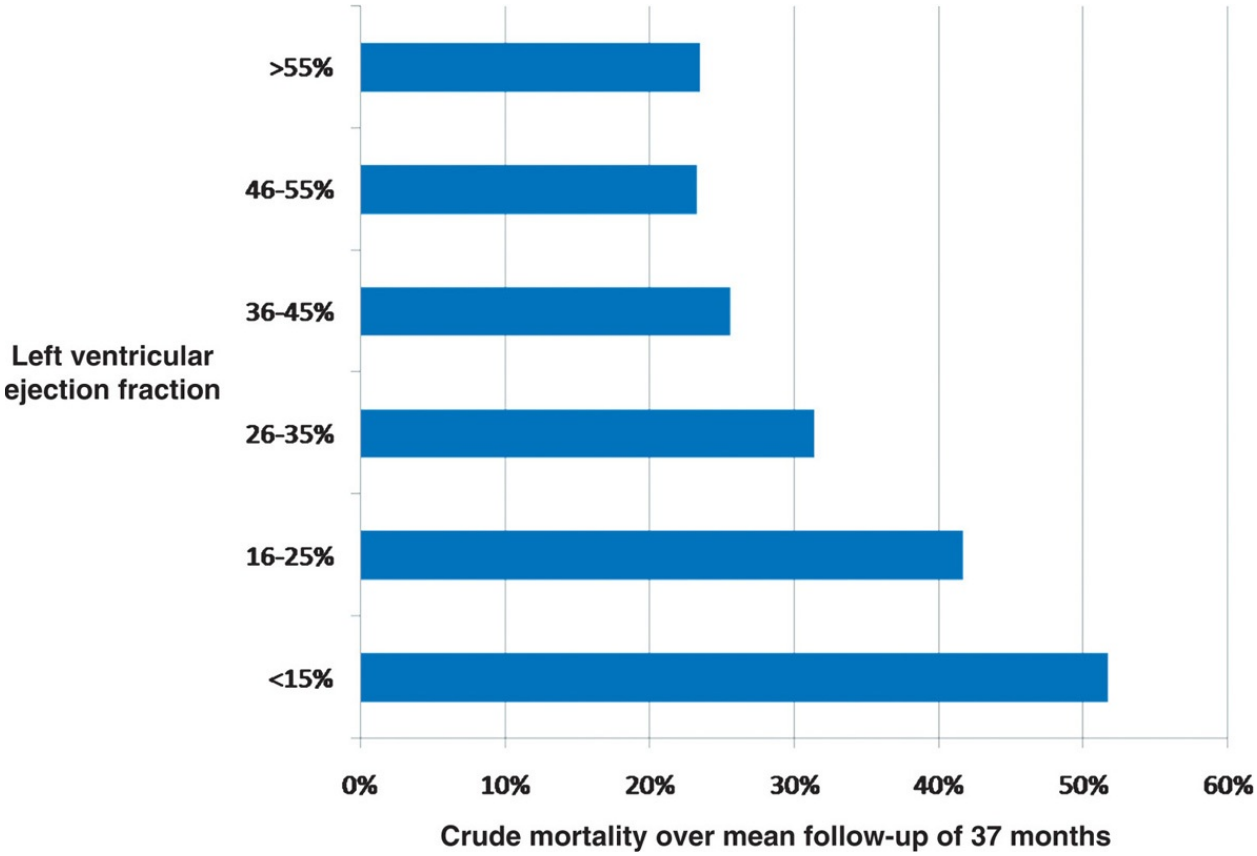

FIGURE 4.1 Relationship between left ventricular ejection fraction and survival. Note the negative, almost linear, relationship between survival and left ejection fractions <45%. (Based on numeric data from Curtis et al.[6])

By definition, LVEF is the percentage of the end-diastolic volume that is ejected with each systole as the stroke volume. Thus, to calculate the LVEF, one needs to estimate the end-systolic and end-diastolic volume of the left ventricle.

For two-dimensional echocardiography, biplane Simpson's rule is routinely used for estimation of the LVEF.[7, 8] Most modern ultrasound systems provide a semiautomated software package for the Simpson's rule analysis. Operators are usually only required to trace the LV endocardial border at end-diastolic and end-systolic in the apical four-chamber and two-chamber views; the software

package then automatically calculates the LV end-diastolic volume, end-systolic volume, and LVEF (**Figure 4.2**).

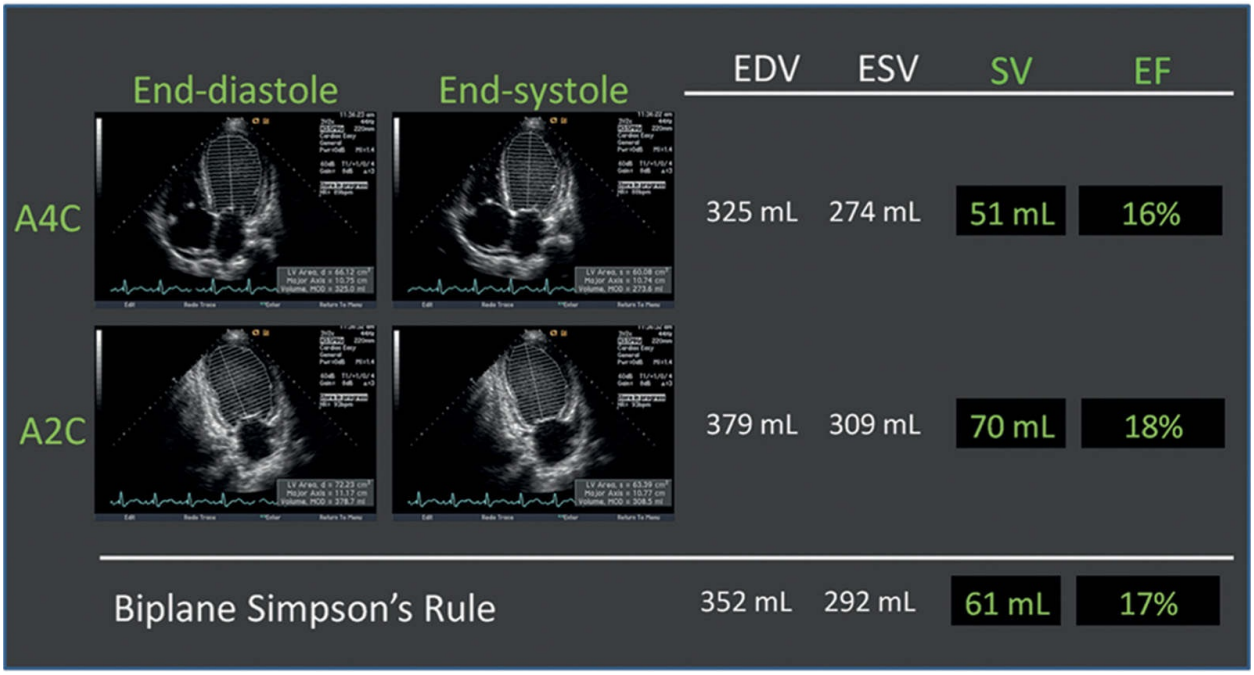

FIGURE 4.2 Calculation of LVEF by biplane Simpson's rule. The operator of an ultrasound system is required to trace the endocardial border of an end-diastolic and an end-systolic frame in the A4C and A2C views. The system then calculates the EDV, ESV, SV, and LVEF. A4C, apical four-chamber; A2C, apical two-chamber; EDV, end-diastolic volume; EF, ejection fraction; ESV, end-systolic volume; LVEF, left ventricular ejection fraction; SV, stroke volume.

With the advent of real-time three-dimensional (RT3D) transthoracic techniques, LV volumes and LVEF can now be calculated with even greater accuracy than is possible with the biplane Simpson's rule (**Figure 4.3**). RT3D-derived LV volume data are now comparable to those obtained by cardiac magnetic resonance imaging, the prior gold standard for such calculations.[8]

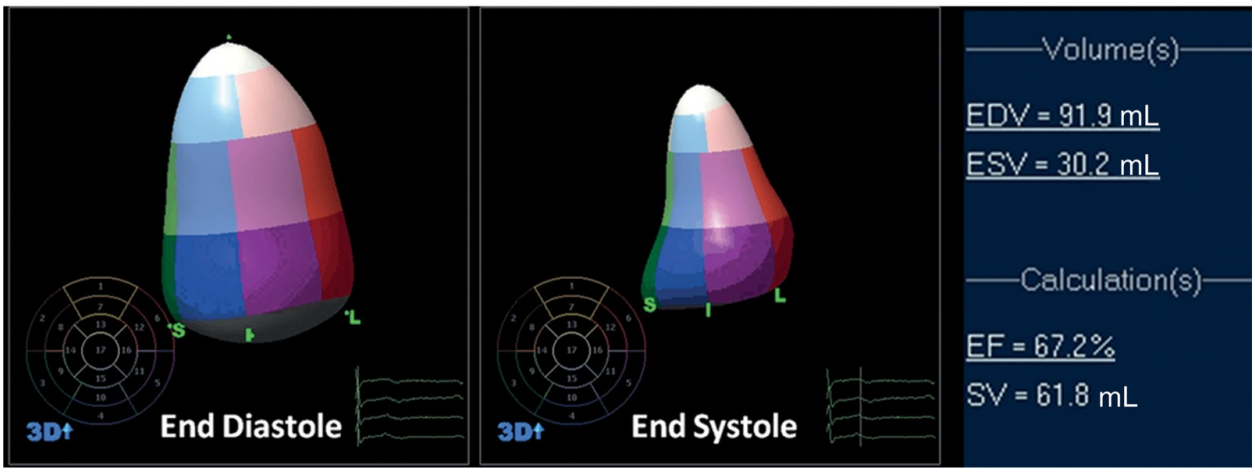

FIGURE 4.3 Calculation of left ventricular volumes and EF by three-dimensional echocardiography. A three-dimensional ultrasound system calculates the EDV, ESV, SV, and LVEF automatically from a three-dimensional data set after an operator manually enters key reference points of the left ventricle. EDV, end-diastolic volume; EF, ejection fraction; ESV, end-systolic volume; LVEF, left ventricular ejection fraction; SV, stroke volume.

Thus, whenever available, LV volumes and LVEF in ACS should be calculated from an RT3D system; the biplane Simpson's rule should be the next best method for such calculations when only a two-dimensional ultrasound system is available.

THE ISCHEMIC CASCADE

The ischemic cascade refers to a sequence of events that occurs in the myocardium after the onset of ischemia.[9] Myocardial perfusion is determined by coronary blood flow and myocardial oxygen consumption. Any imbalance in this supply-and-demand relationship results in myocardial ischemia.[10] The mechanical, electrographic, and clinical events that follow the development of ischemia were formally described in 1985 by Hauser et al.[11] and were later termed the "ischemic cascade."[12] Classically, the observable changes occur sequentially (**Figure 4.4**) starting with perfusion abnormalities leading to abnormalities in wall function, then ischemic electrocardiogram (ECG) changes, and finally angina.[13] Echocardiography has the ability to detect these pathophysiologic changes in the myocardium at the most initial stages and therefore is more sensitive than history, physical examination, and ECG for identification of myocardial ischemia.[14] **Figures 4.5** and **4.6** depict

echocardiographic views of the left ventricle, demonstrating the LV wall segments and their typical corresponding coronary distributions.[3] Additionally, the utilization of image-enhancing agents (echocardiographic contrast microbubbles) has improved the detection of even subtle wall motion abnormalities, improving the confidence in the presence or absence of ischemia, and thereby facilitating further management.

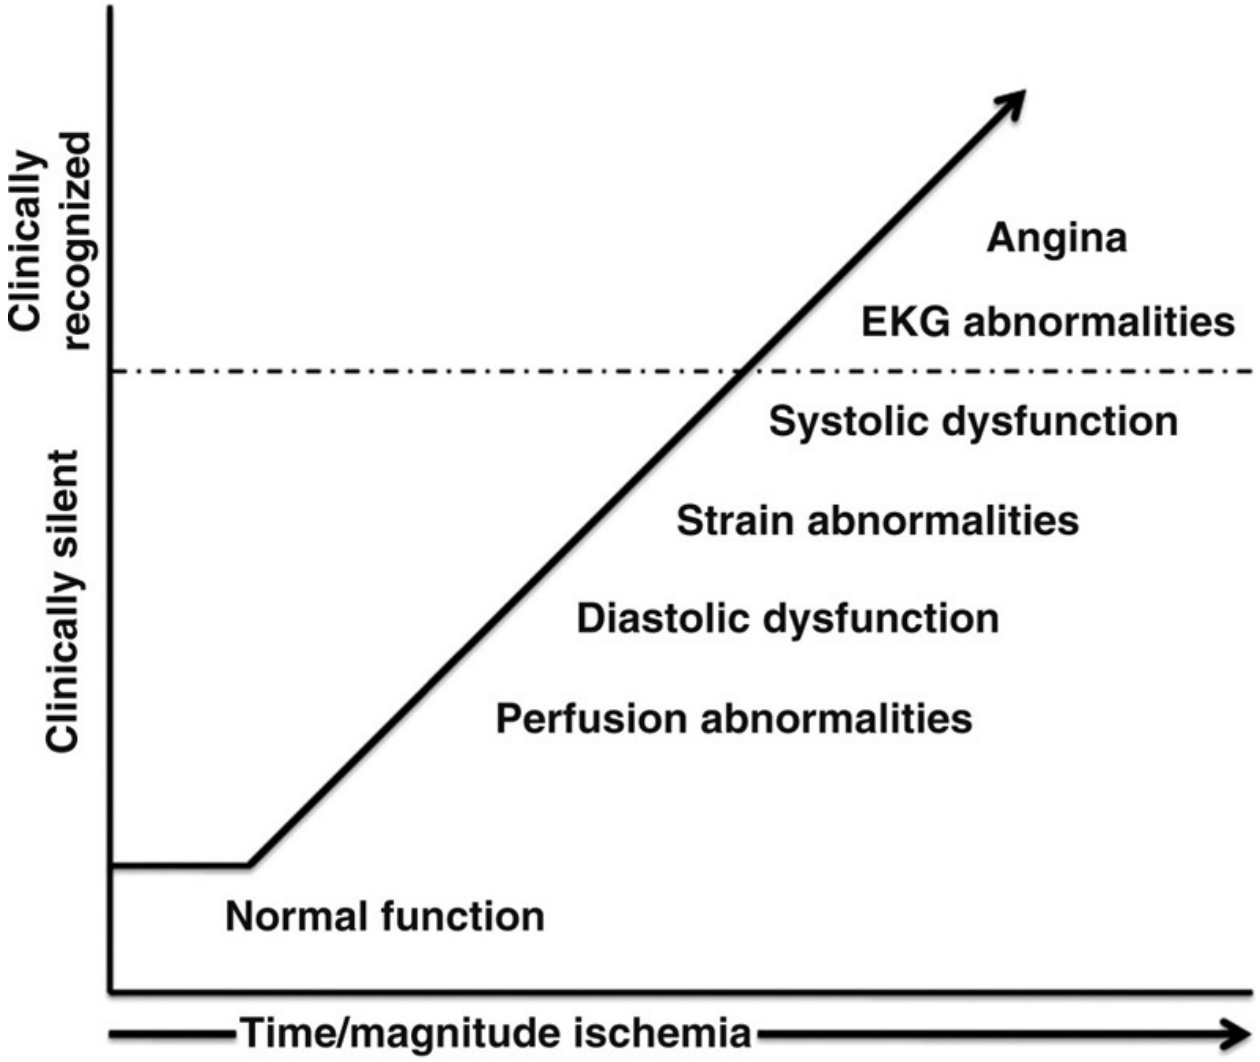

FIGURE 4.4 The ischemic cascade. Myocardial dysfunction occurs in a predictable sequence, which is detectable before clinical symptoms. ECG, electrocardiogram.

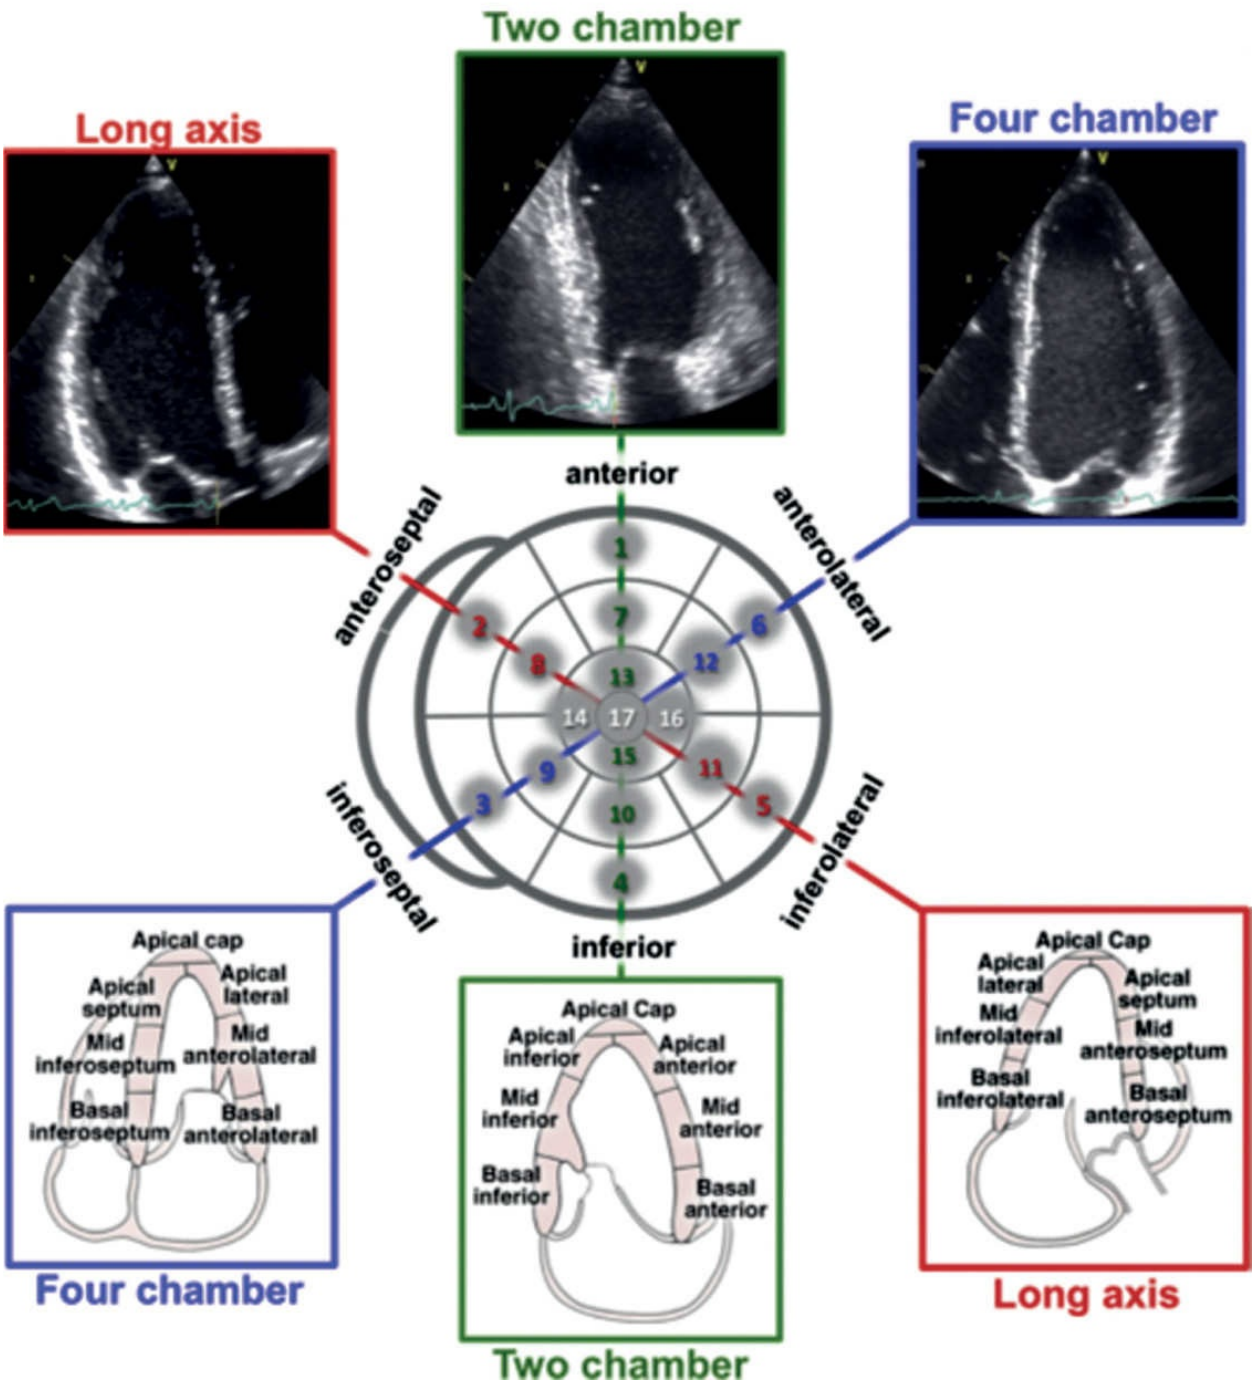

FIGURE 4.5 A4C, A2C, and ALX views in relation to the bull's-eye display of the left ventricular segments (center). Top panels show echocardiographic images and bottom panels depict the left ventricular wall segments visualized in each view. A4C, apical four chamber; A2C, apical two chamber; ALX, apical long axis. (Courtesy of Lang et al.[3])

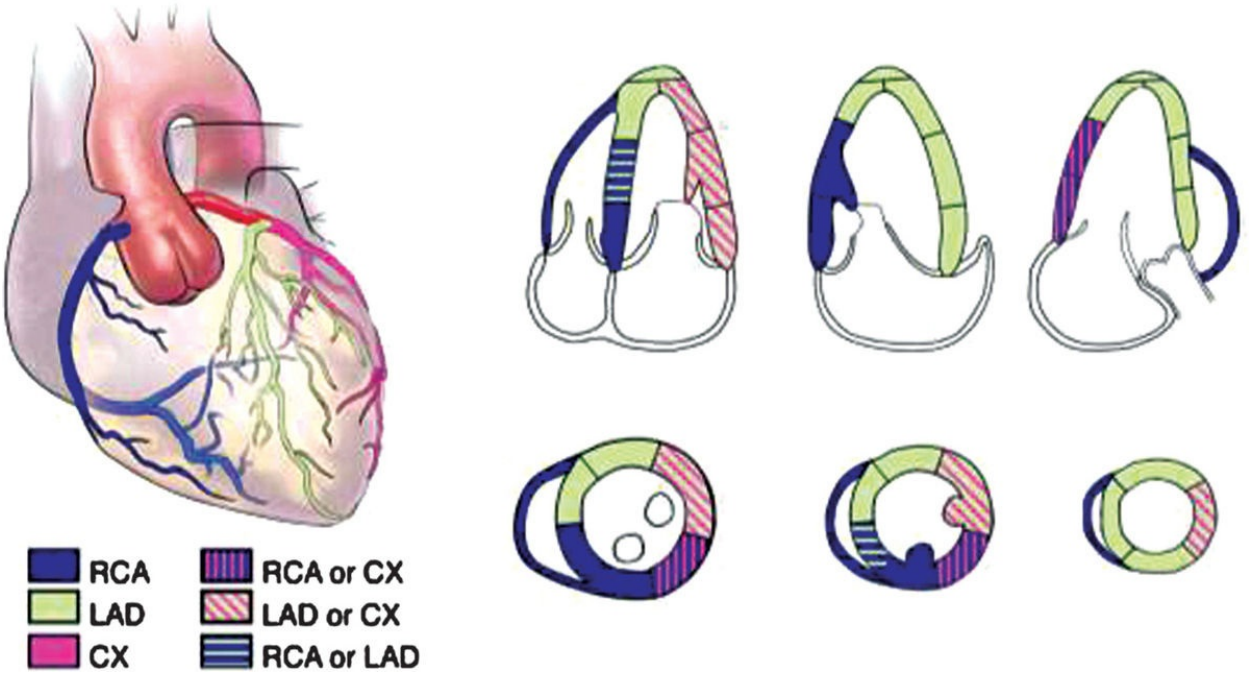

FIGURE 4.6 Distributions of the RCA, LAD, and CX. CX, circumflex coronary artery; LAD, left anterior descending artery; RCA, right coronary artery. (Courtesy of Lang et al.[3])

Echocardiography for the diagnosis of suspected acute ischemia is most helpful in subjects with a high clinical suspicion but nondiagnostic electrocardiograms, as it allows real-time assessment of myocardial function. Additionally, through stress modalities, it offers assessment and risk stratification in patients who present to the emergency department with chest pain.

Of note, troponin elevation with chest pain may not be related to an ACS, but rather be secondary to other cardiovascular pathology such as valvular disease (eg, severe aortic stenosis or regurgitation), which can induce ischemia by causing LV wall stress; acute heart failure due to systolic and/or diastolic dysfunction; or even acute pulmonary embolism with right ventricular strain. Echocardiography is a valuable tool to detect and quantify these other abnormalities, regardless of whether the patient is having an ACS.

STRESS ECHOCARDIOGRAPHY

There are different types of stress echocardiography that can be used in the evaluation of patients with coronary artery disease.[15] For patients who are able

to exercise, treadmill and supine bicycle stress echocardiograms are the preferred techniques. For patients unable to exercise, pharmacologic stress testing using dobutamine, dipyridamole, or adenosine is an alternative method to provoke ischemia.

Table 4.2 outlines the methods to induce stress. The basic principle of stress echocardiography is the identification of new wall motion abnormalities that occur in the presence of provocable ischemia. This involves the comparison of baseline echocardiographic images obtained under resting conditions with those obtained immediately postexercise in the case of treadmill or during peak exercise in the case of bicycle protocol. Parasternal long and short axes as well as apical two-chamber, three-chamber, and four-chamber views are acquired at baseline and Post-stress testing. The left ventricle is divided into 17 segments as per the recommendation of the American Society of Echocardiography. All images are digitized in a continuous-loop format utilizing a quad-screen format to facilitate the detection of new segmental wall motion abnormalities. The best Post-exercise image is selected and compared with the baseline image by side-by-side comparison in the quad-screen image format.

TABLE 4.2 Methods to Induce Stress

Exercise	Pharmacologic
Treadmill	Dobutamine
Supine bicycle	Dipyridamole
Isometric exercise	Adenosine

In the United States, the most commonly used method for provoking ischemia in patients able to exercise is treadmill testing. The sensitivity of exercise testing is strongly dependent upon attaining adequate heart rate and cardiovascular workload. The use of treadmill or bicycle methods of exercise requires the patient to achieve a target heart rate of 85% of the age-predicted maximum heart rate or attain a workload of at least six metabolic equivalents in order to achieve satisfactory sensitivity. In patients who can achieve these workloads, exercise testing is the method of choice to provoke myocardial ischemia.

The most common treadmill protocol used is the Bruce protocol, although other protocols such as the modified Bruce can be used depending upon the level of fitness of the patient. According to standard stress testing protocol, the patient

has continuous ECG monitoring with exercise and blood pressure is checked every 3 minutes. With treadmill exercise, the Post-exercise images are obtained ideally within less than 1 minute.

The exercise test should be terminated if any of the following occurs:

1. Severe symptoms such as chest pain or dyspnea
2. Severe ST depressions
3. Hemodynamically significant arrhythmia
4. Severe hypertensive response (BP > 220/120 mm Hg)
5. Hypotension (a decrease of >20 mm Hg)

PHARMACOLOGIC STRESS ECHOCARDIOGRAM

For those patients who cannot exercise, dobutamine or dipyridamole stress echocardiograms can alternatively be performed. By far, dobutamine is the most common pharmacologic agent used to provoke ischemia in stress echocardiograms. Dobutamine is a synthetic catecholamine that binds to β-1 and β-2 receptors. The affinity of dobutamine for β-1 cardiac muscle receptors results in positive inotropic and chronotropic effects. Therefore, dobutamine induces myocardial ischemia in patients with flow-limiting coronary stenosis by increasing LV contractility, heart rate, wall stress, and therefore myocardial oxygen demand. Dobutamine has a short half-life and is rapidly metabolized once the infusion is discontinued. Any adverse side effects or arrhythmias can usually be quickly terminated by discontinuation of the drip or by intravenous β-blockers.[16]

Pathway for Management of Patients Based on Stress Echocardiography Results

Risk stratification of patients undergoing stress echocardiography should be based both on peak WMSI (which includes both extent and severity of ischemia/infarction) and on LVEF (resting). **Figure 4.7** represents a schematic for the risk stratification of patients with known or suspected coronary artery disease referred for stress echocardiography. These data for risk stratification are based on an analysis of 3259 patients (59 ± 13 years; 48% males) followed for up to 4 years.[17]

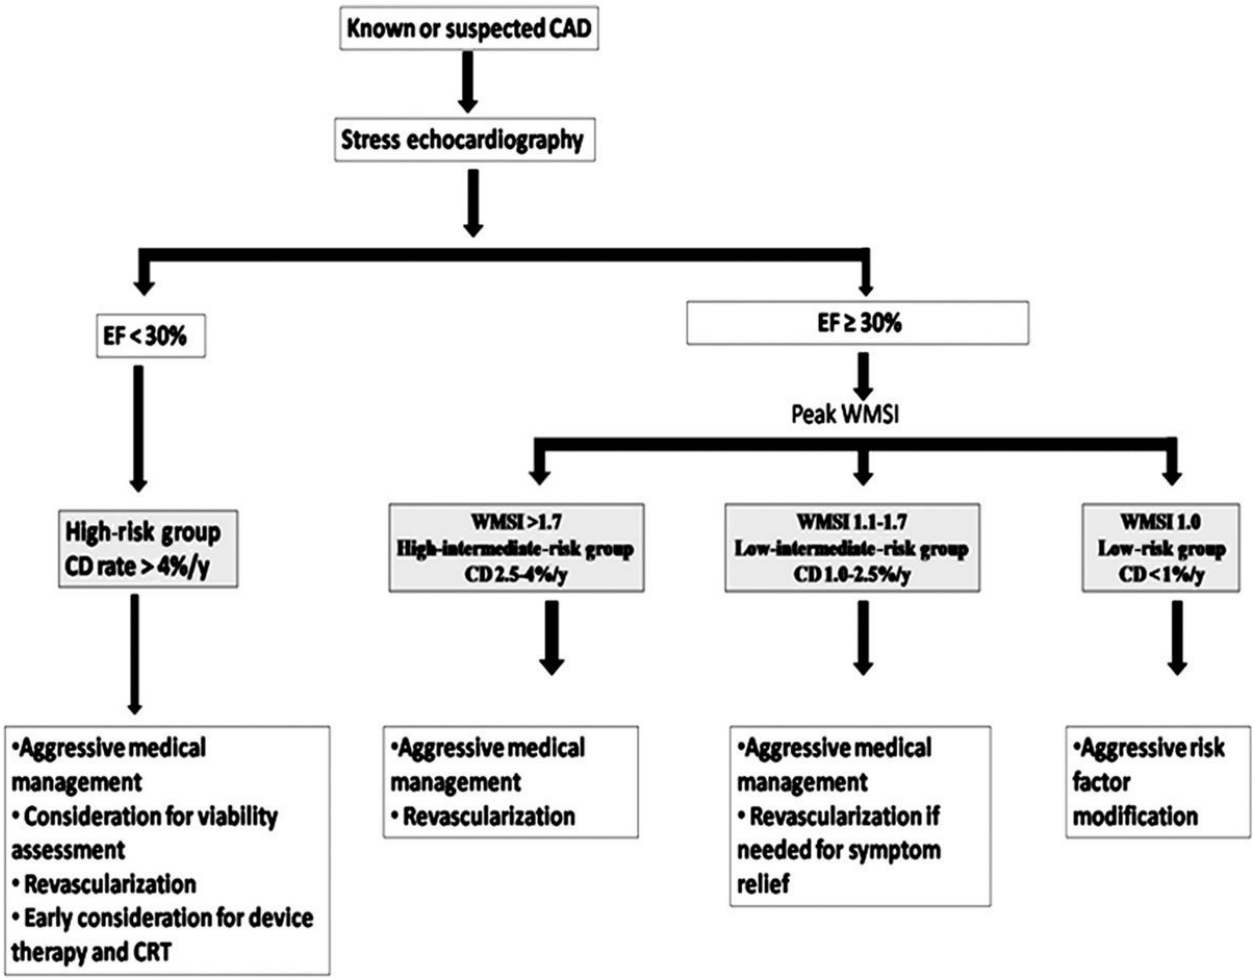

FIGURE 4.7 Schematic for risk stratification of patients undergoing stress echocardiography. CAD, coronary artery disease; CD, cardiac death; CRT, cardiac resynchronization therapy; EF, ejection fraction; WMSI, Wall Motion Score Index.

The first step in the risk stratification process is evaluation of LVEF. Patients with EF <30% are a high-risk group with a cardiac death (CD) rate of >4%/y regardless of the peak WMSI. Such patients should be aggressively managed. These patients may also benefit from viability assessment and consideration for revascularization as deemed necessary. They should also be considered for early device therapy (implantable cardioverter defibrillator/cardiac resynchronization therapy) and for cardiac transplant evaluation.

In patients with EF ≥ 30%, peak WMSI can further risk stratify the patient subgroup into a low-risk group (peak WMSI = 1.0) (CD <1%/y), low-intermediate (peak WMSI 1.1–1.7) (CD 1%–2.5%/y), and a high-intermediate (peak WMSI > 1.7) (CD 2.5%–4.0%/y) risk groups. Patients in the low-risk category will benefit from aggressive risk factor modification. Those in the low-

intermediate risk group may benefit from aggressive medical management and consideration of revascularization for symptom relief only. Patients in the high-intermediate risk group may benefit from aggressive medical management and revascularization therapy. Such a risk stratification approach would potentially avoid unnecessary revascularization procedures for low-risk individuals and at the same time provide a framework for the management of intermediate and high-risk subgroups.

Patient and Family Information for: ECHOCARDIOGRAPHY IN ACUTE CORONARY SYNDROME

INTRODUCTION

The echocardiogram is an ultrasound device that visualizes the heart and surrounding structures in a real-time fashion, which in turn provides important anatomic and physiologic information to the cardiologist. The echocardiogram, like a radar, emits and receives ultrasound waves and constructs an image by employing the differences in the signal properties. At the end of this sophisticated and fast process, an impressive and informative animation of the heart moving in the chest is displayed for further interpretation. In the cardiac care unit (CCU), echocardiography has become an essential tool for real-time bedside diagnosis of heart disease, especially in critical situations. Furthermore, echocardiography lacks any major side effects and is mostly noninvasive.

THE DEVICE STRUCTURE

The echocardiogram itself is made of two major components: the first is the transducer, which is the “radar dish” that relays the ultrasounds waves and is in touch with the patient’s body, and the second is a computer console that functions as the “brain” performing the computation. The transducer is filled with multiple crystals (called piezoelectric crystals) that have the natural property of sending and receiving ultrasound waves. Different transducers have different properties. Lower frequency transducers can emit ultrasound waves deeper into the body, but lack the picture quality of the higher frequency ones.

When placing the transducer over the chest (this common procedure is referred to as a transthoracic echocardiogram or TTE), a real-time moving image of the heart appears. By rotating and manipulating the transducer over the chest, different areas of the heart are seen; those are referred to as windows. Gel is used to improve the contact between the transducer and the skin, which helps with improving image quality. In TTE, four major areas over the chest are used to create heart images. These include the left chest area between the third and fourth ribs (parasternal), the tip of the heart (apical), under the ribs (subcostal), and above the chest (suprasternal). Several views of the heart are created in each location by rotating the transducer.

THE ECHOCARDIOGRAM ROLE IN THE CCU

In the CCU, echocardiography studies are performed to answer complex clinical questions. Of particular concern in the CCU are the function and integrity of the heart muscle walls (myocardium), the valves, and the heart sac (pericardium). The echocardiogram can provide information such as which chamber of the heart is involved in the disease, the heart's squeezing efficiency, the amount of fluid in the heart's sac, and the presence of clots in the heart chambers.

In the case where there is fluid in the heart sac that compresses the heart (a condition called pericardial tamponade), the echocardiogram can detect this acute life-threatening situation promptly and guide an immediate draining procedure.

"HEART ATTACKS" AND ECHOCARDIOGRAPHY

The majority of disease treated in the CCU is of coronary origin. The coronary arteries are the vessels that feed blood to the heart muscle itself. "Heart attack" or acute myocardial infarction is the condition where a coronary vessel is blocked and thereby prevents oxygenated blood from being delivered to the heart muscle. This in turn causes the heart muscle to start dying, and losing its ability to contract and pump blood. In contrast to a complete blockage, a partial blockage of the coronary artery may result in symptoms such as chest pressure on exertion (referred to as angina), but no impairment in the heart's squeezing function. Interestingly, the patient's symptoms are the last to develop in the

cascade of coronary artery blockage. After complete cessation of blood supply to the heart muscle, a sequence of event occurs that is referred to as the ischemic cascade, where the heart muscle wall motion is affected before any ECG changes and before the patient develops symptoms. Therefore, the echocardiogram potentially can detect, in a noninvasive way, heart wall motion contraction impairments in situations where the ECG is nondiagnostic and the patient's symptoms are unclear. During a complete coronary occlusion, the echocardiogram is able to show which wall of heart is not contracting and is thus affected directly by the occlusion. The degree of muscle contraction impairment has a scoring system that provides information about the extent of occlusion and function of the muscle. The walls of the heart are divided into 17 segments. Normal wall motion gets a score of 1; *hypokinesis* is the term used to describe decreased contractility and receives a score of 2; *akinesis* is when no wall motion is seen, with a score of 3; and *dyskinesis* is when the wall motion direction is occurring in the opposite direction, with a score of 4. The sum of the scores of each segment is then divided by 17. A normal score would be 1 (17 divided by the 17 segments) and a score above 1.7 represents significant wall motion abnormality.

There are three major coronary arteries in the heart, and each of them provides blood supply to a certain muscle wall of the heart (with some overlap). The echocardiogram is able to pinpoint the culprit vessel that is occluded. The occluded coronary artery is represented in the echocardiographic study by a specific area of impaired contraction. The assessment of the heart muscle contraction is also assessed as a whole, that is, the heart's overall pumping efficiency. This is referred to as EF. The EF denotes the percentage of blood squeezed from the left ventricle of the heart in one heartbeat to the rest of the body (normal value is 60%). It is known from numerous studies that the lower the EF is, the worse the outcome of the patient.

For example, a patient with an acute myocardial infarction is admitted to the CCU with a LAD occlusion. The LAD supplies blood to the front side of the left heart chamber (main pumping chamber). During the performance of the echocardiogram study, the cardiologist notices that the front portion of the left heart chamber is not squeezing optimally (ie, there is hypokinesis), with an EF of 30%, and there is also some valve leak. Occlusion of an artery can influence the function of a heart valve because the valve's movement relies on muscles attached to the heart wall. The patient is sent thereafter for a cardiac catheterization where the occluded coronary artery is opened. An

echocardiogram performed 2 days after the procedure shows some recovery in the wall motion of the front wall with resolution of the valve leakage, as blood supply was restored to the region. The echocardiogram provided up-to-date functional information of various structures of the heart such as the muscle wall and the valves. In contrast, a patient whose echocardiogram shows global LV hypokinesis without any regional wall abnormalities likely had a remote myocardial infarction that initially affected the region of the heart distributed by the occluded coronary artery but progressed to a dilated left ventricle, or had small vessel disease that reduced global perfusion.

MANAGEMENT AFTER THE ACUTE EPISODE

The echocardiogram has a role for diagnosing new or recurrent symptoms during the admission of a patient in the CCU after the primary diagnosis was made. For example, if a patient has recurrent chest pain or shortness of breath, or if the patient's blood pressure is coming down without a reason, the echocardiogram can provide answers. New heart wall motion abnormalities could point to new or recurrent coronary vessel occlusions. A new murmur that is first detected on physical exam with a stethoscope could be the result of a new valve problem (eg leakage), or even a rupture between the heart chambers. These conditions require prompt interventions, and at times may require surgery. The echocardiogram can help in diagnosing dehydration (the main pumping chamber of the heart becomes smaller), fluid overload (due to heart failure or administration of too much fluids), or fluid in the heart sac that compresses the heart (eg pericardial effusion, tamponade).

STRESS TESTING

Some patients who are admitted with chest pain with a high suspicion of a coronary artery disease without an overt heart attack require more testing to confirm the diagnosis. This could be accomplished by performing an echocardiogram while the patient's heart is being "stressed," that is, walking on a treadmill or giving the patient a medication that will make the heart beat faster. Actual stressing or exercising is not performed when the patient is suspected of an evolving heart attack (ACS). Images of the patient's heart muscle contraction

are obtained before, during, and after the stress—the muscle could be inspected for wall motion abnormalities that denote probable coronary disease.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Some echocardiographic information could be better acquired by using the device in a semi-invasive method called transesophageal echocardiogram—echocardiogram obtained through the esophagus (food pipe). Because there is a short distance between the transducer and the heart while the transducer is positioned in the esophagus, the quality of pictures is better. It is especially useful when imaging cardiac structures that are located at the back part of the heart (eg the left atrium).

LIMITATIONS

There are some limitations in performing an echocardiogram at the bedside as compared with the echocardiography laboratory settings. Usually, the patient is asked to lie on his left side to obtain some of the windows and then to lie on his back for the rest of the images. In the CCU, the patient could be mechanically ventilated, sedated, and might not be able to cooperate. Thus, some of the pictures may be much harder to obtain in order to produce high-quality images.

CONCLUSION

Echocardiography in the CCU provides important anatomic, structural, and clinical information that aids the cardiologist in the diagnosis and treatment of acute heart diseases. It helps to establish a diagnosis in a real-time fashion. It shows the heart muscle function, and this information helps to designate which coronary artery is occluded during heart attacks. It also shows the integrity and function of the heart valves, the amount of fluid in the heart’s sac, and the body’s fluid balance. Echocardiography aids in managing severely sick patients in the CCU by performing sequential studies. Echocardiography has changed the way cardiologists treat patients in the CCU by having the ability to get live, real-time images of the heart apparatus at the bedside.

Use of Radionuclide Imaging in Acute Coronary Syndrome

INTRODUCTION

Chest pain is a common complaint and is often the presenting symptom in patients with acute coronary syndrome (ACS). The evaluation of chest pain as a presenting symptom for ACS is complicated by: (1) the numerous etiologies that can cause chest pain, (2) the lack of an “ideal” diagnostic test available at the time of initial evaluation, (3) poor clinical outcomes of patients in whom a diagnosis of ACS is missed, and (4) the medicolegal implications. Because patients with ACS are at a high risk for poor outcomes, the ability to identify these patients rapidly during the initial evaluation is critical. The initial diagnostic workup in patients presenting with symptoms suspicious of ACS include a history, physical examination, electrocardiogram (ECG), and serum cardiac biomarkers (such as cardiac troponins). The ECG is the key diagnostic test used to determine whether the patient has ongoing myocardial ischemia. Unfortunately, the ECG is often nondiagnostic in many patients who present with symptoms suspicious for ACS. Although serum troponin has been shown to be a sensitive test for myocardial damage, there are certain drawbacks to the test, for example, the need for ischemia of sufficient time for myocardial necrosis to take place, and thus the initial serum troponin is often negative in patients with

ACS. Patients with unstable angina often do not have significant troponin elevation. Although the newer generation assays (“high-sensitivity troponin”) may affect the accuracy and timing of ACS diagnosis significantly, one should bear in mind that troponin elevation (especially mild degrees) is not exclusive to ACS but may happen in other conditions, primarily nonischemic cardiovascular diseases, for example, pulmonary embolism, acute heart failure, and severe sepsis. Based on the pathophysiology of coronary artery plaque rupture as the cause of ACS, one of the earliest signs of ACS is the decrease in blood flow to the myocardium (**Figure 5.1**). This decrease in myocardial blood flow can be evaluated using single photon emission computed tomography (SPECT) myocardial perfusion imaging (MPI), which images the relative amount of myocardial blood flow to all segments of the left ventricle. The use of SPECT MPI in the patient presenting with chest pain has developed over the last several decades to allow for rapid triage in chest pain patients with a view to initiating the necessary medical therapy and revascularization. However, we would also like to identify those patients whose chest pain is not caused by ACS so they are not unnecessarily admitted to the hospital, thus better utilizing health care resources. Stress SPECT MPI can be used for risk stratification in low-risk patients admitted for suspected ACS. It can also identify areas of ischemia in patients with ACS who were not fully revascularized. Finally, radionuclide imaging can assist in assessment of myocardial viability. In this chapter, we will explore the technical, physiologic, and current outcome data of using SPECT MPI in patients with acute chest pain.

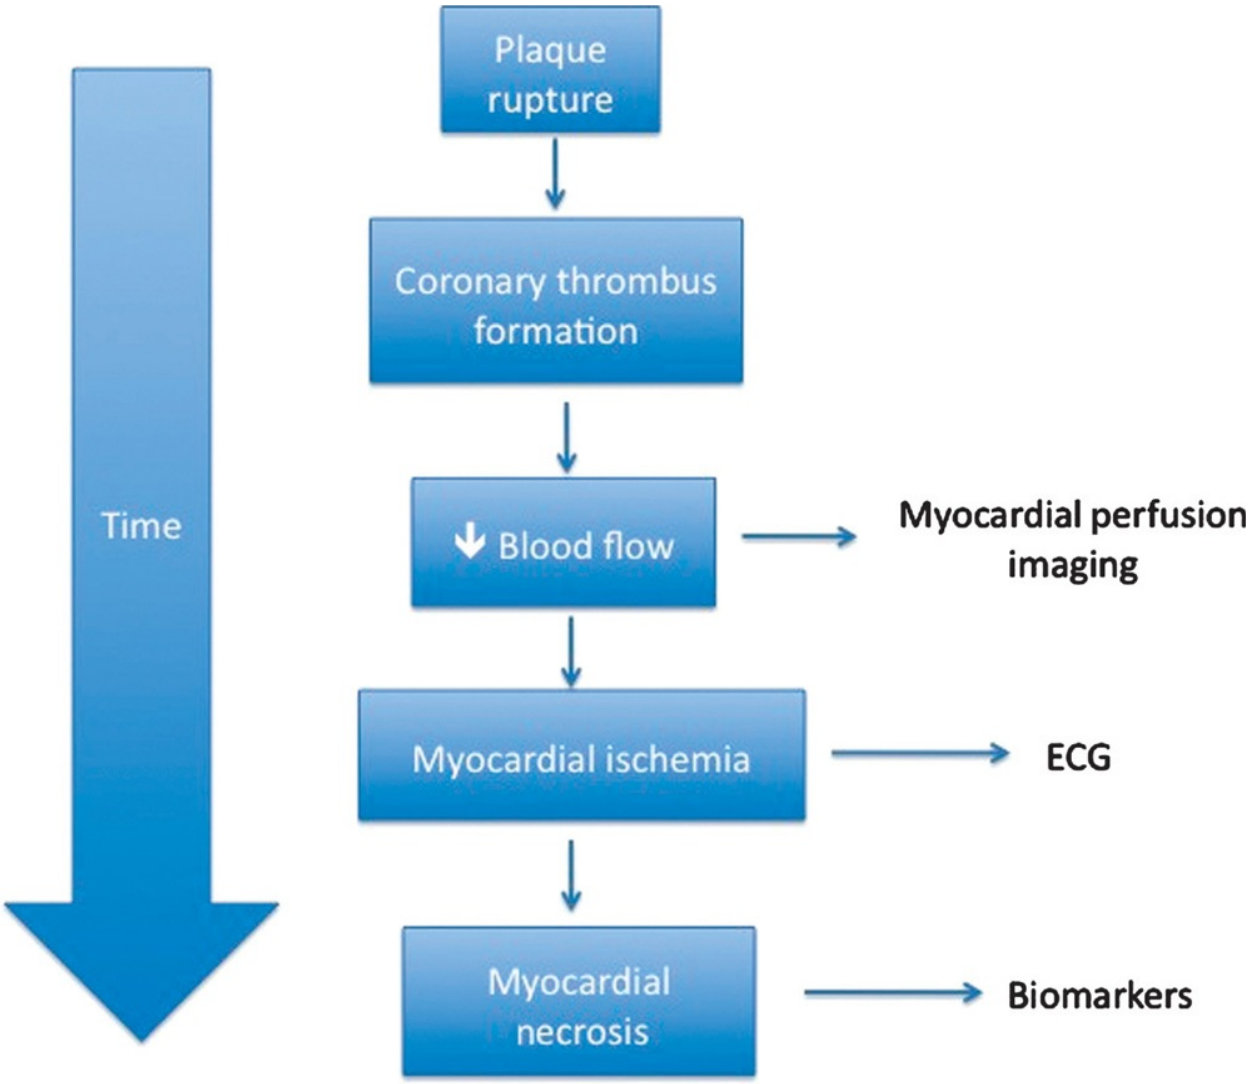

FIGURE 5.1 The ischemic cascade. ECG, electrocardiogram.

OVERVIEW OF SPECT MYOCARDIAL PERFUSION IMAGING

MPI was introduced into clinical practice in the 1970s as a tool to noninvasively assess for myocardial ischemia. In the 1980s, planar imaging gave way to the more robust SPECT imaging most commonly used today. The theory behind SPECT MPI relies on the fact that blood flows preferentially down the path of least resistance, that is, the vessel without coronary occlusion versus the vessel with coronary occlusion (**Figure 5.2**). When comparing myocardial regions with each other, a decrease in tracer uptake in a region is a sign of myocardial

hypoperfusion. SPECT MPI utilizes radiotracers whose activity can be detected with a special camera called a scintillation camera. The most commonly used radiopharmaceuticals are Thallium-201 (Tl-201), Technetium-99m (Tc-99m) sestamibi, and Tc-99m tetrofosmin. Radiopharmaceuticals contain atoms that undergo radioactive decay by emitting a particle that can be detected using a SPECT camera. Once injected intravenously, the radiotracer is taken up by the myocardium proportionally to regional coronary blood flow, and the relative "amount" of tracer in each region of the myocardium can be measured and imaged.

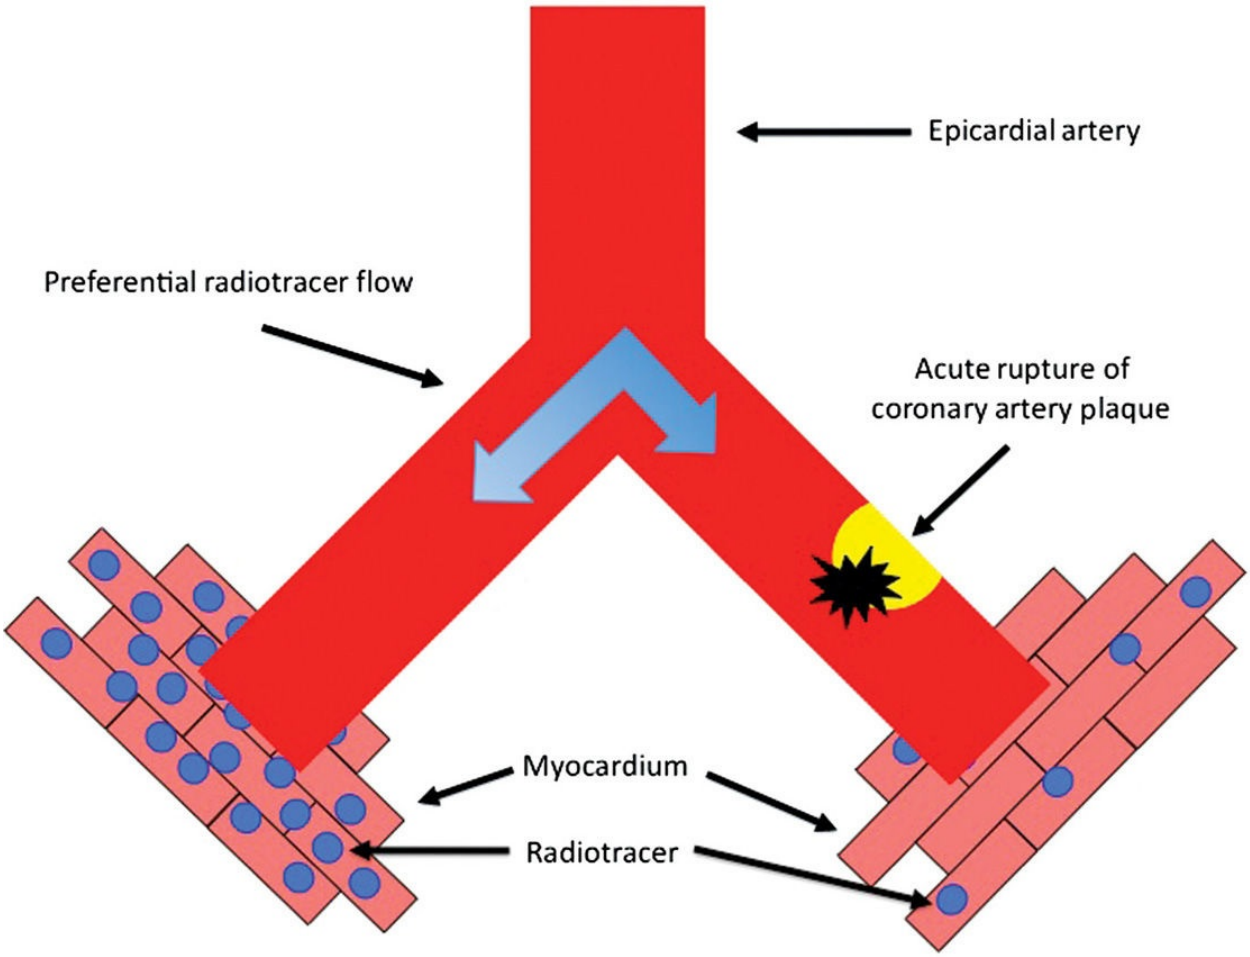

FIGURE 5.2 Differential myocardial radiotracer uptake in myocardium subtended by a normal coronary and a coronary with a ruptured atherosclerotic plaque.

SPECT CAMERA

The SPECT camera is designed to detect the radioactivity emitted from a patient

after injection of a radiotracer. After injection of the radiotracer, patients are placed in the camera and the images are acquired.

RADIOTRACERS

Radiotracers are tagged molecules that emit radioactivity. The ideal radiotracer has several features:

1. Linear relationship between myocardial uptake and blood flow.
2. High myocardial extraction rate.
3. Low extracardiac uptake.

The most commonly used radiotracers in nuclear cardiology are Tl-201 and Tc-99m. Tc-99m has several advantages over Tl-201, including a shorter half-life, higher energy photons, no redistribution, and availability on site from a Mo-99 generator or in unit doses from a local commercial radiopharmacy. The process whereby Tl-201 decays is called electron capture or isomeric transition (Tl-201 + e^- → Hg-201 + ϒ), whereas Tc-99m decays by a process called gamma decay (Tc-99m → Tc-99 + ϒ).

RESTING MYOCARDIAL PERFUSION IMAGING

MPI imaging is based on the concept that the injected radiotracer is taken up by the myocardium in proportion to the amount of blood flow that the myocardial region receives. If the blood flow to an area of myocardium is reduced at rest because of coronary occlusion, this area of the myocardium will receive less radiotracer relative to those areas in which blood flow is not reduced (**Figure 5.2**). The resulting SPECT images will have a decrease in tracer activity in the myocardial segments subtended by the diseased coronary artery. In patients with chest pain caused by ACS, there is rupture of coronary plaque, resulting in the formation of intracoronary thrombus and a subsequent decrease in myocardial blood flow to the myocardium supplied by that artery. On the other hand, in patients without coronary occlusion, there will be no decrease in blood flow to the myocardium, and no decrease in tracer activity will be seen.

STRESS MYOCARDIAL PERFUSION IMAGING

In patients with coronary artery disease but with preserved resting blood flow to the myocardium, MPI may appear normal at rest. Stress testing can be used to

diagnose physiologically significant coronary artery stenosis in these patients. Stress testing can be performed using exercise or pharmacologic agents. In nuclear cardiology, pharmacologic stress testing is typically performed using a vasodilator agent (such as adenosine, dipyridamole, and regadenoson). During exercise, there is disproportional increase in coronary blood flow to the nondiseased coronary arteries compared with the stenosed coronary arteries. Similarly, during vasodilator pharmacologic stress, coronary vasodilation and increase in blood flow are attenuated in areas supplied by stenosed coronary arteries. As a result, stress testing creates inhomogeneity in myocardial perfusion with decreased regional radiotracer uptake in patients with hemodynamically significant coronary artery disease that can be detected and quantified by MPI.

INTERPRETATION OF SPECT MYOCARDIAL PERFUSION IMAGING

By convention, SPECT images are displayed in three orientations: short axis, vertical long axis, and horizontal long axis (**Figure 5.3**). The left ventricle can be divided into the anterior wall, lateral wall, inferior wall, and septum. While interpreting stress SPECT MPI, images are displayed with the poststress images on the top line and the rest images below (**Figure 5.4**). The short axis images are displayed apex to base, followed by the vertical long axis and the horizontal long axis. As previously discussed, SPECT MPI measures relative blood flow to the various segments of the myocardium. When interpreting stress SPECT MPI, one compares the amount of tracer uptake on the stress images with the amount of tracer uptake in the rest images for each myocardial segment. Broadly speaking, if the tracer uptake is homogeneous in both the rest and stress images, there is no decrease in blood flow to the myocardium, that is, no ischemia or scar (**Figure 5.4**). However, if there is a decrease in perfusion on the stress images in a region of normal tracer uptake on the resting images, that is termed a “reversible” defect and may be indicative of ischemia (**Figure 5.5**). If there is a matched in tracer uptake in both the stress and rest images, that is termed a “fixed” defect and may be indicative of myocardial scar (**Figure 5.6**).

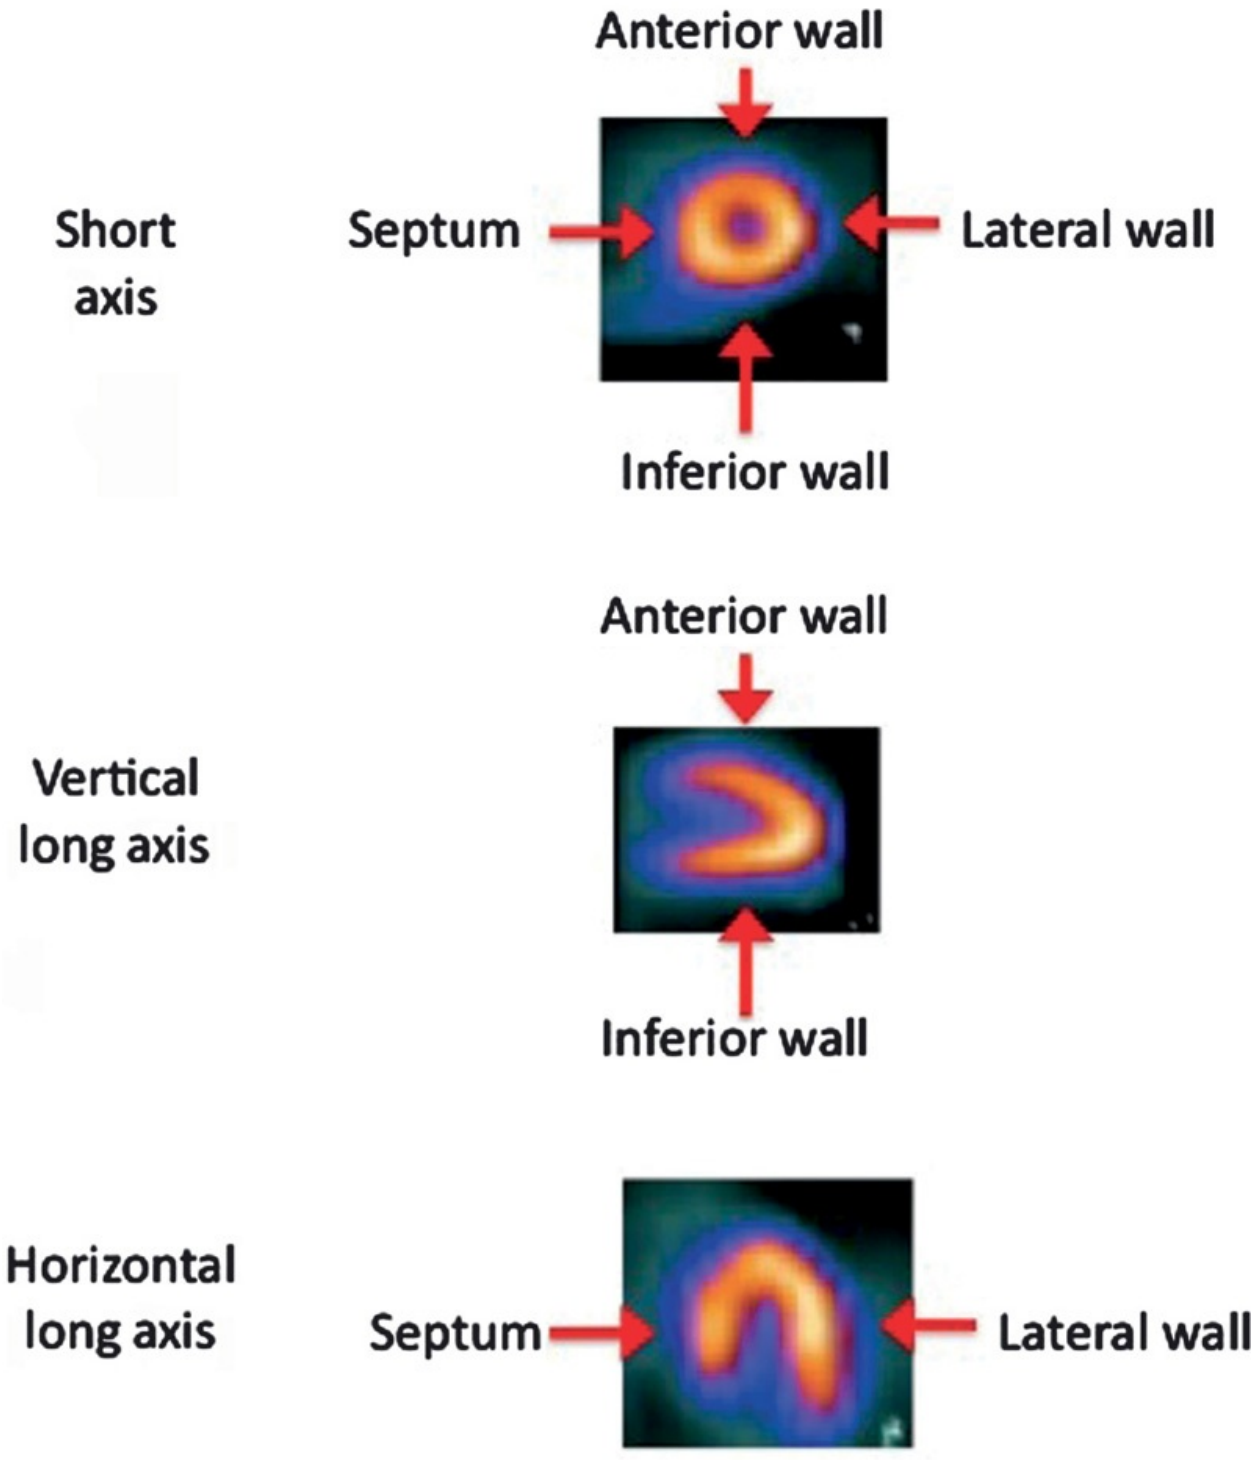

FIGURE 5.3 Short-axis, vertical long-axis, and horizontal long-axis slices with labeled myocardial regions.

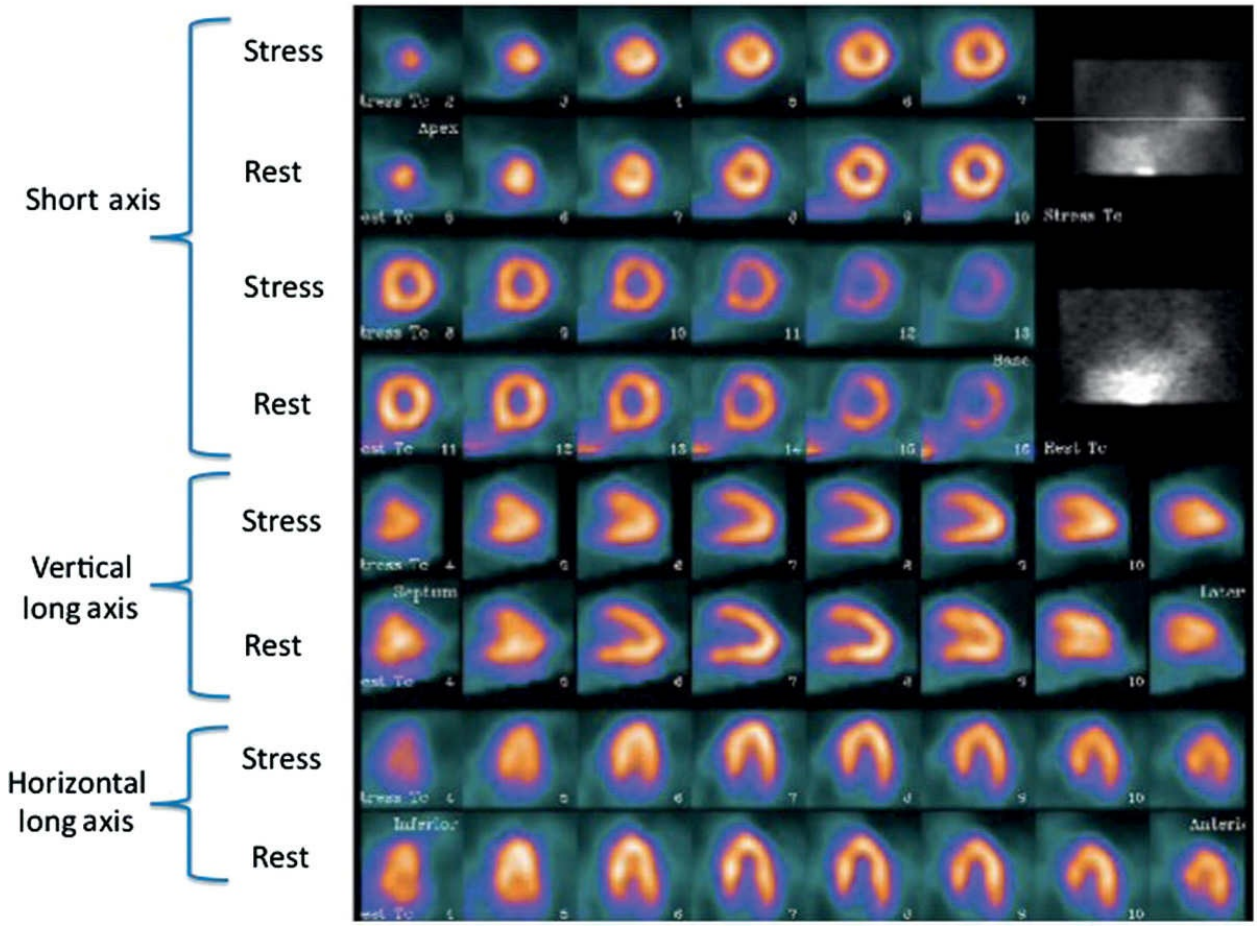

FIGURE 5.4 Normal single photon emission computed tomography myocardial perfusion imaging with homogeneous tracer uptake.

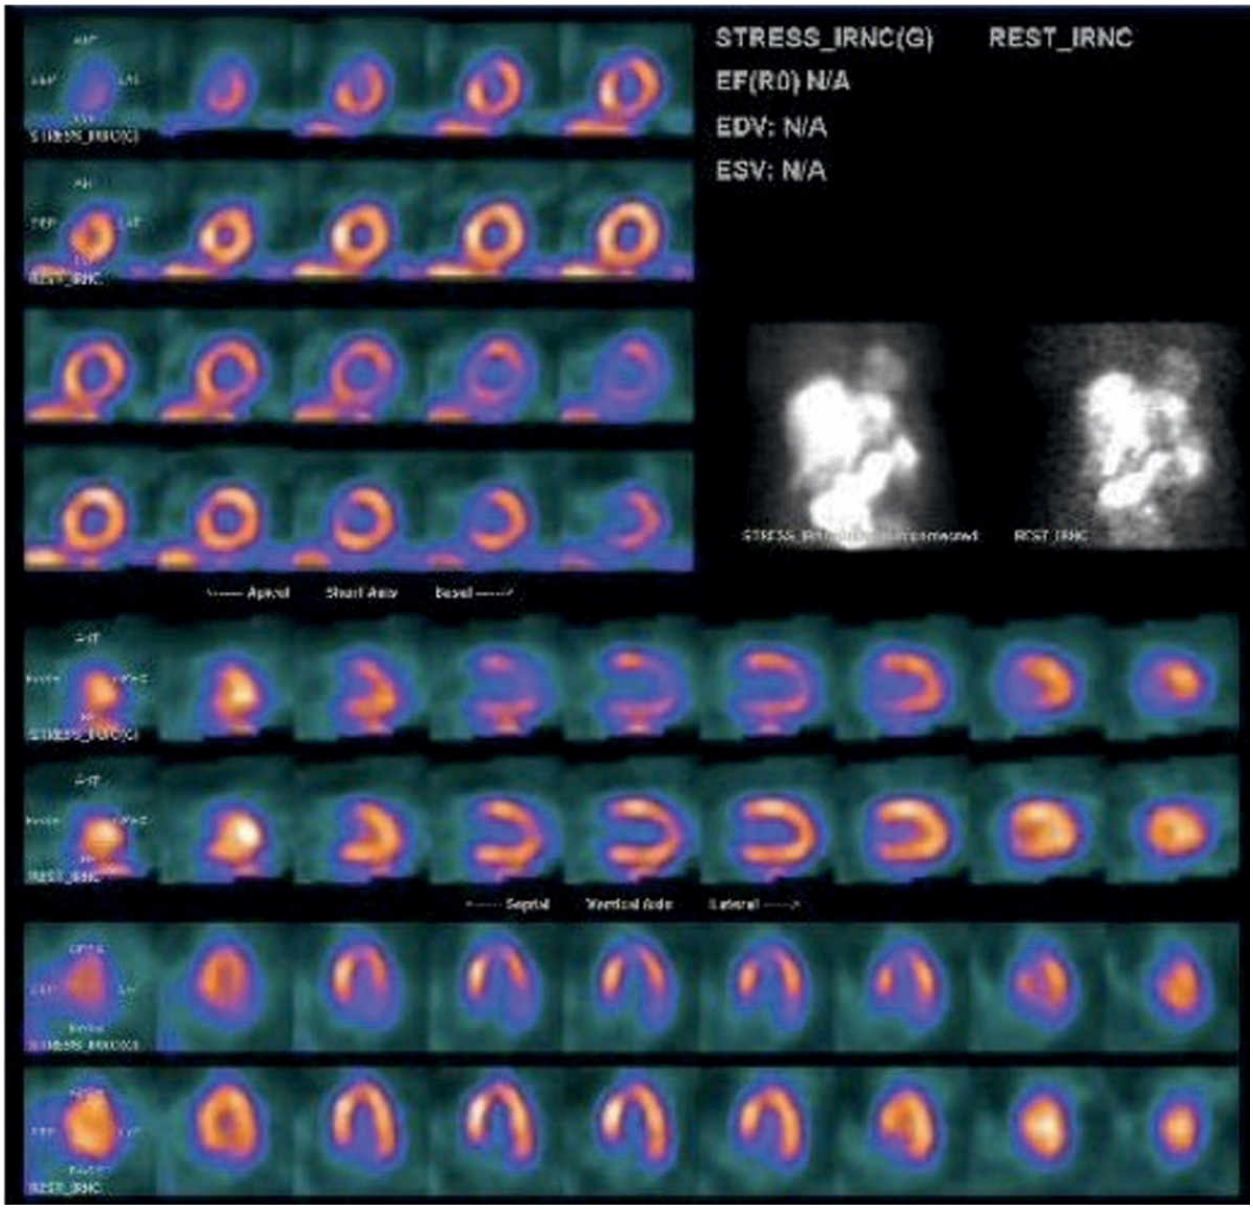

FIGURE 5.5 An example of a reversible perfusion defect. A decrease in tracer uptake is noted in the apical region that reverses on the resting images. This is a reversible perfusion defect and is indicative of ischemia in the distribution of the left anterior descending artery.

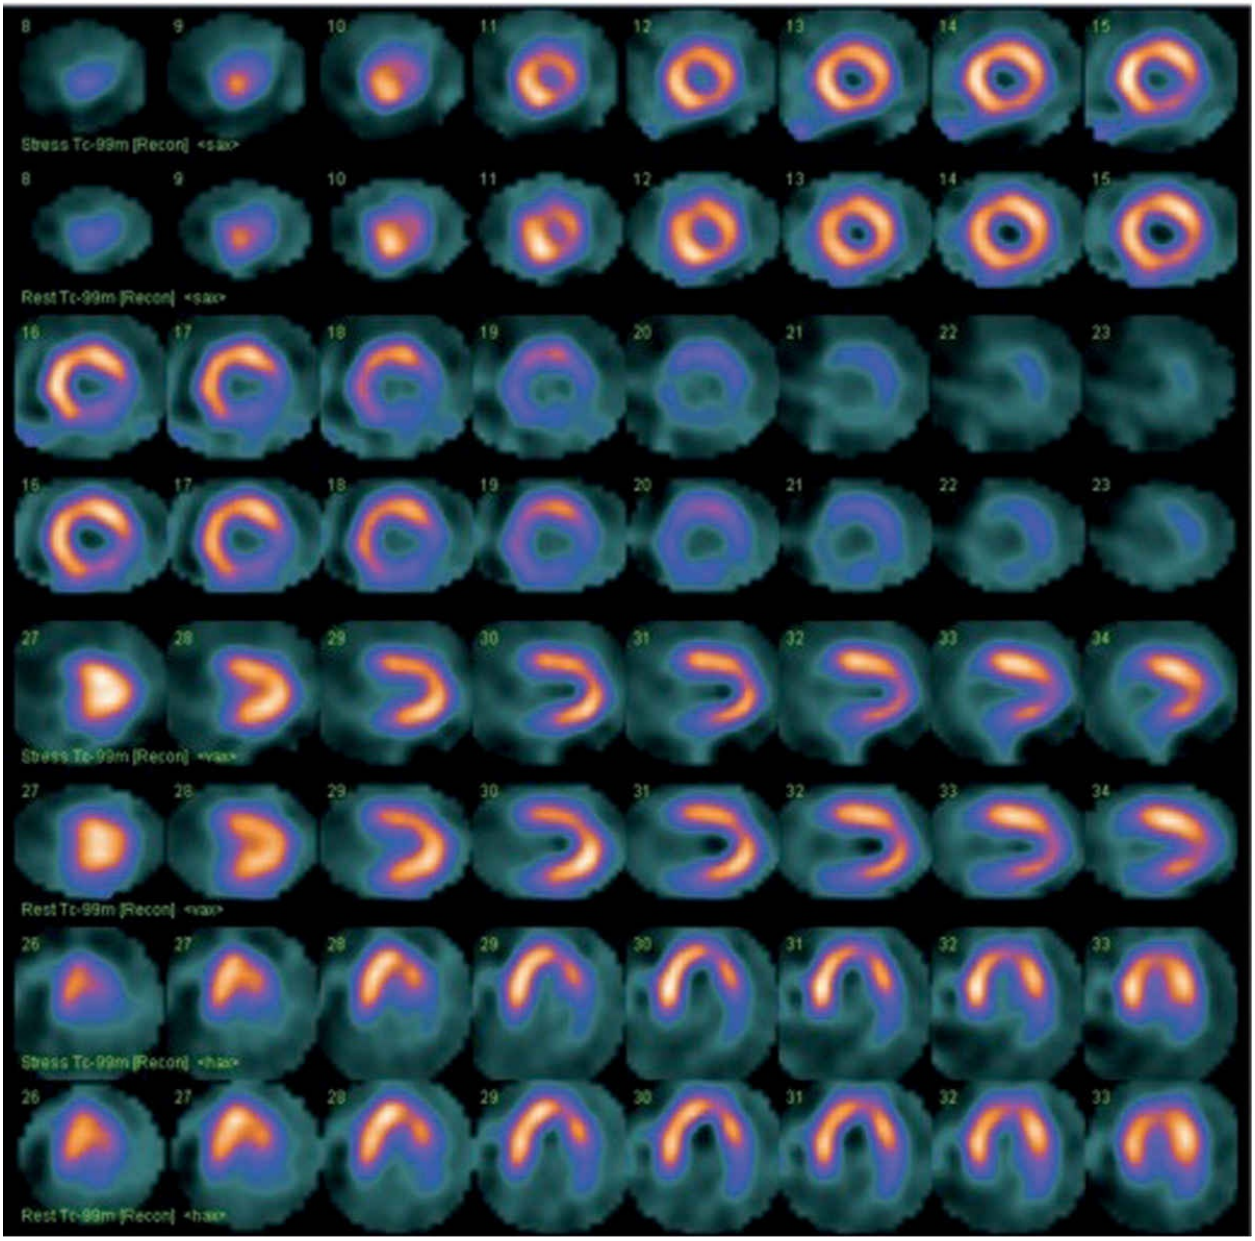

FIGURE 5.6 An example of a fixed perfusion defect. There is a decrease in tracer uptake noted in the lateral and inferior walls at the midventricle and at the base of the stress images. This finding is also noted in the rest images and is termed a fixed defect indicative of myocardial scar.

VIABILITY ASSESSMENT

In patients with established coronary artery disease and ischemic cardiomyopathy, resting wall motion abnormalities may be present, signifying areas of noncontractile myocardium. However, noncontractile myocardium is not synonymous with scarred and nonviable myocardium. In patients with acute ischemic event, the myocardium can still be viable but stunned (ie regionally

decreased contractile function) and may recover contractility over time. In patients with a high-degree coronary stenosis and limited resting blood flow, the myocardium can be in a state of hibernation and can maintain viability. With the restoration of blood flow, the hibernating myocardium can return to its contractile state and improve systolic heart function. SPECT imaging can discern viable myocardial tissue from myocardial scar by taking advantage of the redistributive properties of Tl-201. When Tl-201 is injected, it is initially distributed and taken up by the myocardium with good blood flow. Myocardial segments with limited blood flow that are viable and those myocardial segments that are scarred do not take up Tl-201 initially. Over several hours, Tl-201 will redistribute and be taken up by the myocardium that is alive but has limited blood flow, that is, the viable myocardium. Initial defects on imaging study may show reversibility upon redistribution imaging, and the extent of viable myocardium can be assessed.

ROLE OF SPECT MYOCARDIAL PERFUSION IMAGING IN PATIENTS WITH SUSPECTED ACUTE CORONARY SYNDROME

RESTING SPECT MYOCARDIAL PERFUSION IMAGING

The ideal test in patients with suspected ACS enables the clinician to diagnose it early in the course of the disease as well as stratify those patients who are at low risk and can be safely discharged compared with those who are at high risk and need further workup. As previously stated, the combination of history, physical examination, ECG, and serum troponin may be indeterminate at the time of initial evaluation, and the clinician cannot confidently determine whether the patients are experiencing an ACS. Resting SPECT MPI protocols have been developed and well studied in patients with suspected ACS having active ongoing chest pain. Multiple studies have shown that resting SPECT MPI can identify patients undergoing ACS and also those who can be safely discharged. Heller et al. studied 357 patients who presented with chest pain suspicious for myocardial ischemia and a non-diagnostic EKG. Patients underwent rest SPECT MPI with Tc-99m.[1] Among the 20 patients with myocardial infarction, 18 (90%) had abnormal SPECT images, whereas 2 had normal SPECT images, for a negative predictive value of 99%. In this study, SPECT MPI gave incremental diagnostic value over clinical and ECG variables alone, and an abnormal SPECT

was the strongest predictor of myocardial infarction. The Emergency Room Assessment of Sestamibi for Evaluation of Chest Pain (ERASE) trial was a prospective multicenter randomized trial of 2475 patients who presented with chest pain and a normal or nondiagnostic ECG.[2] The patients were randomized to usual care or usual care plus rest SPECT MPI. The authors report that there was no difference in the rate of hospitalization between the study arms among the patients with myocardial infarction. However, among those without ACS, fewer patients were hospitalized in the rest SPECT strategy than in standard care (42% vs 52%).

TRIAGING LOW-RISK PATIENTS HAVING CHEST PAIN WITH SUSPECTED ACUTE CORONARY SYNDROME

Low-risk patients with chest pain evaluated in the acute settings often have nondiagnostic initial ECG and negative cardiac biomarkers. Stress SPECT MPI can be used safely in this patient group for diagnosis and risk stratification. Multiple studies have addressed the role of different imaging modalities in assessing low-risk patients with chest pain in the emergency department and those admitted to the hospital. Most of the studies compared coronary computed tomography (CT) angiography with different stress testing modalities (such as traditional stress SPECT MPI, stress-only SPECT MPI, and stress echocardiography).[3–6] The studies showed largely comparable outcomes among patients assigned to different modalities, and the decision to proceed with a particular test should be determined by patient-specific and institution-specific characteristics. SPECT MPI tests the functionality of the heart (whether occluded coronary arteries cause ischemia of wall segments). In contrast, CTA shows the anatomy of the coronary arteries (whether there is any stenosis) but provides no information about the physiologic significance of the stenosis. Thus, both modalities can be used in complementary ways.[7]

ROLE OF SPECT IN MANAGING PATIENTS POST–MYOCARDIAL INFARCTION

Stress SPECT MPI can also be used in hemodynamically stable patients within 3 months of myocardial infarction to assess for the presence and degree of ischemia and for risk stratification purposes. It can also be used to evaluate for stent thrombosis or restenosis in patients who become symptomatic after revascularization. In general, stress testing is not used in asymptomatic patients

if they were fully revascularized, but it can be considered in asymptomatic patients with no or partial revascularization to evaluate for the usefulness of additional revascularization.[8] Myocardial perfusion SPECT using adenosine or dipyridamole infusion can be safely performed 48 hours post–myocardial infarction once the patient is hemodynamically stable.

ROLE OF RADIONUCLIDE IMAGING IN ASSESSING MYOCARDIAL VIABILITY

Thallium-201 SPECT can be used in patients with ischemic cardiomyopathy to assess viability, with the goal of revascularizing viable myocardium. Often, patients admitted to the hospital with heart failure symptoms are found to have new reductions in left ventricular ejection fraction (LVEF) without a known ischemic insult. These patients may have had silent myocardial infarction or may not have presented to the hospital when they had an acute myocardial infarction. Sometimes, patients with newly diagnosed reductions in LVEF may have nonischemic cardiomyopathy caused by long-standing hypertension or myocarditis, in which case revascularization would not be useful. SPECT MPI is useful in differentiating between ischemic and nonischemic cardiomyopathy. Other tests that are used to distinguish viable myocardium from irreversible injury include positron emission tomography, dobutamine echocardiography, and cardiac magnetic resonance.[9] Accumulating evidence is inconclusive about the role of routine viability assessment in patients with ischemic cardiomyopathy, but it can be useful in certain clinical scenarios.[10]

CONCLUSION

Although the cardiac imaging modalities have been rapidly evolving over the past decade, SPECT MPI has been shown to be a useful tool in diagnosing and risk stratifying patients with suspected ACS. It can also be occasionally used in patients post–myocardial infarction and for viability assessment in patients with ischemic cardiomyopathy.

Patient and Family Information for: USE OF RADIONUCLIDE IMAGING IN ACUTE CORONARY SYNDROME

Radionuclide imaging, often called nuclear imaging, has been used since the 1970s to image the heart. Radionuclide imaging uses radiopharmaceuticals that are given via intravenous injection. One component of a radiopharmaceutical is a tracer, a substance that is taken up from the blood by the heart muscle. The amount of the tracer extracted from the blood by the heart muscle is proportional to the amount of the blood flow to the heart muscle. The radiopharmaceutical is a radioactive substance that emits photons that can be captured by a special camera. The information from the camera allows physicians to take pictures of the heart muscle. Essentially, those pictures represent “the map” of blood flow to the heart muscle and identify the areas where the blood flow is compromised because of a blockage in the blood vessels supplying the heart.

Although nuclear imaging employs radioactive substances, the dosage given to an individual patient is relatively small. Mostly, it is in the range of radioactivity comparable to other imaging procedures such as a CT scan and is considered safe. The injection is given by a technician or a doctor. The patient is then imaged by the camera that detects the photons emitted by the radiotracer. This part of the test is crucial: the technician explains to the patient the position they need to maintain and the necessity of staying still while the pictures are obtained. The patient needs to follow the instructions carefully so that high-quality images can be obtained.

Heart attacks are caused by a decrease in the blood flow that nourishes the heart muscle. If blood flow to a part of the heart muscle is blocked, the patient

will have a heart attack and the heart muscle can die. In patients who experience chest pain, it is often difficult to determine if the pain is a sign of heart disease. The initial tests for patients with chest pain include an ECG and blood tests. If these tests are inconclusive, the physician may opt to perform radionuclide imaging. Radionuclide imaging maps the blood flow to the heart and is useful in identifying a blood vessel blockage that may signify a heart attack. In patients who have experienced a heart attack, radionuclide imaging enables physicians to determine who will benefit from procedures that restore blood flow to the heart muscle.

The idea behind the stress test is to compare resting images of the heart to those obtained after the stress test. The stress portion can be performed with either exercise or medication. During an exercise stress test, the patient is asked to exercise on a treadmill or a stationary bicycle. If the patient cannot exercise or the physician thinks it is unsafe for the patient to exercise, a medication can be used. The physician or a trained health care professional is always present in the room for the stress test. In general, stress testing is safe and well tolerated, although some patients may experience brief side effects (headache, nausea, chest discomfort) from the medication. Serious events, including heart attacks and heart rhythm disturbances, are rare.

During radionuclide stress testing, two sets of heart images—the rest images and the stress images—are usually obtained as previously described. By comparing the two sets of images, the physician can determine whether there is an impairment of blood flow to the heart. If significant blood flow impairment is identified by the stress test, the patient may be referred for an invasive procedure called cardiac catheterization.

Computed Tomographic Angiography in Acute Cardiac Care

INTRODUCTION

Contrast-enhanced multidetector computed tomography (MDCT), which provides high-quality noninvasive images of the heart, great vessels, and coronary vasculature, has been shown to be useful and reliable in the triage of patients with chest pain of possible ischemic origin and specifically in the diagnosis of acute coronary syndrome. Current generation computed tomography (CT) scanners (64-slice and higher) require minimal patient cooperation (short breath hold) and have improved image quality (better spatial and temporal resolution) and high diagnostic accuracy. MDCT can visualize coronary plaques and is also gaining a role in the evaluation of coronary stents and bypass grafts and for evaluation of patients undergoing structural or electrophysiologic cardiac interventions.

TECHNICAL CONSIDERATION

New generation CT scanners allow rapid scanning of the heart by a high gantry

rotation speed and wider coverage of the field of view than initial scanners, thus allowing a “freeze” in cardiac motion and overcoming many previously observed breathing artifacts. Some scanners allow a single beat acquisition and very rapid reconstruction of scanned data to be presented to the reader.

However, despite these advancements, it is still recommended to lower the patient heart rate to <65 beats/min to optimize image quality. In the absence of contraindications, it is also recommended to administer sublingual nitroglycerin just prior to scanning to allow coronary vasodilation and improved image quality.

The scan itself is performed using electrocardiogram (ECG) gating to image and reconstruct the heart and the coronary vessels during a certain phase in the cardiac cycle, usually diastole.

About 50 to 100 mL of intravenous contrast media (iodine-based) is typically used to allow opacification of the coronary vessels.

After scanning, the data can be viewed and manipulated on a PC-based or dedicated workstation that utilizes sophisticated software to optimize analysis and overcome artifacts.

CLINICAL USEFULNESS OF CARDIAC CT

NONCONTRAST CALCIUM SCORING

Quantitative assessment of the extent of coronary arterial calcification by electron beam CT had been available for several years before the advent of MDCT. When categorized according to a defined scoring system (eg, the Agatston calcium score), calcification can predict subsequent coronary events in various cohorts. However, calcium scoring is usually performed for screening asymptomatic subjects, especially those with intermediate risk for future cardiovascular adverse events. Those are the patients in whom calcium scoring may identify or rule out definite coronary atherosclerosis (coronary calcifications) and may impact the physician’s decision in regard to primary preventive therapies.

CONTRAST-ENHANCED CARDIAC CT APPLICATIONS

Coronary CT angiography (CCTA) is used to diagnose coronary atherosclerosis and coronary narrowing. CCTA is considered the noninvasive test with the highest sensitivity to diagnose coronary stenosis when compared to invasive

coronary angiography as the reference standard. This test has a very high negative predictive value (>98%), making it a useful tool to rule out coronary stenosis. On the other hand, because of motion artifacts and coronary calcifications, the positive predictive value is somewhat lower but still very good (85% to 92%).

One of the areas where CCTA has been shown to be especially useful is in the emergency department setting. Patients with acute chest pain but without high-risk features (such as elevated troponin, ECG changes indicative of ischemia, or recurrent/ongoing chest pain) are good candidates for CCTA. A normal or near-normal scan has been shown to be safe and effective in shortening hospital stay (**Figure 6.1**). Infrequently, a "triple rule out" protocol may be used to exclude pulmonary emboli or thoracic aortic dissection in addition to coronary stenosis.

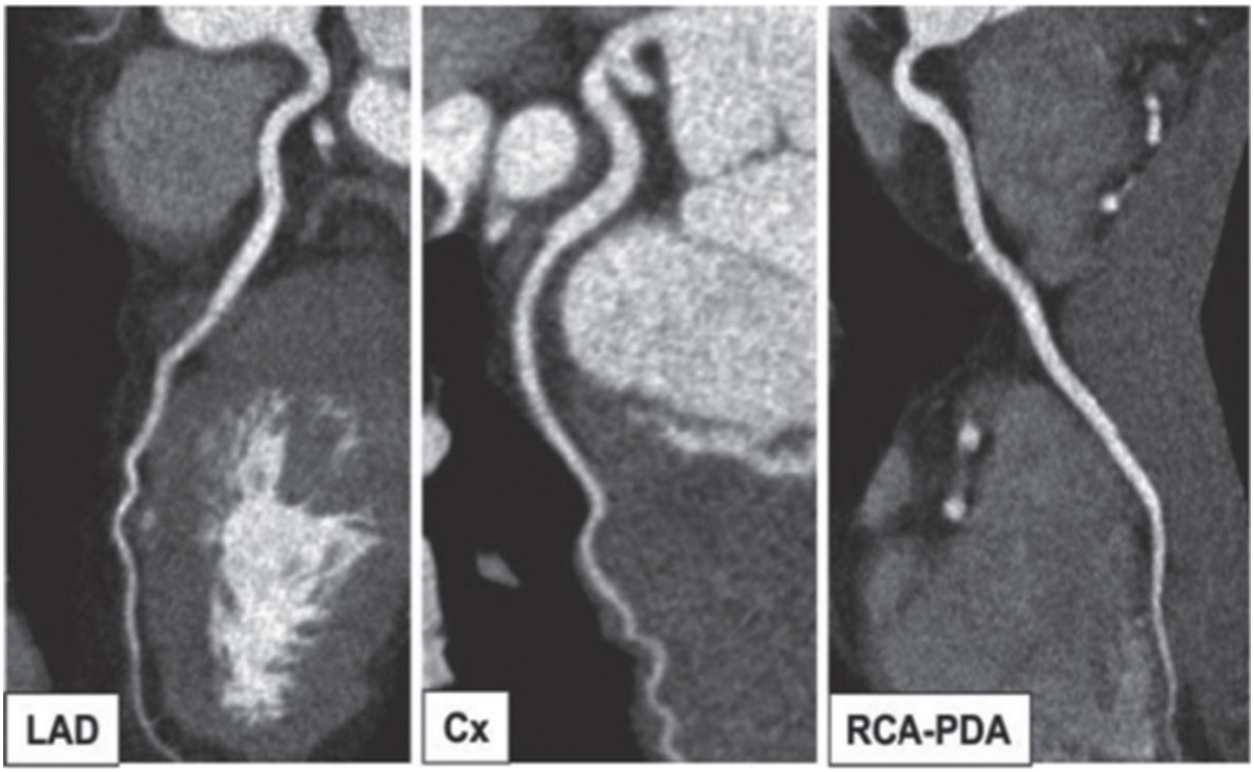

FIGURE 6.1 Normal coronary arteries by coronary computed tomography angiography in a patient with acute chest pain. Cx, circumflex coronary artery; LAD, left anterior descending artery; PDA, posterior descending artery; RCA, right coronary artery.

In contrast to conventional invasive coronary angiography, which allows visualization of the coronary lumen but provides only minimal details of the coronary plaque, CCTA can demonstrate the details of coronary plaques

(noncalcified/calcified/mixed), and several features that may be demonstrated by CCTA have been suggested to be associated with higher risk of adverse coronary events. Those include low attenuation plaque (<30 Hounsfield units), spotty calcifications (within a non-calcified plaque), and “napkin ring” sign (**Figure 6.2**). Other features shown to be of clinical relevance are plaque eccentricity and positive remodeling.

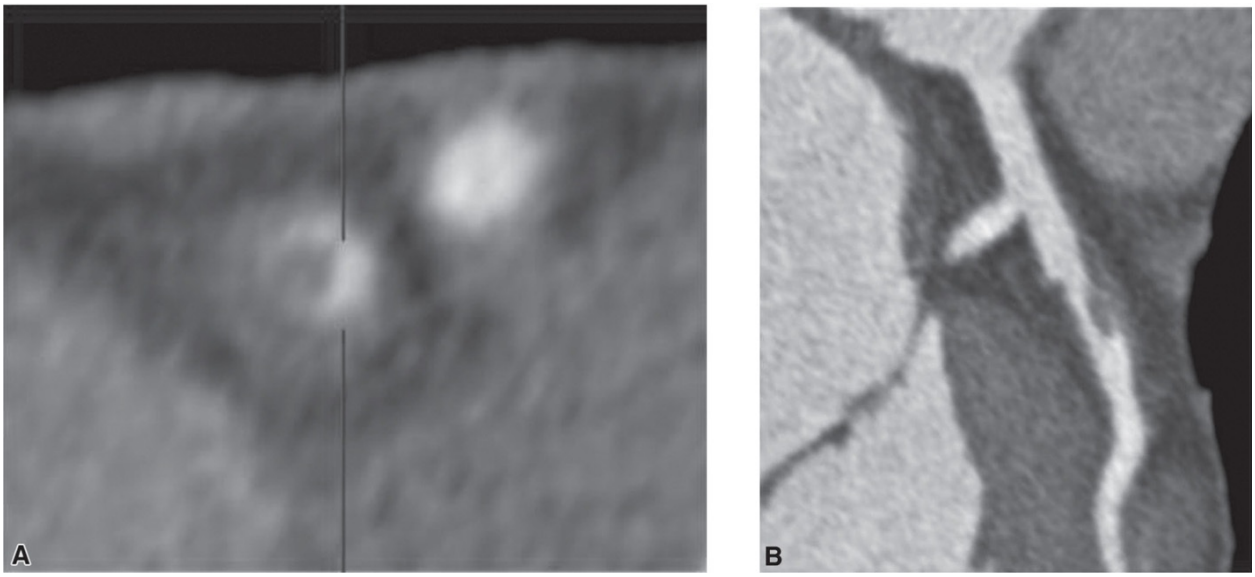

FIGURE 6.2 Cross-section view (A) and long axis (multiplanar reformation) (B) of the left anterior descending coronary artery showing a possible ruptured plaque (napkin ring sign) and stenosis.

The presence of nonobstructive coronary atherosclerosis as well as obstructive disease on CCTA has been shown to be of prognostic value. The higher the burden of disease, the higher the likelihood of future cardiovascular events (and vice versa).

Recently, it has been shown that CCTA can also be used to evaluate the physiologic significance of a coronary stenosis (computed tomographic fractional flow reserve) using complex models of computational flow dynamics.

Of note, this may also be shown by using CT for assessment of myocardial perfusion (rest or stress induced), where myocardial hypoenhancement limited to a vessel territory may be indicative of ischemia or infarction.

CCTA is also very useful in the characterization of coronary anomalies or myocardial bridging.

Beyond evaluation of the native coronary vessels, CCTA can evaluate the patency of coronary stents, especially stents ≥3 mm wide, albeit with reduced

diagnostic accuracy related to metallic artifacts (**Figure 6.3**). Diagnosis is also possible in patients with coronary bypass grafts (**Figure 6.4**), but again with somewhat reduced accuracy because of the presence of metallic clips in the distal anastomosis and the diffuse nature of calcified coronary atherosclerosis in those patients.

FIGURE 6.3 Patent stent in the left anterior descending coronary artery demonstrated by coronary computed tomography angiography.

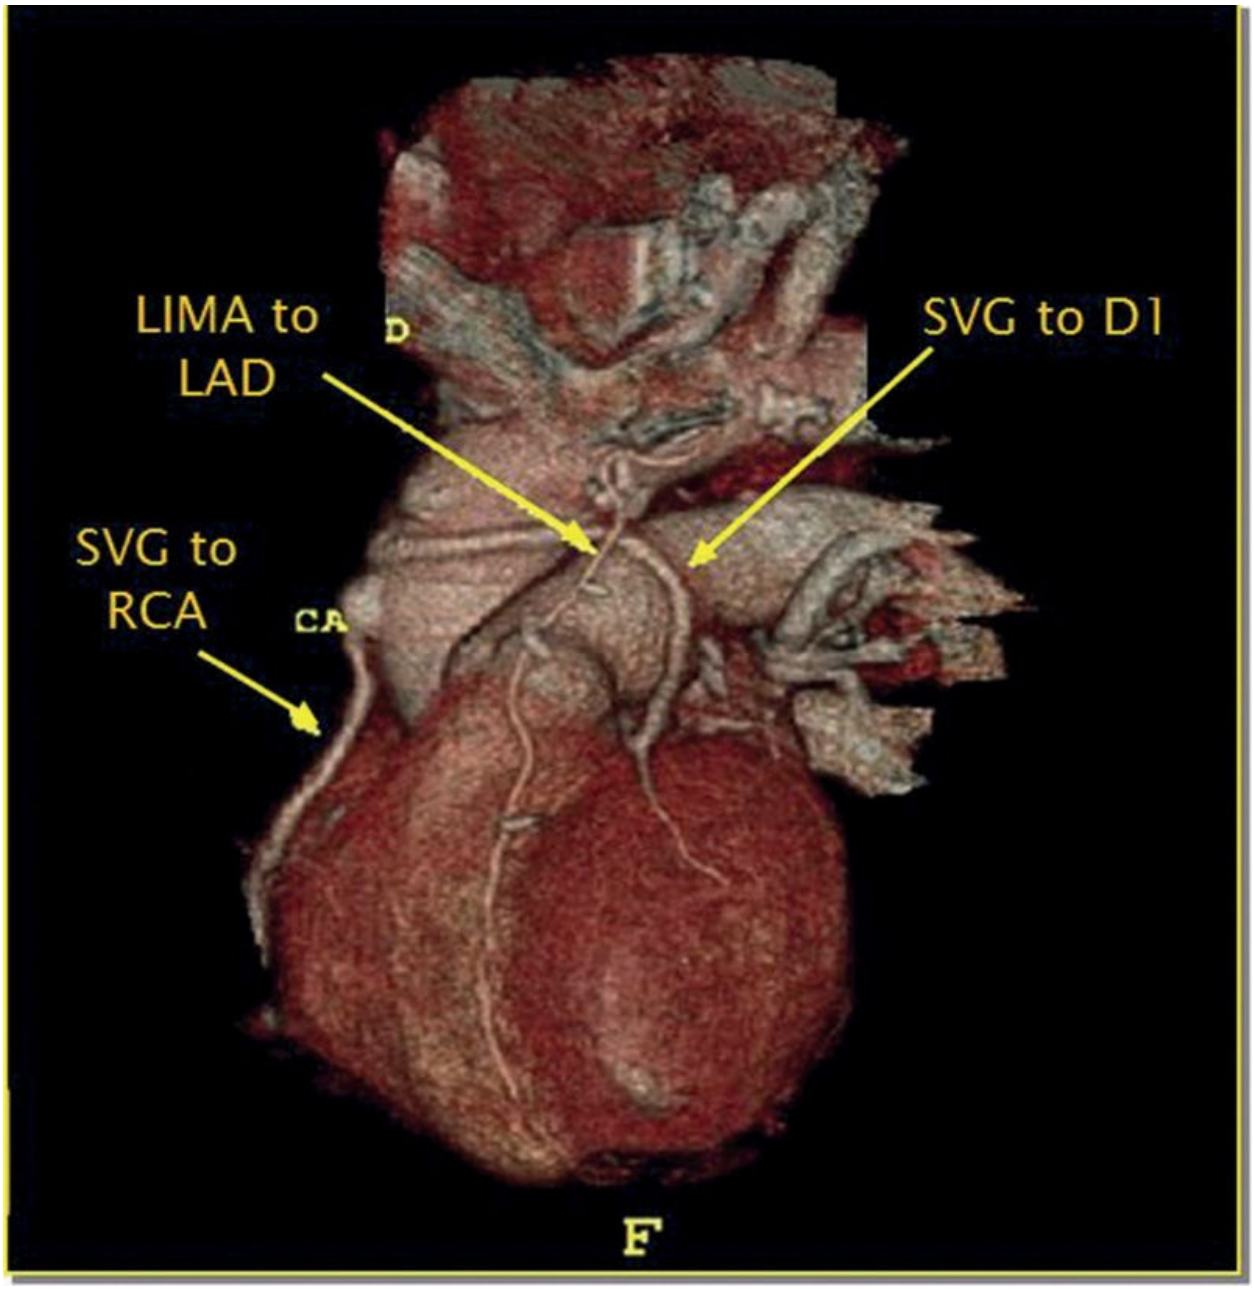

FIGURE 6.4 Volume-rendered image of the heart in a patient with a history of coronary bypass grafting. D1, first diagonal batch; LAD, left anterior descending artery; RCA, right coronary artery; SVG, saphenous vein graft; LIMA, left internal mammary artery.

An increasing indication is the evaluation of cardiac structures before interventional cardiac procedures, most importantly for evaluation of the aortic valve and root before transarterial aortic valve replacement or evaluation of the pulmonary veins draining into the left atrium before pulmonary vein isolation (ablation) in patients with atrial fibrillation.

SUMMARY

Cardiac CT is a powerful diagnostic tool, mostly used for the diagnosis of obstructive coronary atherosclerosis in symptomatic patients. Technical advancement in recent years has led to a significant reduction in radiation exposure to patients without compromising image quality. Several future trends in the development of cardiac CT systems may also increase its usefulness for clinical use. Those include the development of dual energy or spectral CT systems that may improve tissue diagnosis and the rapid development in the field of fusion imaging allowing visualization (even in real time) of images derived from two different modalities (eg, two-dimensional angiography and CT or echocardiography and CT).

The exponential increase in the number of structural heart interventions and the increased usefulness that may be derived from combining anatomic and physiologic assessment of the coronary tree are expected to accelerate the use of this imaging modality for cardiovascular diagnosis.

Patient and Family Information for: COMPUTED TOMOGRAPHIC ANGIOGRAPHY IN ACUTE CARDIAC CARE

Coronary computed tomographic angiography (CTA) is a simple X-ray study involving injection of approximately 6 ounces of contrast containing iodine into an arm vein while the patients hold their breath for 5 seconds. This will be accompanied by a warm sensation throughout the body some patients may find this mildly uncomfortable.

If there is a known allergy to intravenous contrast, premedication with steroids and diphenhydramine will be required. There is no relationship between seafood and contrast allergies. Patients will be able to leave unaccompanied immediately afterward. The X-ray machine is open and does not produce claustrophobia. The CTA provides very detailed pictures of the coronary arteries that are very accurate in determining whether there is narrowing in the arteries. It also produces excellent pictures of the aorta and heart muscle.

Coronary Angiography and Percutaneous Coronary Intervention

CARDIAC CATHETERIZATION AND ANGIOGRAPHY

Sones and colleagues performed the first coronary arteriography in 1959. Since its advent, cardiac catheterization and coronary angiography have remained the gold standard for diagnosis of coronary artery disease (CAD) as well as structural and valvular heart disease. Although advances in imaging, including cardiac computed tomography and cardiac magnetic resonance imaging, have enhanced the diagnosis of many forms of heart disease, coronary angiography along with advances in percutaneous coronary intervention (PCI) and structural heart disease intervention has revolutionized our ability to manage patients with ischemic, non-ischemic and structural heart disease.

Indications

The indications for cardiac catheterization and coronary angiography are varied. They include acute coronary syndromes such as ST-elevation myocardial infarction (STEMI) as well as non-ST-elevation myocardial infarction (NSTEMI), unstable coronary syndromes without infarction, heart failure,

valvular heart disease, arrhythmia, and sudden cardiac death. In some of these instances, the procedure will be for diagnostic purposes only, but for others, it will be a prelude to intervention.

STABLE ISCHEMIC HEART DISEASE

Coronary angiography is performed in patients with stable ischemic heart disease (SIHD) either as an initial strategy to assess risk or after a workup with noninvasive testing. The 2012 and 2014 multisociety guidelines on diagnosis and management of patients with SIHD have recommended diagnostic angiography based on clinical presentation, symptoms, and findings on noninvasive testing (**Tables 7.1 and 7.2**).[1, 2]

TABLE 7.1 Noninvasive Risk Stratification in Patients With Stable Ischemic Heart Disease[1, 2]

HIGH RISK (>3% ANNUAL DEATH OR MI)
Severe resting LV dysfunction (LVEF<35%) not readily explained by noncoronary causes
Resting perfusion abnormalities ≥10% of the myocardium in patients without prior history or evidence of MI
Stress ECG findings including ≥2 mm of ST-segment depression at low workload or persisting into recovery, exercise-induced ST-segment elevation, or exercise-induced VT/VF
Severe stress-induced LV dysfunction (peak exercise LVEF <45% or drop in LVEF with stress ≥10%)
Stress-induced perfusion abnormalities encumbering ≥10% myocardium or stress segmental scores indicating multiple vascular territories with abnormalities
Inducible wall motion abnormality (involving >2 segments or 2 coronary beds)
Wall motion abnormality developing at low dose of dobutamine (≤10 mg/kg/min) or at a low heart rate<120 beats/min)
CAC score >400 Agatston units
Multivessel obstructive CAD (≥70% stenosis) or left main stenosis ≥50% stenosis) on CCTA
INTERMEDIATE RISK (1-3% ANNUAL DEATH OR MI)
Mild/moderate resting LV dysfunction (LVEF 35% to 49%) not readily explained by noncoronary causes
Resting perfusion abnormalities in 5% to 9.9% of the myocardium in patients without a history or prior evidence of MI
≥1 mm of ST-segment depression occurring with exertional symptoms
Stress-induced perfusion abnormalities encumbering 5% to 9.9% of the myocardium or stress segmental scores (in multiple segments) indicating 1 vascular territory with abnormalities but without LV dilation
Small wall motion abnormality involving 1 to 2 segments and only 1 coronary bed
Coronary Artery Calcium score 100 to 399 Agatston units
One vessel CAD (≥70% stenosis) or moderate CAD stenosis (50% to 69% diameter stenosis) of CCTA in ≥2 arteries on CCTA
LOW RISK (< 1% ANNUAL DEATH OR MI)
Low-risk treadmill score (score ≥5) or no new ST segment changes or exercise-induced chest pain symptoms; when achieving maximal levels of exercise
Normal or small myocardial perfusion defect at rest or with stress encumbering <5% of the myocardium
Normal stress or no change of limited resting wall motion abnormalities during stress
CAC score <100 Agatston units
No coronary stenosis >50% on CCTA

CAC, coronary artery calcium; CAD, coronary artery disease; CCTA, coronary computed tomography angiography; ECG, electrocardiogram; LV, left ventricular; LVEF, left ventricular ejection fraction; MI, myocardial infarction; VF, ventricular fibrillation; VT, ventricular tachycardia.

TABLE 7.2 Indications for Coronary Angiography in Stable Ischemic Heart Disease[1, 2]

INDICATIONS FOR CORONARY ANGIOGRAPHY IN STABLE ISCHEMIC HEART DISEASE			
Class I	***Class IIA***	***Class IIB***	***Class III***
Coronary angiography is useful in patients with presumed SIHD who have unacceptable ischemic symptoms despite GDMT and who are amenable to, and candidates for, coronary revascularization. (Level of Evidence: C)	Coronary angiography is reasonable to further assess risk in patients with SIHD who have depressed LV function (Ejection Fraction <50%) and moderate risk criterion noninvasive testing with demonstrable ischemia. (Level of Evidence: C)	Coronary angiography might be considered in patients with stress test results of acceptable quality that do not suggest the presence of CAD when clinical suspicion of CAD remains high and there is a high likelihood that the findings will result in important changes to therapy. (Level of Evidence: C)	Coronary angiography for risk assessment is not recommended in patients with SIHD who elect not to undergo revascularization or who are not candidates for revascularization because of comorbidities or individual preferences. (Level of Evidence: B)
Patients with SIHD who have survived sudden cardiac death or potentially life-threatening ventricular arrhythmia should undergo coronary angiography to assess cardiac risk. (Level of Evidence: B)	Coronary angiography is reasonable to further assess risk in patients with SIHD and inconclusive prognostic information after noninvasive testing or in patients for whom noninvasive testing is contraindicated or inadequate. (Level of Evidence: C)		Coronary angiography is not recommended to further assess risk in patients with SIHD who have preserved LV function (Ejection Fraction >50%) and low-risk criteria on noninvasive testing. (Level of Evidence: B)
Patients with SIHD who develop symptoms and signs of heart failure should be evaluated to determine whether coronary angiography should be performed for risk assessment. (Level of Evidence: C)	Coronary angiography for risk assessment is reasonable for patients with SIHD who have unsatisfactory quality of life because of angina, have preserved LV function (Ejection Fraction >50%), and have intermediate risk criteria on noninvasive testing. (Level of Evidence: C)		Coronary angiography is not recommended to assess risk in patients who are at low risk according to clinical criteria and who have not undergone noninvasive risk testing. (Level of Evidence: C)
Coronary arteriography is recommended for patients with SIHD whose clinical	Coronary angiography is reasonable to define the extent and severity of CAD in patients with suspected SIHD whose		Coronary angiography is not recommended to

characteristics and results of noninvasive testing indicate a high likelihood of severe IHD and when the benefits are deemed to exceed risk. (Level of Evidence: C)	clinical characteristics and results of noninvasive testing (exclusive of stress testing) indicate a high likelihood of severe IHD and who are amenable to, and candidates for, coronary revascularization. (Level of Evidence: C)	assess risk in asymptomatic patients with no evidence of ischemia on noninvasive testing. (Level of Evidence: C)
	Coronary angiography is reasonable in patients with suspected symptomatic SIHD who cannot undergo diagnostic stress testing or have indeterminate or nondiagnostic stress tests, when there is a high likelihood that the findings will result in important changes to therapy. (Level of Evidence: C)	

CAD, coronary artery disease; GDMT, guideline-directed medical therapy; IHD, ischemic heart disease; LV, left ventricular; SIHD, stable ischemic heart disease.

REDUCED LEFT VENTRICULAR EJECTION FRACTION

Coronary angiography is considered reasonable when ischemia may be a contributing factor for heart failure to assess the patency of coronary arteries.[3] This may be part of a workup that includes echocardiography, viability studies, and MRI.

SUDDEN CARDIAC DEATH OR VENTRICULAR ARRHYTHMIA

Coronary angiography is an important tool in the assessment of CAD in survivors of cardiac arrest and patients with life-threatening ventricular arrhythmia.[4] If cardiac arrest is associated with ST elevations, coronary angiography should be performed emergently.

PREOPERATIVE CORONARY ANGIOGRAPHY

Routine use of preoperative coronary angiography for noncardiac surgery is not recommended. Indications of coronary angiography are similar to those applied in a nonoperative setting.[5]

For patients who are undergoing cardiac surgery for valvular heart disease, aortic disease, or other structural heart disease, coronary angiography is recommended as part of the preoperative workup for nonemergency indications.

CORONARY ANATOMY

Optimal myocardial function is based on a delicate balance of supply and demand achieved through coronary arterial circulation. Coronary arterial circulation consists of two parts—the conduit vessels formed by large epicardial coronary arteries and resistance vessels formed by medium- and small-sized coronary arterioles. The coronary arterial circulation originates from the aorta as two main branches—the left coronary artery, which consists of the left main coronary artery (LMCA), the left anterior descending and the circumflex artery —and the right coronary artery (RCA). There can be some anatomic variations to this pattern. The left and right coronary arteries arise from the left and right coronary cusps, respectively. Dominance is referred to as right or left, depending on whether the RCA or the left coronary artery supplies the posterior descending artery (PDA). In about 70% of patients, the PDA is a branch of the RCA, and this is referred to as a right dominant circulation. In 20% of individuals, the PDA is codominant or balanced in both the left circumflex artery (LCx) and the RCA, and in 10% of individuals, the PDA arises from the LCx.

In order to correlate angiographic views with coronary anatomy, it is useful to consider the main coronary arteries in two orthogonal planes. The left anterior descending and the posterior descending arteries course along the plane of the interventricular septum. The LCx and the RCA run along the plane of the atrioventricular valve perpendicular to the plane of the interventricular septum.

LEFT CORONARY ARTERY

The LMCA is the first portion of the left coronary artery. The LMCA usually bifurcates into the left anterior descending artery (LAD) and the LCx. In some individuals, there may be a trifurcation into a ramus intermedius branch. The LAD artery initially runs along the anterior interventricular groove and terminates at the apex in most individuals. During its course, it gives out septal branches that supply the anterior two-thirds of the interventricular septum, and diagonal branches that supply the anterolateral wall of the left ventricle. The LCx travels along the left atrioventricular groove and gives rise to the obtuse marginal branches. The obtuse marginal branches supply the lateral wall of the left ventricle.

RIGHT CORONARY ARTERY

The RCA runs along the right atrioventricular groove in a mirror fashion to the LCx artery, perpendicular to the long axis of the heart. The first branch arising from the RCA is called the conus artery, which supplies the right ventricular outflow tract. The second branch arising from the RCA is a sinoatrial branch, which supplies the sinus node. It arises out of the RCA in about 60% cases and from the LCx in 40% of individuals. The acute marginal branch arises from the midsegment of the RCA supplying the right ventricle. The RCA gives off the PDA and at least one posterolateral branch in a right dominant circulation.

POSTERIOR DESCENDING ARTERY

The PDA runs along the posterior interventricular groove parallel to the LAD running in the anterior interventricular groove and meeting the LAD along the apical portion of the interventricular septum. It supplies the inferoposterior aspects of the left ventricle and gives off septal branches to supply the inferior aspect of the interventricular septum.

POSTEROLATERAL BRANCHES

The posterolateral branches arise as terminal portions of either the RCA after the origin of the PDA or the LCx. They supply the inferior and posterior segments of the left ventricle.

ANGIOGRAPHIC PROJECTIONS

An accurate assessment of coronary arteries requires obtaining multiple angiographic projections to avoid any overlap of vessels. The position of the image intensifier in relation to the patient's body defines the projections. Left anterior oblique (LAO) and right anterior oblique (RAO) describe the position of the image intensifier to the left or right of a patient's chest, respectively. The anteroposterior (AP) views describe the image intensifier directly over the patient. Cranial and caudal projections describe the position of the image intensifier toward the head (cranial) or feet (caudal). The left coronary system requires an AP caudal to assess the LMCA, LAO cranial for the LAD and its branches. The LAO caudal (spider view) is helpful for assessment of the LMCA, proximal LAD, and proximal LCx. The RAO caudal view is useful for the LCx and its obtuse marginal branches, and the RAO cranial view for mid- and distal

LAD along with diagonal branches (**Figure 7.1A** and **B**). The RCA should be visualized in LAO cranial, which shows the RCA along with the PDA and a RAO projection with cranial angulation for mid-RCA and the entire course of the PDA (**Figure 7.2**). Additional views may be obtained based on the individual patient's coronary anatomy.

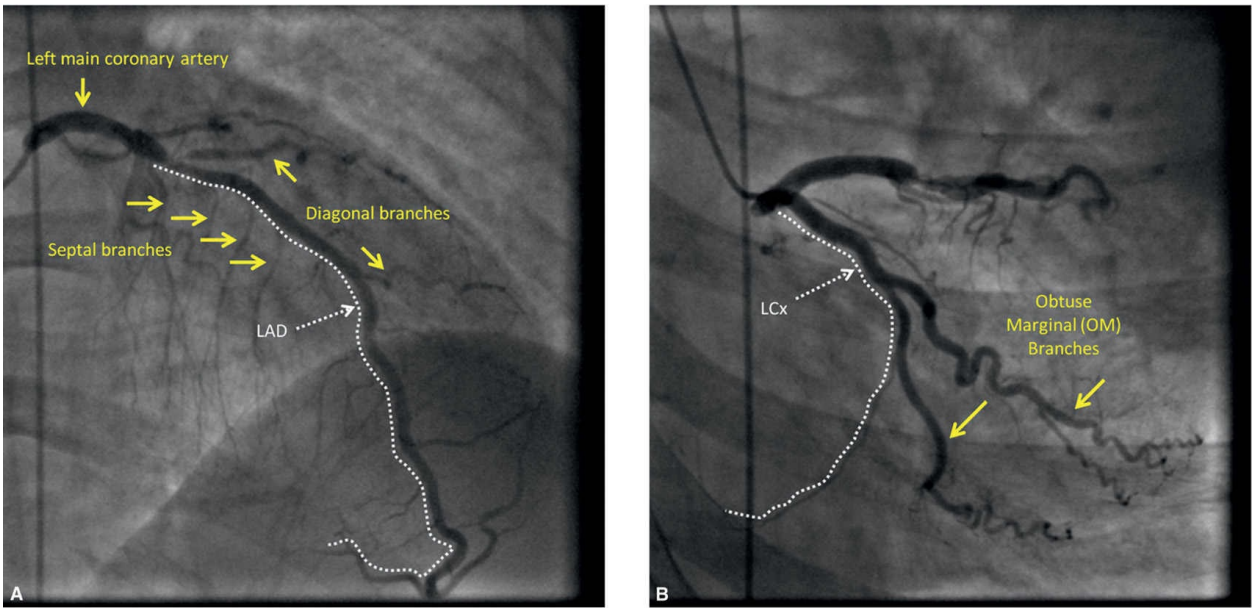

FIGURE 7.1 A, Left anterior descending artery (LAD) and its major branches visualized in a cranially and a slightly rightward angulated view (right anterior oblique [RAO] –9°; cranial +36°). B, Nondominant left circumflex (LCx) artery and its major branches visualized in a caudally and a slightly rightward angulated view (RAO –6°; caudal –21°).

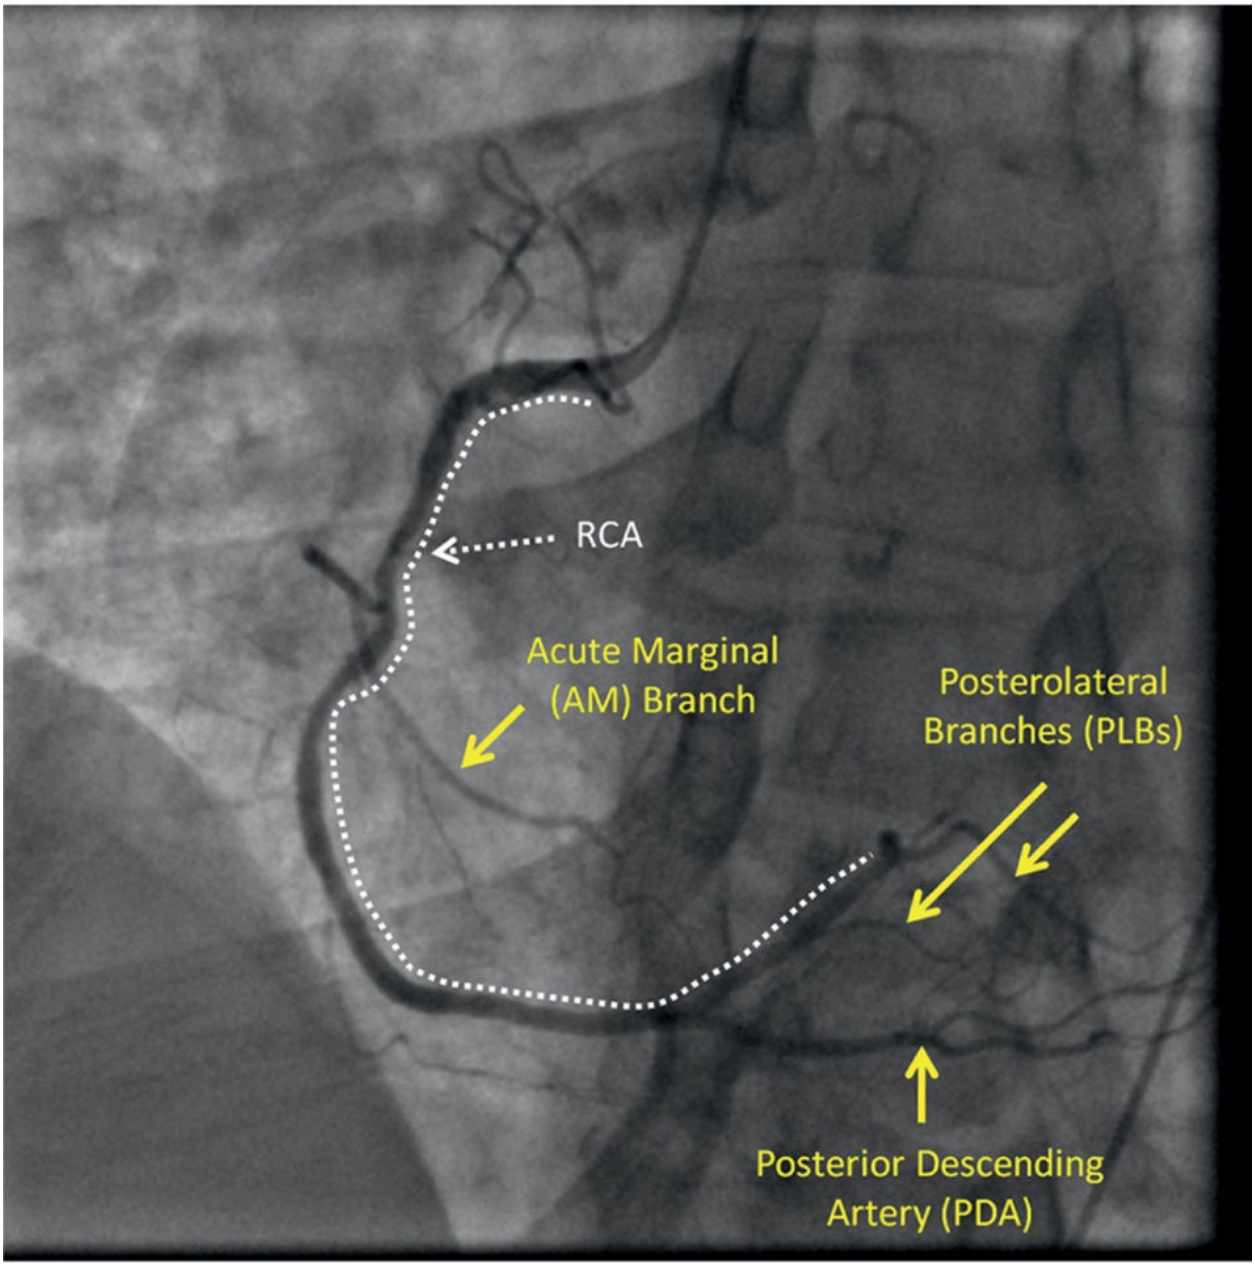

FIGURE 7.2 Dominant right coronary artery (RCA) and its major branches visualized in a slightly cranially angulated left anterior oblique (LAO) view (LAO +28°; cranial +3°).

PREPROCEDURE PREPARATION

CONSENT

The physician performing the cardiac catheterization should obtain informed consent from the patient. The discussion should include the indication for

coronary angiography and PCI if indicated, an overview of the procedure, and risk/benefits of the procedure. The following risks, although not inclusive, should be reviewed with the patient.[6]

Mortality (0.1%)
Myocardial infarction (0.05%)
Cerebrovascular accident (0.07%)
Arrhythmia (0.38%)
Vascular complications and bleeding (0.43%)
Contrast reaction (0.37%)
Hemodynamic complication (0.26%)
Perforation of heart chamber (0.03%)

MEDICATIONS AND ALLERGIES

Complete medication reconciliation along with a review of allergies should be performed before the procedure. Special attention should be given to prior allergies to contrast agents. Mild to moderate reactions can usually be pretreated with diphenhydramine and/or steroids. Careful assessment of risk and benefits along with allergy consultation should be done for more serious reactions. Metformin should be discontinued on the day of the procedure and 48 hours thereafter. Patients on chronic warfarin therapy should have an international normalized ratio < 1.8 for femoral access if anticoagulation can be withheld.[7] Alternatively, radial access can be considered for these patients. The timing of discontinuation for newer oral anticoagulants is guided by the patient's renal function and the particular agent but should be discontinued at least 1 to 2 days prior to the procedure.[7]

PREPROCEDURE WORKUP

A recent laboratory evaluation with baseline renal function, hemoglobin, and coagulation studies (if indicated) should be performed within 30 days in the outpatient setting and within 24 hours in the inpatient setting.[7] Patients with preexisting renal dysfunction or elevated risk scores[8] are at high risk for contrast-induced nephropathy (CIN) and should be considered for adequate hydration with normal saline pre- and periprocedural. The electrocardiogram should be reviewed for all patients because it can help localize the culprit vessel, particularly in the setting of ST-elevation myocardial infarction. Prior

angiograms and operative reports for patients with a history of coronary artery bypass grafting (CABG) should also be reviewed if available.

CONSCIOUS SEDATION

A complete assessment of comorbidities and physical examination should be performed before the procedure. Airway assessment using the Mallampati classification and the American Society of Anesthesiologists Physical Status Classification can help in assessing the patient's eligibility for conscious sedation. Conscious sedation is usually achieved with short-acting agents such as midazolam and fentanyl.

A physical exam should be performed prior to the procedure and include auscultation of the heart for previously undiagnosed murmurs and documentation of neurologic exam, including any pre-existing deficits. A careful assessment of peripheral pulses, including femoral, dorsalis pedis, and posterior tibial, should be recorded in the chart.

ARTERIAL ACCESS

Coronary angiography can be performed using a modified Seldinger technique at three possible sites:

1. Femoral artery
2. Radial artery
3. Brachial artery

FEMORAL ARTERY

The common femoral artery courses medial to the femoral head and bifurcates into the superficial femoral artery and profunda femoris artery distal to the midpoint of the femoral head. The femoral artery should ideally be accessed above the bifurcation and below the inferior epigastric artery. The femoral artery (right or left) is accessed using a modified Seldinger technique with anatomic landmarks and fluoroscopy guidance to locate the midpoint of the femoral head. A 5F or 6F sheath is usually used for diagnostic cardiac catheterization (**Figure 7.3**). There is a risk of retroperitoneal bleeding if the sheath is placed above the inguinal ligament. The risk of a pseudoaneurysm increases if the sheath is placed

below the bifurcation of the common femoral artery.

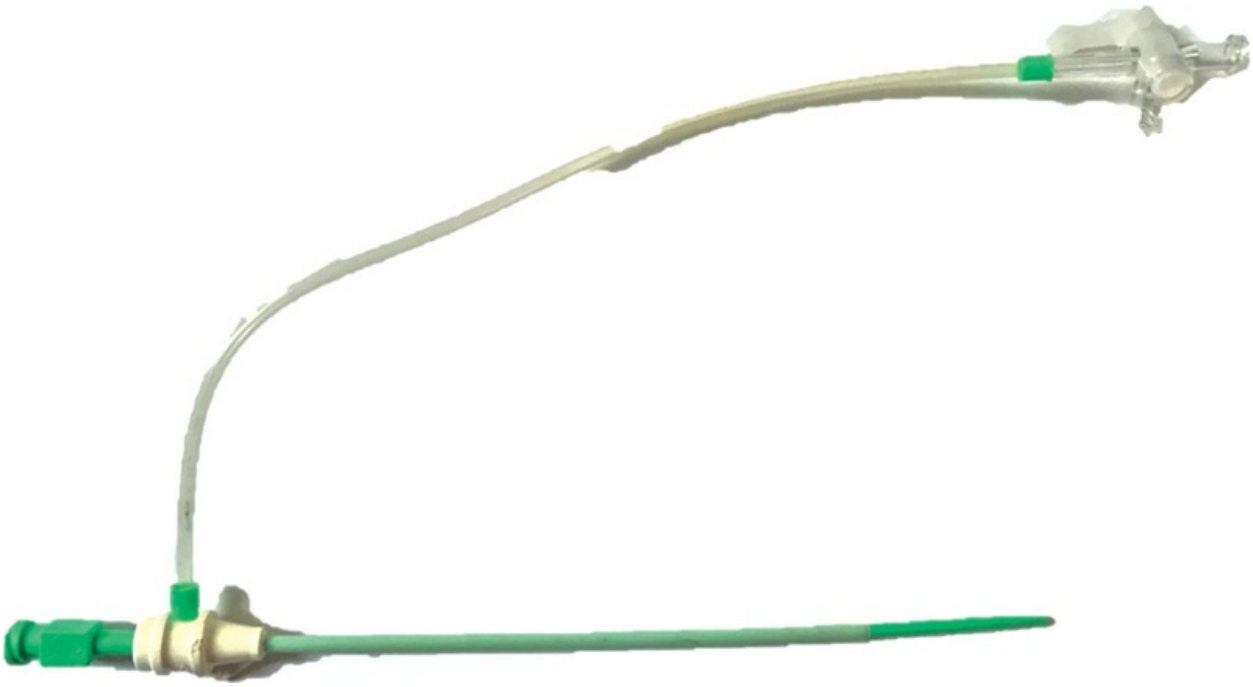

FIGURE 7.3 A 6F arterial sheath is shown here. This serves as the access point for left heart catheterization and coronary angiography.

RADIAL ARTERY

Radial artery catheterization has been shown to reduce mortality and major adverse cardiovascular events and reduce major bleeding and vascular complications across the entire spectrum of patients with CAD.[9] Before this procedure, an Allen test is performed to assess the patency of ulnar artery flow. The radial artery is accessed using a modified Seldinger technique. Heparin is injected directly into the sheath upon access to prevent thrombosis. Radial artery spasm is prevented by injecting nitroglycerin and Verapamil.

BRACHIAL ARTERY

The brachial artery can also be used for coronary angiography; however, there is a higher risk of compromising the blood supply to the hand in the event of vessel closure.

DIAGNOSTIC CARDIAC CATHETERIZATION

After access has been obtained from any of the sites previously mentioned, coronary angiography and left ventriculography are performed through the sheath. With the help of a J-tipped guidewire, the catheter is advanced through the sheath and into the ascending thoracic aorta under fluoroscopy. The guidewire is removed, and catheters are aspirated followed by a flush with heparinized saline.

CORONARY ANGIOGRAPHY

The LMCA is usually engaged using a Judkins left catheter (**Figure 7.4C**), and the RCA is engaged using a Judkins right catheter through the femoral approach (**Figure 7.4B**). In addition, other catheters are available in cases where Judkins catheters fail to engage the coronary arteries. Similarly, catheters are specially designed to access the coronary arteries from a radial approach. On successful cannulation of coronaries, contrast is injected under fluoroscopy, and various angiographic views are obtained as previously mentioned for each coronary artery.

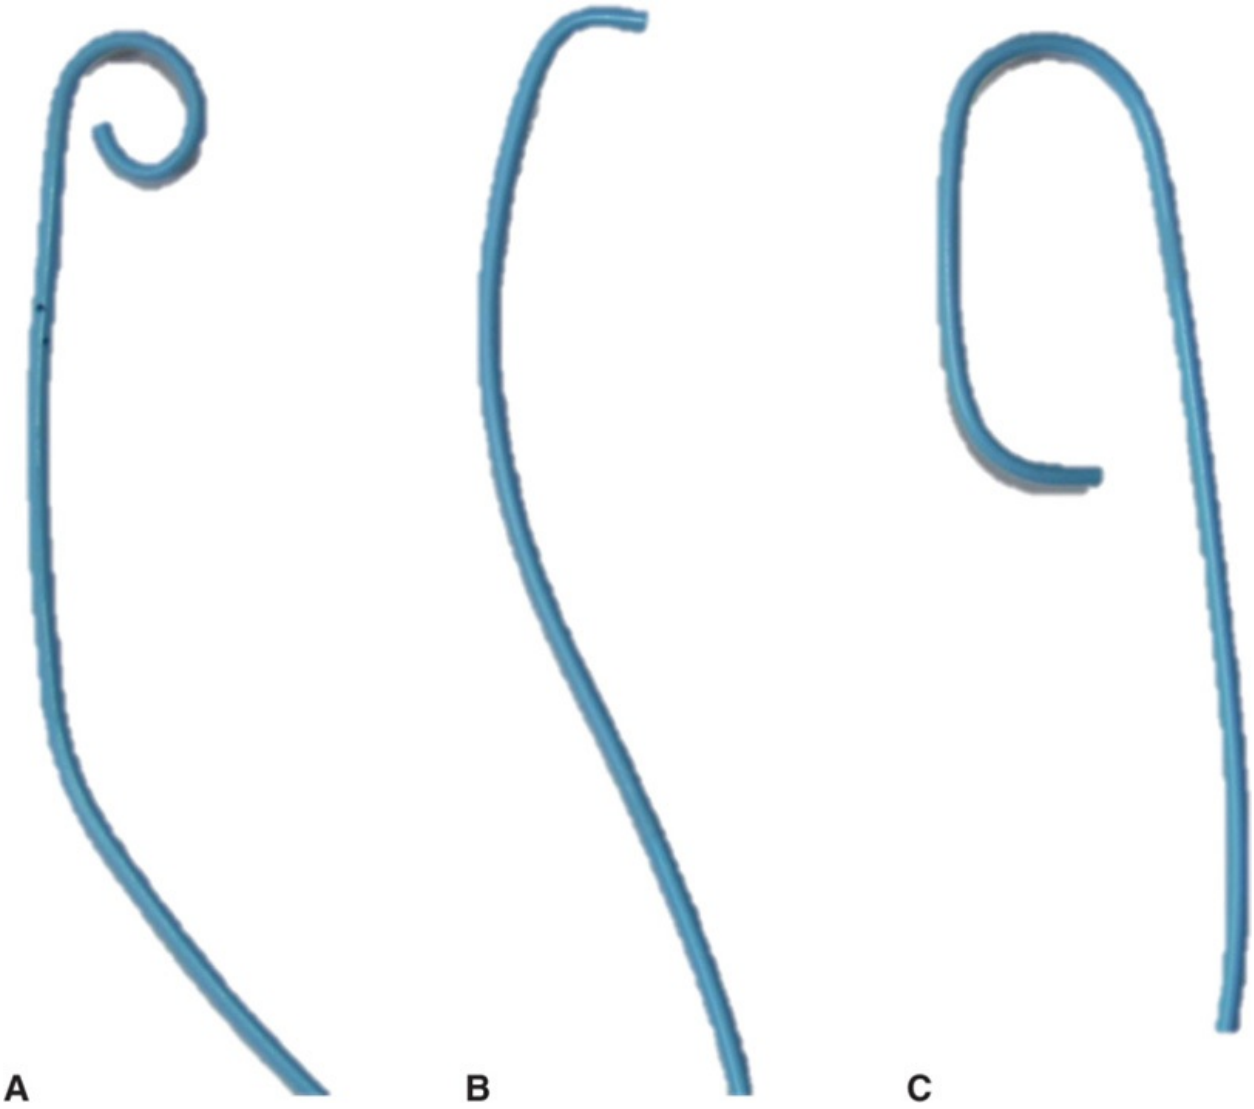

FIGURE 7.4 Coronary artery catheters used in coronary angiography and left heart catheterization. A, A pigtail catheter is placed across the aortic valve to assess left ventricular function and hemodynamics. B, A Judkins right catheter, shown here, is used to cannulate the right coronary artery. C, A Judkins left catheter, shown here, is used to cannulate the left coronary artery.

LEFT VENTRICULOGRAPHY

Left ventriculography is performed with the help of a pigtail catheter in most cases **(Figure 7.4A)**. The pigtail catheter is advanced through the aortic valve and positioned in the center of the left ventricle. An RAO projection is obtained as the contrast is injected into the left ventricle. The figure shows left ventriculography performed in an RAO view. This view gives an assessment of the anterolateral wall, inferior wall, and apex. An LAO projection can be performed to visualize the interventricular septum and lateral wall. Left

ventriculography can also be used to assess the severity of mitral regurgitation based on the degree of opacification of the left atrium. Left ventriculography should be avoided in patients with underlying chronic kidney disease unless deemed necessary for diagnosis.

SUPRA-AORTIC ANGIOGRAPHY

Positioning the pigtail catheter just above the aortic valve is useful for assessing the ascending aorta as well as evaluating aortic insufficiency.

LEFT HEART HEMODYNAMICS

Intracavitary pressure tracings can be obtained from the pigtail catheter placed in the left ventricle. Left ventricular end-diastolic pressure can be measured from these pressure tracings, which can help in the management of patients presenting with acute coronary syndrome, heart failure, and cardiogenic shock and to guide fluid strategy postprocedure. Aortic stenosis can be assessed from the transvalvular gradient obtained as the pigtail catheter is withdrawn from the left ventricle into the aorta or with simultaneous pressure measurements in the left ventricular (LV) and aorta. Mitral stenosis can be assessed by measurement of gradients between the pulmonary capillary wedge pressure and the LV cavity, and atrial septal defect as well as ventricular septal defect can be evaluated with an oxygen saturation series.

ARTERY BYPASS GRAFTS

It is helpful to know the anatomy of the bypass grafts before cardiac catheterization. Specialized catheters are available to engage the bypass grafts.

POSTPROCEDURE CARE

VASCULAR SITE HEMOSTASIS

After completion of cardiac catheterization, the femoral sheath is removed, and hemostasis is achieved either by manual compression or vascular closure devices. Manual compression can be applied directly at the access site for a minimum of 15 minutes, depending on the size of the sheath. If anticoagulation is given with heparin during the procedure, sheath removal and manual

compression can be done if activated clotting time (ACT) is less than 180 seconds. For patients receiving bivalirudin, the sheath can be removed 2 hours after the infusion has stopped. Bed rest of at least 4 hours is advised following manual compression for hemostasis.

A variety of vascular closure devices are available. These achieve hemostasis either with an extravascular plug (Angio-seal/Mynx) or through sutures (Perclose). The Angio-seal vascular closure (St. Jude Medical) device consists of a bioabsorbable intravascular anchor and a collagen extravascular plug to seal the arteriotomy site. Components are absorbed within 60 to 90 days, and the site is available after this time for access. A potential complication is embolization of the intravascular component. Mynx vascular closure (Access closure) uses a bioabsorbable sealant that absorbs blood and expands to seal the arteriotomy site. Perclose (Abbott Laboratories) is a suture-based vascular closure device that functions by percutaneous delivery of sutures. Perclose is also used as a preclosure device when managing a large femoral arteriotomy, as with the use of Impella or Transcatheter Aortic Valve Replacement. Careful assessment of distal pulses is a mandatory part of postprocedure care.

Compared to manual compression, vascular closure devices are noninferior regarding access-site complications but have a higher incidence of infection. They have been shown to have a reduced time to hemostasis and earlier time to mobilization.[10] Careful selection of patients is advised to avoid potential complications.

Radial artery hemostasis is achieved by immediately removing the sheath postprocedure irrespective of anticoagulation status and applying wristband compression devices. Radial artery occlusion is a potential complication. It is important to assess the radial artery flow with pulse oximetry of the corresponding finger by compressing the ulnar artery while using the wristband compression devices. There are no restrictions to ambulation after wristband compression devices, but the patient is advised not to perform strenuous activities using their hand for 2 to 4 hours after the procedure.[7, 11]

POSTPROCEDURE MONITORING

Complete bed rest for 2 hours is advised when a vascular closure device has been used in a patient who has not received anticoagulation. Manual compression requires 4 to 6 hours of bed rest. The patient should be recovered in an area with careful monitoring of vital signs and distal pulses to identify early

signs of bleeding or vessel closure. Postprocedure labs are recommended in patients undergoing PCI and those with preexisting renal dysfunction. Patients undergoing PCI may be considered for monitoring in a telemetry setting if they are at increased risk for postprocedural adverse cardiac event or CIN or require continuous use of intravenous medications.

COMPLICATIONS

The risk of major adverse cardiac and cerebrovascular events for diagnostic cardiac catheterization occurs in <0.1% of procedures. Vascular site complications include bleeding, retroperitoneal hemorrhage, hematoma, pseudoaneurysm, arteriovenous (AV) fistula formation, dissection, and embolization and are less than 0.5%. Patients with a small pseudoaneurysm (less than 2 cm) can be observed for spontaneous closure. Large pseudoaneurysms (more than 3 cm) require ultrasound-guided compression or, more frequently, ultrasound-guided thrombin injection. Retroperitoneal hemorrhage should be suspected in patients with back or flank pain along with hemodynamic instability. Diagnosis can be confirmed with CT scan without contrast. Management includes close monitoring of vitals and complete blood count in a coronary care unit setting, fluid resuscitation, and transfusion as indicated. Anticoagulation reversal may be indicated and vascular surgery consultation is advised. AV fistula is a relatively rare complication. Small AV fistulas can be followed serially with ultrasound. Large fistulas associated with swelling, deep vein thrombosis, or high-output failure may require ultrasound-guided compression or surgical closure.

The risk for CIN increases with preexisting renal insufficiency, DM, and with patients with elevated risk scores.[8] The ideal strategy for preventing CIN includes adequate hydration and minimizing the contrast load.[7]

Coronary artery spasm, dissection, and air embolism are infrequent complications. Cardiac perforation is a rare complication after right heart catheterization. Other complications include cardiac arrhythmia, particularly ventricular fibrillation after injecting the RCA, vagal response, heart failure, and rarely infection. Allergic reaction to contrast dye can range from mild to severe anaphylaxis. Patients at high risk should be premedicated as outlined earlier.

PERCUTANEOUS CORONARY INTERVENTION

Andreas Gruentzig ushered in a new era in the management of CAD when he performed the first percutaneous transluminal coronary angioplasty (PTCA) in 1977. PCI has now grown into a complex field of diagnosis and management of CAD. With a marked improvement in safety and efficacy, it is one of the remarkable achievements of modern cardiovascular medicine.

INDICATIONS FOR PERCUTANEOUS CORONARY INTERVENTION

The American College of Cardiology/American Heart Association task force has published guidelines on indications for PCI.[12] In addition, a multisociety committee has developed the appropriate use criteria for nonemergent PCI based on the severity of angina, findings on the noninvasive study, medical therapy, and extent of CAD.[13]

ST-ELEVATION MYOCARDIAL INFARCTION

Coronary angiography and PCI is a Class I indication in STEMI as primary therapy in patients with ischemic symptoms of less than 12 hours' duration or in patients in cardiogenic shock or acute severe heart failure regardless of time to presentation. Delayed PCI of the infarct-related artery in patients who were initially managed either with fibrinolytic or no reperfusion therapy should be performed in the setting of cardiogenic shock, high-risk findings on noninvasive testing, or spontaneous or easily provoked myocardial ischemia. It is not recommended to perform delayed PCI of a totally occluded artery more than 24 hours after STEMI presentation in stable patients (**Tables 7.3** and **7.4**).[14]

TABLE 7.3 Indications for Primary PCI in STEMI[14]

PRIMARY PCI IN STEMI			
Class I	***Class IIA***	***Class IIB***	***Class III***
	Primary PCI is reasonable in patients with STEMI if there	PCI of a noninfarct artery may be considered in selected patients	

Primary PCI should be performed in patients with STEMI and ischemic symptoms of less than 12 h duration. (Level of Evidence: A)	is clinical and/or ECG evidence of ongoing ischemia between 12 and 24 h after symptom onset. (Level of Evidence: B)	with STEMI and multivessel disease who are hemodynamically stable, either at the time of primary PCI or as a planned staged procedure
Primary PCI should be performed in patients with STEMI and ischemic symptoms of less than 12 h duration who have contraindications to fibrinolytic therapy, irrespective of the time delay from FMC. (Level of Evidence: B)		
Primary PCI should be performed in patients with STEMI and cardiogenic shock or acute severe HF, irrespective of time delay from MI onset. (Level of Evidence: B)		

ECG, electrocardiogram; FMC, first medical contact; HF, heart failure; MI, myocardial infarction; PCI, percutaneous coronary intervention; STEMI, ST-elevation myocardial infarction.

TABLE 7.4 Coronary Angiography in Patients Who Received Firbrinolytic Therapy or No Reperfusion Therapy

CORONARY ANGIOGRAPHY IN PATIENTS WHO RECEIVED FIBRINOLYTIC THERAPY OR NO REPERFUSION THERAPY

Class I	*Class IIA*	*Class IIB*	*Class III*
Cardiac catheterization and coronary angiography with intent to perform revascularization should be performed after STEMI in patients with any of the following: • Cardiogenic shock or acute severe HF that develops after initial presentation. (Level of Evidence: B) • Intermediate- or high-risk findings on predischarge noninvasive ischemia testing. (Level of Evidence: B) • Myocardial ischemia that is spontaneous or provoked by minimal exertion during hospitalization. (Level of Evidence: C)	Coronary angiography with intent to perform revascularization is reasonable for patients with evidence of failed reperfusion or reocclusion after fibrinolytic therapy. Angiography can be performed as soon as logistically feasible. (Level of Evidence: B)		
	Coronary angiography is reasonable before hospital discharge in stable patients with STEMI after successful fibrinolytic therapy. Angiography can be performed as soon as logistically feasible, and ideally within 24 h, but should not be performed within the first 2–3 h after administration of fibrinolytic therapy. (Level of Evidence: B)		

HF, heart failure; STEMI, ST-elevation myocardial infarction.

NON–ST-ELEVATION ACUTE CORONARY SYNDROME

The management of non-ST-elevation acute coronary syndromes (NSTE-ACS) revolves around two pathways, either an invasive strategy or an ischemia-guided strategy. The invasive strategy is designed to perform coronary angiography initially, with intent to revascularize. In the ischemia-guided strategy, angiography is performed in patients who do not respond to medical therapy, have high-risk findings on noninvasive testing, or have a high non-ST-elevation acute coronary syndromes or Thrombolysis in Myocardial Infarction (TIMI) score (**Table 7.5**).[15]

TABLE 7.5 Management of Patients With NSTE-ACS[15]

Non--ST-Elevation Acute Coronary Syndromes

Class I	*Class IIA*	*Class IIB*	*Class III*
An urgent/immediate invasive strategy (diagnostic angiography with intent to perform revascularization if appropriate based on coronary anatomy) is indicated in patients (men and women) with NSTE-ACS who have refractory angina or hemodynamic or electrical instability (without serious comorbidities or contraindications to such procedures). (Level of Evidence: A)	It is reasonable to choose an early invasive strategy (within 24 h of admission) over a delayed invasive strategy (within 25–72 h) for initially stabilized high-risk patients with NSTE-ACS. For those not at high/intermediate risk, a delayed invasive approach is reasonable. (Level of Evidence: B)	In initially stabilized patients, an ischemia-guided strategy may be considered for patients with NSTE-ACS (without serious comorbidities or contraindications to this approach) who have an elevated risk for clinical events. (Level of Evidence: B)	An early invasive strategy (ie, diagnostic angiography with intent to perform revascularization) is not recommended in patients with: a. Extensive comorbidities (eg, hepatic, renal, pulmonary failure, cancer), in whom the risks of revascularization and comorbid conditions are likely to outweigh the benefits of revascularization. (Level of Evidence: C) b. Acute chest pain and a low likelihood of ACS who are troponin-negative (Level of Evidence: C), especially women (Level of Evidence: B)
An early invasive strategy (diagnostic angiography with intent to perform revascularization if appropriate based on coronary anatomy) is indicated in initially stabilized patients with NSTE-ACS (without serious comorbidities or contraindications to such procedures) who have an elevated risk for clinical events. (Level of Evidence: B)		The decision to implement an ischemia-guided strategy in initially stabilized patients (without serious comorbidities or contraindications to this approach) may be reasonable after considering clinician and patient preference. (Level of Evidence: C)	

CHRONIC STABLE ANGINA

Revascularization in patients with chronic stable angina is recommended on the basis of either improved survival or improved symptoms and is outlined in a document termed the Appropriate Use Criteria. This is a detailed compilation of scenarios based on symptoms, extent of ischemia, and current medications. A full discussion is included in the reference.[13, 16]

For patients with complex coronary anatomy, left main disease, or severe LV dysfunction, a "heart team" approach is recommended with input from both cardiac surgery and interventional cardiology with regard to risks and benefits of each approach.

The success of PCI revolves around the following:

- Guiding catheters and guidewires
- Balloon dilatation and coronary stents
- Anticoagulation during PCI
- Lesion modification devices
- Embolic protection devices
- Diagnostic ancillary devices
- Mechanical supportive devices

GUIDE CATHETERS AND GUIDEWIRES

Appropriate choice of the guide catheter is a key first step in the treatment of a lesion. An ideal catheter should be of sufficient design to deliver equipment, provide adequate support to advance the equipment, and provide monitoring of aortic pressure. Similar to diagnostic angiography, luminal diameter size of guide catheters for PCI is denoted by French size (6F approximately 2 mm). In most cases, a 6F guide catheter will be adequate for percutaneous intervention. However, a large French size guide catheter (7F or 8F) is required for performing complex PCI. Despite the extra support provided by guide catheters, a flexible tip is available to reduce damage to the coronary ostium. Guide catheters also help in monitoring the aortic pressure and alert the operator in case of dampening or ventricularization of the waveform. Dampening of the pressure wave (drop in systolic pressure) is seen when a guide is larger than the coronary ostium or when the guide is deep-seated and pressing against the wall or plaque. In addition to appropriate choice of the guide catheter, additional maneuvers

such as a long arterial sheath, guideliner delivery system, or buddy wire techniques may be used to achieve optimal support.

GUIDEWIRES

The next step after the choice of the optimal guide catheter is an appropriate selection of coronary guidewire. An optimal guidewire will cross the lesion without trauma and provide a rail for device delivery. A coronary guidewire consists of an inner core, outer covering, and tip. The choice of guidewire depends on the lesion complexity and type of device delivery. In most cases, “workhorse” wires will suffice for the noncomplex lesion. Complex lesions such as chronic total occlusions may require more advanced techniques and different wires. Soft tip and hydrophilic wires can help navigate tortuous lesions but are more liable to cause dissection and perforation.

BALLOON DILATATION

After the guidewire is advanced distally across the lesion, the next step is to select balloon dilatation catheters. There are two types of balloon dilatation catheter: monorail and over-the-wire. Monorail or rapid-exchange system is designed for a single operator to advance the system while maintaining the distal wire. The over-the-wire system allows delivery to tortuous, calcified vessels and better support for certain devices. Inflation of the balloon is done with a device called an indeflator that measures and controls the amount of pressure. The purpose of predilatation prior to stent implantation includes evaluation of the characteristics and length of the stenosis, determination of the diameter of the stent to be used, and aid in the delivery of the stent. Successful predilatation of the stenosis occurs when both the pressure and the duration of inflation inside the balloon causes the stenotic lesion to yield completely in its entire length. With increasing balloon diameters and higher pressures, inflation can result in an increased risk of vessel injury. On the contrary, lower inflation pressures may not cause sufficient yielding of the stenosis, complicating adequate stent placement.

Compliance of the balloon must be considered while planning PTCA. Compliant balloons can increase in size by >20% when pressure is increased beyond nominal pressure, whereas noncompliant balloons change very little at higher pressures. Noncompliant balloons are better suited for the calcified or fibrotic lesions or for postdilatation of stents. There are many ways to approach

balloon inflation, including size, inflation time, and pressures, but the overall concept is to eliminate the “waist” or area of stenosis.

CORONARY STENTS

Before the advent of stents, plain old balloon angioplasty (POBA) was met with the risk of abrupt vessel closure, requiring CABG, in the short term and the risk of restenosis in the long term because of intense smooth muscle proliferation at the site of POBA. These problems were addressed with the introduction of bare metal stents (BMS) and improved upon in the current era of drug-eluting stents (DES). In its basic design, a DES consists of a mesh of metal that is polymer coated with an antiproliferative drug. Despite the reduction in the incidence of abrupt vessel closure with coronary stents, two issues have plagued the use of coronary stents—stent thrombosis and in-stent restenosis (ISR).

Stent thrombosis can be acute (<24 hours), subacute (<30 days), late (30 days to 1 year), and very late (>1 year). Stent thrombosis results from a lack of endothelialization of the stent, resulting in contact between stent struts and platelets. Endothelialization is usually completed within 4 weeks in BMS. This is markedly delayed in DES because of the release of the antiproliferative drug. In addition to the type of stent, several other factors, including lack of stent apposition or malposition/dissection, can increase the risk of stent thrombosis. The use of dual antiplatelet therapy (DAPT) has reduced the incidence of stent thrombosis, but very late thrombosis has been seen rarely after termination of DAPT beyond the 1-year mark. The duration of DAPT has been a matter of intense debate. The recent 2016 AHA/ACC focus update on the duration of DAPT recommends that patients with SIHD who are treated with DES should be treated for at least 6 months and for at least 1 month following BMS (Class I). Treatment beyond the recommended duration may be considered for those patients who can tolerate DAPT without significant bleeding risk (Class IIb). In patients with ACS treated with either BMS or DES, DAPT should be continued for at least 1 year, and continuation beyond that may be reasonable for patients without any bleeding complication or elevated risk for bleeding (Class IIb).[17]

ISR is caused by neointimal hyperplasia. Neointimal hyperplasia refers to smooth muscle proliferation leading to stenosis at the site of stent implantation. The incidence of ISR has significantly decreased with the use of DES. Risks for ISR include stent underexpansion, diabetes, small vessel size, and long lesions.

Besides neointimal hyperplasia, de novo neoatherosclerosis caused by chronic inflammation has been proposed as a potential mechanism for late ISR and thrombosis.[18]

ANTICOAGULATION DURING PERCUTANEOUS CORONARY INTERVENTION

Anticoagulation is required during PCI to prevent thrombus formation on the guide catheters, coronary wire, or at the site of any arterial injury.[12] There are several different anticoagulation alternatives for PCI.

UNFRACTIONATED HEPARIN

Unfractionated heparin (UFH) is one of the most commonly used anticoagulants because of ease of use, rapid action availability of the reversal agent, and cost. The degree of anticoagulation with UFH is measured by the ACT using either Hemochron or Hemotec devices. The dosing of heparin is weight-based. UFH should be titrated to achieve an ACT of 200 to 250 seconds if glycoprotein IIb/IIIa receptor inhibitors (GPI) is administered; if no GPI is given, ACT should be targeted toward 250 to 350 seconds (Class I; Level of Evidence C).[12]

BIVALIRUDIN

Bivalirudin is a direct thrombin inhibitor that is used across the entire spectrum of patients undergoing PCI, including STEMI, where it has been shown to reduce cardiac mortality and major bleeding (Class I; Level of Evidence B).[14,19,20] However, recent trials have failed to show a mortality benefit or superiority over heparin.[21, 22] Bivalirudin should be the agent of choice for patients with heparin-induced thrombocytopenia. Bivalirudin is given as a bolus of 0.75 mg/kg followed by infusion of 1.75 mg/kg/h for the duration of the procedure. If the patient receives a load of Prasugrel or Brilinta at the time of PCI or is on maintenance therapy with either drug, then bivalirudin can be stopped immediately after PCI. In patients receiving a plavix load at the time of PCI or within 2 hours of PCI, bivalirudin should be continued for at least 2 hours post-PCI until the antiplatelet effect has been achieved.

ENOXAPARIN

Enoxaparin, or low-molecular-weight heparin, can be used in patients with NSTE-ACS undergoing PCI. Enoxaparin may be considered for patients who have not received prior antithrombin therapy or who have received subcutaneous enoxaparin "upstream" for management of NSTE-ACS (Class IIb; Level of Evidence B).[12] An additional dose of enoxaparin is recommended if the patient has received less than 2 doses or if the last dose was received more than 2 hours before PCI (Class I; Level of Evidence B).[12]

FONDAPARINUX

Fondaparinux is an indirect thrombin inhibitor. It is not recommended for use because of an increased risk of catheter thrombosis.[12]

DIAGNOSTIC ANCILLARY DEVICES

Although considered "the gold standard," coronary angiography comes with some limitations. Coronary angiography merely outlines the vessel lumen and provides no information on the anatomic configuration of the vessel wall or functional significance of the lesion. These problems are addressed by recent advances in intravascular ultrasound (IVUS), optical coherence tomography (OCT), and fractional flow reserve (FFR).

INTRAVASCULAR ULTRASOUND

IVUS creates a cross-sectional tomographic image of the vessel wall. A standard IVUS image provides a minimal luminal area (MLA, plaque burden, and some characterization of lesion morphology and contents). Criteria for MLA with IVUS have been correlated with FFR. An MLA < 6.0 mm^2 is suggestive of significant hemodynamic lesion in left main, whereas an MLA of <4.00 mm^2 is used as cutoff for non–LMCA. In addition to assessment of lesion severity, IVUS has substantial clinical utility in coronary stenting. IVUS-guided coronary stenting can be useful in assessing vessel size, stent deployment, and proper stent apposition. It can also guide in the identification and management of complications post-stenting such as ISR and coronary dissection.

OPTICAL COHERENCE TOMOGRAPHY

OCT uses scattering and absorption of near infrared emitted from an optical fiber of an imaging catheter. Tomographic images are generated through an automated pullback requiring contrast infusion because OCT cannot image through blood. OCT has far superior resolution compared to IVUS. However, it falls behind in image penetration. OCT can identify thrombus, plaque rupture, stent malapposition, edge dissection, and prolapse of tissue (**Figure 7.5**). A 2014 consensus document of the Society of Cardiovascular Angiography and Interventions gives OCT a "probably beneficial" rating for stent deployment and "possibly beneficial" for plaque morphology.[23]

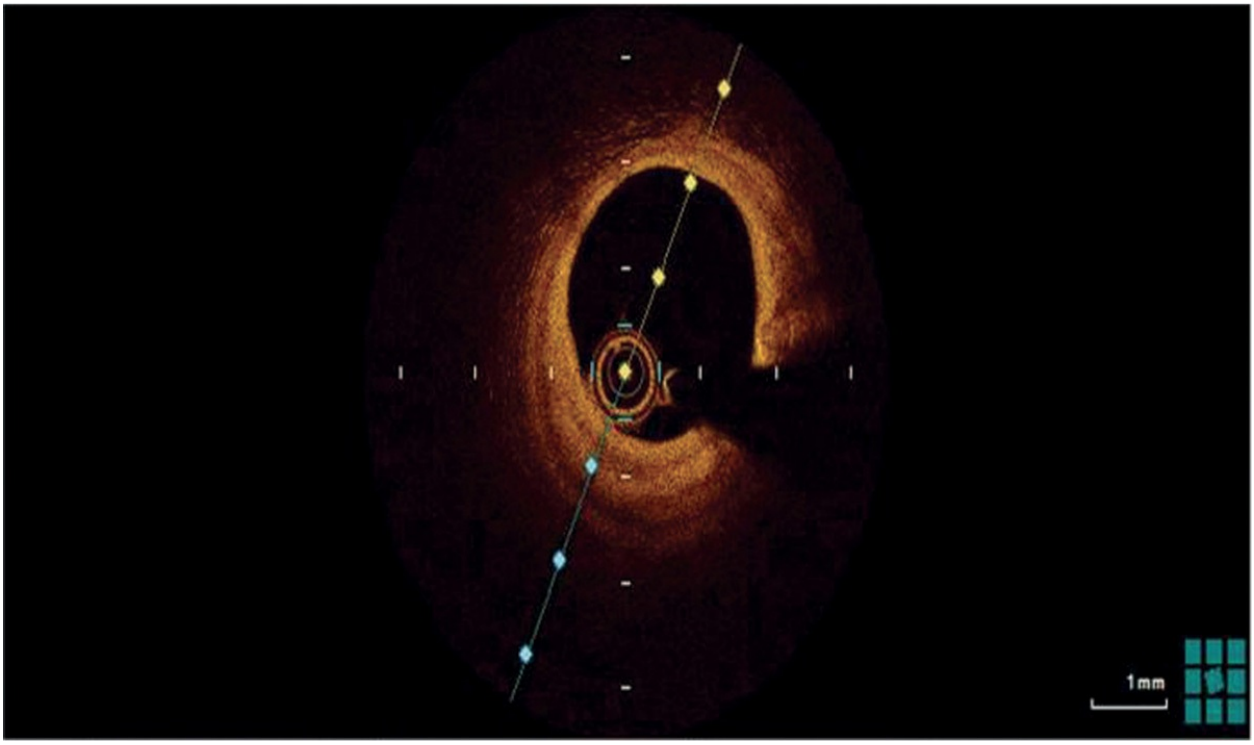

FIGURE 7.5 A cross-sectional optical coherence tomography image of coronary artery.

FRACTIONAL FLOW RESERVE

As compared to the anatomic assessment of lesion severity provided by IVUS and OCT, FFR provides physiologic significance of lesion severity. FFR is the ratio of mean distal coronary pressure after the lesion divided by mean pressure proximal to the lesion during maximal hyperemia achieved with IV adenosine (**Figure 7.6**). Although first validated at a significant level of 0.75, the value was extended to 0.80 to improve sensitivity. The FAME trial randomized patients with multivessel disease to either FFR-guided PCI or to angiographic-guided

PCI. The primary outcome of death, MI, or repeat revascularization was significantly lower in the FFR-guided PCI arm.[24] FAME 2 demonstrated that FFR-guided PCI with optimal medical therapy in patients with stable CAD showed better outcomes than did medical therapy alone.[25] FFR is useful in guiding the management of a patient with SIHD and in assessing the angiographic significance of intermediate lesions (Class IIa; Level of evidence A).[12]

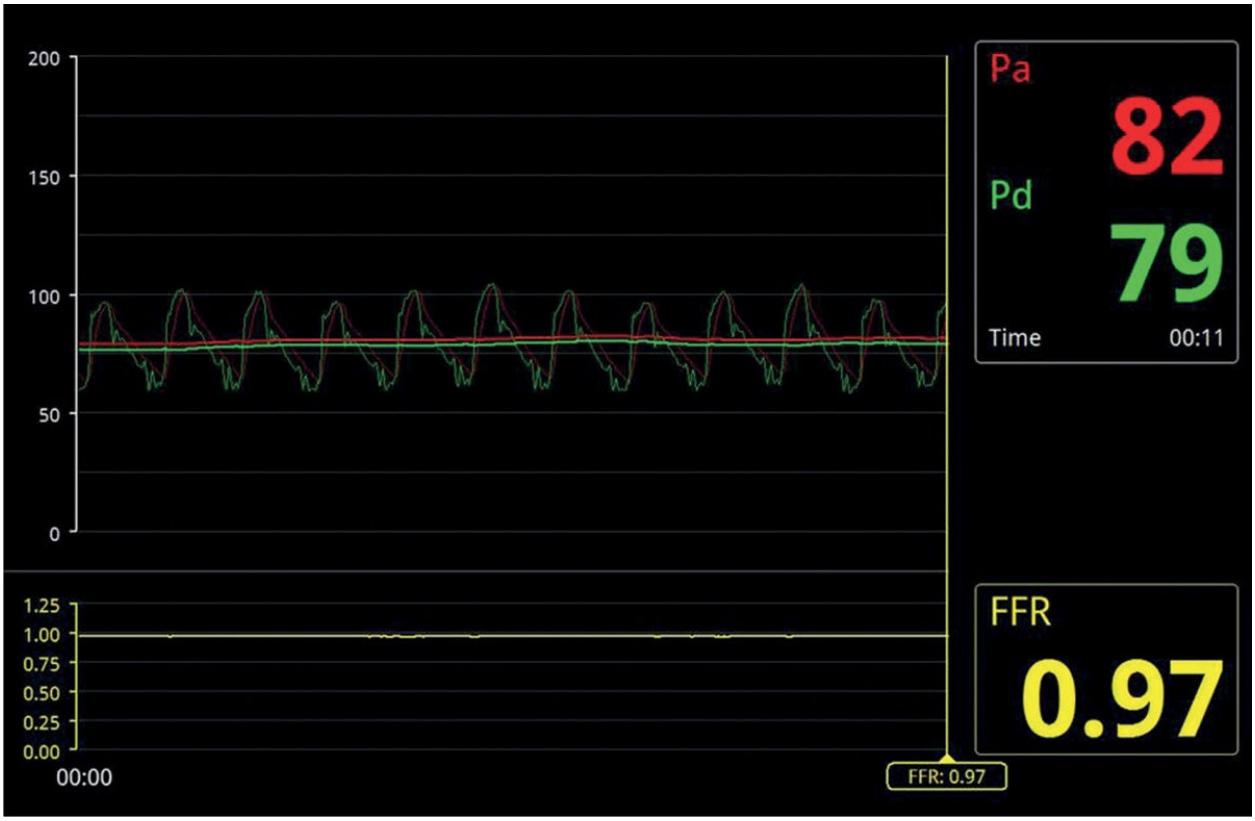

FIGURE 7.6 Normal fractional flow reserve of an indeterminate lesion coronary after IV adenosine infusion.

LESION MODIFICATION DEVICES

The procedural success of a calcified lesion depends on the adequate preparation of the vessel. Mild calcification can be managed with routine PTCA followed by stent. Moderate to severe calcification may require the use of the atherectomy devices to both debulk the lesion and modify the architecture of the vessel. Device selection is based on the degree of calcification, operator experience, and

clinical presentation of the patient.

Atherectomy devices include rotational atherectomy, orbital atherectomy, excimer laser atherectomy, and cutting balloon atherectomy.

Rotational atherectomy works on the principle of “differential cutting,” involving selective ablation of calcium, leaving healthy tissue intact, unlike balloon angioplasty, which causes several intimal tears. Rotational atherectomy ablates plaque using a diamond elliptical burr rotating concentrically on a wire at 140,000 to 160,000 revolutions per minute. It comes in sizes ranging from 1.25 to 2.5 mm. Particulates released from RA can pass through coronary microcirculation and eventually undergo phagocytosis in the body. Occasionally, the microparticles can cause microcirculation obstruction, thereby increasing the risk of slow flow or no-reflow.[26] This can be reduced by gradual burr advancement, short ablation runs, and avoidance of deceleration.[26] Despite its clinical utility, rotational atherectomy has not been shown to improve clinical outcomes. Current guidelines recommend that rotational atherectomy be used in the setting of severely calcified or fibrotic lesions that are not amenable to adequate balloon dilatation prior to stent implantation (Class IIa; Level of Evidence C).[12]

Diamondback 360 Coronary Orbital Atherectomy System works on the principle of differential sanding and centrifugal force for plaque modification. The system consists of a diamond-coated crown eccentrically mounted on a guidewire. The crown is available in a 1.25-mm size, but the maximum orbit is determined by the rotational speed of the crown. Compared to rotational atherectomy, orbital atherectomy produces microparticles that are smaller in size and allows continuous blood flow.

Excimer laser atherectomy uses laser energy to modify calcified lesions. Similar to rotational atherectomy, guidelines recommend use of excimer laser in fibrotic or moderately calcified lesions that cannot be adequately crossed or dilated with balloon angioplasty (Class IIb; Level of Evidence C).[12]

Cutting balloon atherectomy utilizes a balloon mounted with metallic blades that cut the plaque, allowing balloon dilatation at a lower pressure. Two such devices are available: The Flextome cutting balloon consists of three to four longitudinally directed microsurgical blades on the balloon surface. AngioSculpt consists of a nitinol cage over a balloon that cuts the plaque and also prevents balloon slippage. Cutting balloon atherectomy is frequently used in the setting of ostial lesions and mild- to moderate calcified lesions. Cutting balloon is also recommended to avoid coronary artery trauma caused by balloon slippage during

PCI of ISR (Class IIb; Level of Evidence C).[12]

THROMBECTOMY

Thrombectomy devices incorporate removal of complete or partially occluding thrombus in patients with ST-elevation myocardial infarction. In light of recent studies, the 2015 focused update on primary PCI for patients with ST-elevation myocardial infarction has modified the recommendation from Class IIa to Class III for Routine aspiration thrombectomy before primary PCI.[27] Aspiration thrombectomy is performed using a catheter to remove thrombus using negative pressure applied through a syringe with a locking plunger controlled with a three-way stopcock. Angiojet is a rheolytic device based on the Venturi Bernoulli principle. It consists of a flexible catheter, pump, and angiojet console. The console energizes the pump to send pressurized saline to the catheter tip. A vacuum effect is created as the saline jet travels backward in the catheter. The net result is disruption and aspiration of thrombus, which can then be retrieved. Although not routinely recommended, it is extremely useful in patients with heavy clot burden.

EMBOLIC PROTECTION DEVICES

Embolization of atherosclerotic debris into systemic circulation is a complication sometimes encountered during saphenous vein graft intervention. There are two devices currently available for prevention of embolization. The Filterwire EZ uses a distal filter over a fixed wire that is advanced across a saphenous vein graft lesion. The filter prevents embolization of debris but does not compromise the blood flow through the filter pores. The Guardwire uses a balloon mounted on the distal end of the wire. The balloon is inflated distal to the lesion followed by rapid stenting and aspiration of the content of the vessel. Unlike the filter wire, there is the possibility of compromise to blood flow and hemodynamic compromise.

MECHANICAL SUPPORTIVE DEVICES

One of the significant advances in interventional cardiology is the availability of mechanical circulatory support devices. The purpose of the mechanical support device is to provide end-organ and coronary perfusion and improve myocardial performance in the setting of cardiogenic shock or high-risk PCI.[28] The definition of high-risk PCI has been broad across the literature. It can be defined on the basis of patient-specific, lesion-specific, and clinical-specific variables.[29] Patient-specific characteristics include advanced age, depressed EF <35%, congestive heart failure, chronic kidney disease, diabetes mellitus, severe aortic stenosis, severe mitral regurgitation, or peripheral arterial disease. Lesion-specific characteristics include multivessel disease, left main disease, last patent conduit, bifurcation lesions, or chronic total occlusion. Lastly, clinical presentations include acute coronary syndromes, advanced heart failure, and cardiogenic shock.[29]

Cardiogenic shock and high-risk PCI represent a dynamic patient population group that can have marked hemodynamic and metabolic derangements. It is recommended that a multidisciplinary heart team approach is utilized for prompt identification of these patients. Providing optimal support to these patients may require this team approach and can be accomplished with an array of appropriate mechanical support devices.[30] The 2011 multisociety guidelines for PCI recommend elective insertion of a hemodynamic support device at the time of PCI in carefully selected patient populations as described above (Class IIb; Level of Evidence C).[12] Each device has a particular hemodynamic profile as well as indications and contraindications. It is imperative to carefully consider all clinical parameters before a mechanical support device is selected.

INTRA-AORTIC BALLOON PUMP

The intra-aortic balloon pump (IABP) remains one of the most commonly used support devices. The IABP, which works on the principle of counterpulsation, inflates during diastole to provide diastolic augmentation of pressure and increased coronary perfusion and deflates during systole to reduce afterload and improve cardiac output. The device consists of a balloon catheter and a console. The balloon catheter has a polyethylene balloon attached to its body with two lumens. One lumen is for guidewire insertion and pressure monitoring, and the other lumen is for balloon inflation with helium. The IABP is inserted through the femoral artery and placed in the descending thoracic aorta under fluoroscopic guidance. The position of the balloon should be 1 to 2 cm below the subclavian

artery and above the renal artery. A daily chest X-ray should confirm the tip of the IABP between the second and third intercostal spaces. The IABP uses either the electrocardiogram or pressure triggers for timing the balloon cycle. Moderate to severe aortic regurgitation is considered a contraindication for IABP placement, and careful attention is required for patients with severe peripheral arterial and aortic disease. Despite the widespread use of IABP, clinical trials have failed to show a mortality benefit. The Intra-aortic Balloon Pump in Cardiogenic Shock II (IABP-SHOCK II) trail randomized 600 patients with cardiogenic shock complicating acute myocardial infarction into IABP or no IABP. All patients received optimal medical therapy and were expected to undergo revascularization with either PCI or CABG. This trial failed to show a significant reduction in 30-day mortality between the two groups.[31] Despite the lack of evidence, the 2013 guideline for management of ST-elevation myocardial infarction recommends use of IABP for patients with cardiogenic shock who fail to stabilize with pharmacologic therapy (Class IIa; Level of evidence B).[14] Alternate devices for circulatory support may be indicated for patients with refractory cardiogenic shock (Class IIb; Level of Evidence C).[14]

IMPELLA

The Impella device provides a nonpulsatile axial flow of blood from the LV to the ascending aorta. It is available as Impella 2.5 and Impella CP, which can be inserted percutaneously, and as Impella 5.0, which requires a surgical cutdown. The device consists of a pigtail catheter that crosses the aortic valve and is connected to a cannula that contains the pump inlet and outlet.[29] Impella 2.5 can provide an outflow of 2.5 L/min, Impella CP provides support between 3.0 and 4.0 L/min, and Impella 5.0 can provide support of 5.0 L/min. Left ventricular thrombus is an absolute contraindication for the use of Impella. The PROTECT II trial randomized 452 symptomatic patients with complex three-vessel disease or unprotected left main CAD and reduced ejection fraction to intra-aortic balloon or Impella 2.5T support during nonemergent high-risk PCI. The Impella provided superior hemodynamic support compared to IABP, but the 30-day incidence of major adverse events was not statistically significant between the two groups. At 90 days, a trend toward improved outcomes was observed for the Impella 2.5 group.[32]

TANDEM HEART

The Tandem Heart provides extracorporeal circulation up to 5.0 L/min, utilizing a centrifugal pump from the left atrium to the femoral artery. It consists of an inflow cannula inserted into the left atrium through the femoral vein via the transseptal approach and an outflow cannula placed in the femoral artery.

EXTRACORPOREAL MEMBRANE OXYGENATION

Extracorporeal membrane oxygenation (ECMO) can be either Veno-venous ECMO to support oxygenation or veno-arterial ECMO to support both oxygenation and circulation. Veno-arterial is the device of choice for patients with biventricular failure requiring oxygenation and circulatory support.[29] The ECMO system consists of a venous reservoir, external centrifugal pump, membrane oxygenator, and a rewarming heparin-coated circuit.[28] Veno-arterial ECMO can provide circulatory flow up to 6 to 7 L/min, but its use can cause LV distension, and adequate venting with an Impella or IABP may be required.[30]

Patient and Family Information for: CORONARY ANGIOGRAPHY AND PERCUTANEOUS CORONARY INTERVENTION

CARDIAC CATHETERIZATION AND CORONARY ANGIOGRAPHY

Cardiac catheterization is a procedure that is performed to obtain X-ray pictures of arteries that supply the muscles of the heart. It can also be used to measure the pressures in the right- and left-sided chambers of the heart. This procedure is performed through a blood vessel either in the leg or in the arm or wrist. The doctor may recommend this procedure for a variety of cardiac diseases:

1. CAD: If the doctor is suspecting blockages in coronary arteries, the blood vessels that nourish the heart walls, he/she may recommend cardiac catheterization for identification and assessment of severity of blockages by injecting the coronary arteries with a contrast material that is seen under X-ray.
2. Valvular heart disease: Diseases affecting valves of the heart can be assessed by measuring the pressures in the chambers of the heart and by injecting contrast in the ventricles or the aorta.
3. Congenital heart disease: Some forms of congenital heart disease can be evaluated with cardiac catheterization by pressure measurements and oxygen analysis in the chambers of the heart.

PREPARATION FOR THE PROCEDURE

The patient will most likely be asked not to eat several hours before the procedure, but most medications can be taken with a sip of water. If the patient takes any blood thinners other than aspirin, plavix, prasugrel, ticagrelor, or other antiplatelet drugs, the doctor may discontinue these or modify the doses before the test. For diabetic patients, the doctor may hold or reduce the dose of medications before the procedure.

When the patient arrives in the catheterization laboratory, an intravenous line is started in the arm by the nurse so that medication, including sedation, can be given to the patient during the test. An electrocardiogram and blood tests will be performed before the test. ECG monitoring electrodes will be placed on the chest so that continuous recordings of the heartbeat can be performed throughout the test. To reduce the risk of infection, hair will be shaved from the groin area if the doctor chooses to use the femoral artery in the leg for the insertion of the catheter. The doctor will review the procedure and obtain informed consent from the patient before the procedure.

PROCEDURE

Once the patient is inside the cardiac catheterization room, the doctor will give medications to help relax and relieve any anxiety. The patient will be most likely awake or in a light sleep. The entire body from neck to toe will be covered with a sterile drape. For the catheterization performed through the artery in the leg, the doctor will palpate the femoral artery in the groin. Thereafter, he will inject numbing medication to relieve any pain before inserting a thin plastic sheath into the artery. The doctor may place a similar sheath in the femoral vein that runs next to the femoral artery to measure the pressures in the right-sided chambers of the heart. A similar technique will be used if the catheterization is performed through the wrist of the hand by accessing the radial artery.

LEFT HEART CATHETERIZATION AND CORONARY ANGIOGRAM

After the plastic sheath is placed in the femoral artery, the doctor will pass the catheters through the sheath, which will be advanced under X-ray guidance up to the aorta, the main artery leading to the heart, and reach the left side of the heart. The doctor will then access the coronary arteries and inject “dye” to perform a “coronary angiogram.” Digital X-ray pictures will be obtained at the same time to diagnose blockages in coronary arteries. The doctor may also obtain pressures in the left ventricle, which is the main pumping chamber of the heart, by passing

a catheter into the left ventricle to perform “left heart catheterization.”

RIGHT HEART CATHETERIZATION

After the plastic sheath is placed in the femoral vein, the doctor will pass the catheter under X-ray guidance to the right-sided chambers of the heart. “Right heart catheterization” will be completed by obtaining the pressure measurements of the right-sided chambers of the heart. A combined “right heart catheterization” and “left heart catheterization” will be performed to diagnose the disease of heart valves and muscles of the heart.

POST PROCEDURE

The entire procedure of “left heart catheterization,” “coronary angiogram,” and “right heart catheterization” will be completed in approximately 30 to 45 minutes if no further procedure is planned. The doctor will then remove the small plastic sheath from the wrist or the leg. If the procedure were performed through the wrist, a small pressure band would be applied and removed in approximately 2 hours. For the procedure performed through the leg, the sheath will be removed, and either manual pressure will be applied for 15 to 20 minutes or a “closure device” will be used. The use of a “closure device” will allow the patient to ambulate earlier compared to the case with manual pressure. The doctor will provide information about postprocedure care required. Typically, the patient is required to stay in bed for about 2 to 4 hours.

After coronary angiogram is performed, the doctor will review the X-ray pictures and decide whether the patient requires an intervention. If the review of X-ray pictures reveals “blockages,” the doctor will review the best treatment option for the patient, which can range from medical treatment to PCI or bypass surgery. The choice of treatment option depends on the number of arteries involved and the complexity of the blockages, pumping function of the heart, symptoms of the patient, and presence or absence of diabetes.

The foregoing procedures of “coronary angiogram” and “PCI” may be performed in an elective setting or, in some cases, emergently if the patient presents with symptoms of a heart attack. Two scenarios may occur. In the first scenario, the patient presents with the clinical condition referred to as STEMI. Patients with STEMI have a coronary artery completely blocked by a blood clot known as a thrombus. If the hospital is capable of performing coronary angiogram and PCI, the patient will be rushed to the cardiac catheterization

laboratory. If such a capability does not exist, the patient will either be transferred to the nearest hospital and/or given medications to dissolve the clot occluding the artery. In the second scenario, patients may present with a condition referred to as NSTE-ACS, in which, unlike in the case of STEMI, the artery is not completely occluded. Patients presenting with NSTE-ACS are treated with either coronary angiogram and/or PCI within a few hours of presentation if indicated on the basis of clinical presentation, or they may undergo further noninvasive testing to determine the need for a coronary angiogram and/or PCI.

PERCUTANEOUS CORONARY INTERVENTION

We will review different forms of PCI if the doctor decides, on the basis of the coronary angiogram, that there is a need for it. The doctor may perform the PCI immediately after the angiogram or later. The percutaneous intervention is performed through the same small plastic sheath using a different set of catheters and wires.

CORONARY ANGIOPLASTY

This procedure is referred to in medical terminology as PTCA. It is usually performed as a precursor to implantation of stent to prepare the coronary artery. Rarely, it is performed as a “stand alone” procedure, but this is associated with increased risk of repeat blockages because of the formation of scar tissue. The procedure is performed by passing what is known as a guide wire across the coronary artery with “blockages.” Once the wire is positioned adequately across the blockage, a flexible catheter with a balloon attached to its distal tip is passed over the wire and placed at the site of the “blockage.” The balloon is inflated, compressing the plaque, and is deflated after a few seconds to open the blockage. This may be repeated as necessary to dilate the coronary artery and prepare it for subsequent stent implantation.

CORONARY STENTS

One of the problems with “stand alone” coronary angioplasty, as previously described, was repeat blockage of the coronary artery caused by the formation of scar tissue. This was greatly reduced with the advent of coronary stents.

Coronary stents are metallic devices that are placed at the site of the blockage usually after balloon dilatation or sometimes directly. There are two types of stents: (1) BMS and (2) DES. A DES delivers a drug locally at the site of the blockage and thereby reduces the problem of restenosis. However, the stent itself is considered a foreign material and is at risk for formation of clot because of the interaction of stent material and blood. This risk is greater with DESs because the release of drug prevents cell growth and keeps them "foreign" for a longer time. To prevent this complication of clotting of the stent, the doctor will prescribe two medications, aspirin and another antiplatelet drug such as plavix, prasugrel, or ticagrelor. This form of therapy is called "DAPT." Depending on type of the stent and clinical condition that prompted the stent implantation, the duration of the therapy may last from 1 month to 1 year or even longer. It is essential that the patient consult a doctor before stopping "DAPT."

ROTATIONAL ATHERECTOMY

In some patients, the coronary arteries are severely calcified at the site of the blockage, making the implantation of stent extremely difficult. In those cases, the doctor may decide to perform rotational atherectomy. Rotational atherectomy is performed with a specialized burr mounted on a catheter. The burr rotates at a very rapid speed to pulverize the calcification. This procedure is usually followed by balloon dilatation and stent implantation.

THROMBECTOMY

In patients presenting with STEMI, a blood clot is formed at the site of the blockage. The clot may be aspirated by a catheter with mechanical suction or by devices that generate suction effect by high-pressure saline jets.

INTRAVASCULAR ULTRASOUND

Because coronary angiogram is a two-dimensional image seen on X-ray films, several other devices may be used to determine the severity of blockages in the coronary artery. One such device is called IVUS. This consists of a miniature ultrasound mounted on top of a catheter. The catheter is inserted into the coronary artery and can help visualize the degree of narrowing, calcification, and composition of plaque. It can also help the doctor to guide the implantation of the stent.

OPTICAL COHERENCE TOMOGRAPHY

OCT is a device similar to IVUS to help better understand the severity of the blockage. It is based on fiber optics, and catheters emit near infrared light. The quality of pictures obtained with OCT is far superior to those obtained with IVUS.

FRACTIONAL FLOW RESERVE

FFR is a technique used to assess whether the blockage visualized by coronary angiogram is physiologically limiting the blood supply to heart muscles. A wire is passed across the blockage, and a medication called “adenosine” is given intravenously to simulate maximal blood flow. The wire compares the pressure before and after the blockage to provide a number. If the number is less than 0.80, the doctor will opt to put a stent at the site of the blockage.

MECHANICAL SUPPORT DEVICES

A doctor may insert mechanical support devices in two scenarios: (1) The patient is presenting with a critical condition called “cardiogenic shock,” where the patient’s blood pressure is extremely low, and the heart is not able to pump sufficient blood to the body despite the use of strong medications. (2) The doctor determines that the blockage is very complex and wants to provide extra support to the heart while the intervention is performed. Several devices are available for use but the most commonly used devices are the IABP and Impella.

Coronary Artery Bypass Surgery

BACKGROUND

Coronary artery bypass surgery (CABG) is a safe and effective method of treating coronary artery disease.[1–3] Surgical bypass for coronary disease may be performed either in the elective setting or after acute myocardial infarction. The ACC/AHA guidelines for elective CABG in patients with coronary artery disease and emergency CABG after acute myocardial infarction are illustrated in **Tables 8.1** and **8.2**. The principles of surgical technique and postoperative care are similar; however, comorbidities strongly influence outcomes in the intensive care unit (ICU). A standardized approach is useful in the management of these complicated postoperative patients.

TABLE 8.1 ACC/AHA Guidelines for CABG in Patients With Coronary Artery Disease

1. ≥50% diameter stenosis in the left main coronary artery
2. ≥70% diameter stenoses in three major coronary arteries, with or without involvement of the proximal LAD artery
3. ≥70% diameter stenosis in the proximal LAD plus one other major coronary artery
4. Survivors of sudden cardiac death with presumed ischemia-mediated ventricular tachycardia caused by significant (≥70% diameter) stenosis in a major coronary artery
5. Patients with one or more significant (≥70% diameter) coronary artery stenoses amenable to revascularization and unacceptable angina despite maximum medical therapy

CABG, coronary artery bypass surgery; LAD, left anterior descending.

TABLE 8.2 Guidelines for Emergency CABG after Myocardial Infarction

1. Patients with acute myocardial infarction (MI) and (a) primary PCI has failed or cannot be performed, (b) coronary anatomy is suitable for CABG, and (c) persistent ischemia of a significant area of myocardium at rest and/or hemodynamic instability refractory to nonsurgical therapy is present
2. Patients undergoing surgical repair of a postinfarction mechanical complication of MI
3. Patients with cardiogenic shock who are suitable for CABG irrespective of the time interval from MI to onset of shock and time from MI to CABG
4. Patients with life-threatening ventricular arrhythmias (believed to be ischemic in origin) in the presence of left main stenosis greater than or equal to 50% and/or 3-vessel CAD

CABG, coronary artery bypass surgery; CAD, coronary artery disease; MI, myocardial infarction; PCI, percutaneous coronary intervention.

BASIC SURGICAL TECHNIQUE AND INTRAOPERATIVE CONSIDERATIONS

CABG is performed under general anesthesia with endotracheal intubation. Patients receive prophylactic antibiotics within 60 minutes prior to incision. Treatment is aimed at normal skin flora; a first-generation cephalosporin is commonly used and redosed in 4 to 6 hours based on clearance during cardiopulmonary bypass (CPB). Vancomycin may be used in regions of high prevalence of methicillin-resistant Staphylococcus species or in those patients with a long preoperative hospital length of stay.[4, 5] Continuation of prophylactic antibiotics is not indicated beyond 24 to 48 hours postoperatively.

Intraoperative monitoring is essential in maintaining appropriate physiologic parameters across all body systems. Arterial, central venous, and pulmonary artery (PA) catheterization are used for hemodynamic monitoring. Placement of a PA catheter is not a necessity in those patients with a normal ejection fraction and uncomplicated surgical procedure. Intraoperative transesophageal echocardiograms provide excellent assessment of cardiac function during and after the time of CPB. A bladder catheter with a temperature probe is placed to monitor urine output and core body temperature. Alternatively, a rectal or esophageal temperature probe may be inserted for monitoring during the warming and cooling process of CPB.

Transesophageal echocardiography (TEE) is essential for the intraoperative evaluation of cardiac anatomy, ventricular function, valve anatomy, and pathology. TEE can also be used to confirm placement of intracardiac catheters and devices, evaluate for air or thrombus within the cardiac chambers, and

record postrevascularization ventricular function. Epicardial probes may be used by the cardiac surgeon to evaluate the ascending aorta for intraluminal plaque.

CPB and cardioplegic arrest are used in many procedures to provide a motionless and bloodless field during surgical revascularization. CPB uses an extracorporeal circuit to drain the venous system; push the patient's blood through an oxygenator, warmer and filter; and return the blood into arterial circulation. Acting as a gravity siphon, a venous cannula removes blood from the right atrium or inferior vena cava (IVC) and superior vena cava directly into a container called the venous reservoir. A pump then pushes the blood through an oxygenator and a specialized filter to remove particulate matter before returning the blood into arterial circulation. The arterial cannula is most commonly located via the ascending aorta. However, in the case of dense calcification or an aneurysmal ascending aorta, cannulation may be performed in the axillary or femoral vessels. Additional cannulas are placed to infuse cardioplegic solutions and/or vent air from the cardiac chambers. Understanding the location of cannulation sites can be vital to postoperative care in the rare cases that the patient bleeds from one of the suture lines, especially if it is in a location outside of the chest (ie, following axillary or femoral cannulation).

Initiating CPB requires systemic anticoagulation for the patient's entire blood volume will be circulating through an extracorporeal circuit. Intravenous heparin is infused, 300 to 400 units/kg, to achieve an activated clotting time >450 seconds. After CPB has been discontinued, heparin is reversed with intravenous protamine sulfate.[6] Protamine is a naturally occurring protein derived from fish and therefore carries a small risk of anaphylaxis-type reaction with its use. The onset of high pulmonary arterial pressures, systemic hypotension, and acute right heart failure during the administration of protamine is concerning for a protamine reaction. Specific patients at risk include those with known fish allergies, or those who have been previously sensitized (reoperations or diabetics using protamine-containing insulins).[7]

In addition to stopping the heart and substituting circulation and ventilation with CPB, another physiologic change is the systemic cooling of patients to temperatures ranging from 28°C to 34°C to reduce cellular metabolism.[6] This provides additional protection to all organ systems. The patient is rewarmed before discontinuing CPB; core temperature is monitored in the immediate postoperative setting to ensure normothermia and prevent abnormal coagulation or an increased risk of infection.[8]

CABG is accomplished by creating a route for blood to travel from a region of

good flow (the aorta or subclavian artery), around an occlusive coronary lesion, to an area deprived of adequate flow. Available conduits include the internal mammary arteries, the greater saphenous veins (GSV), and the radial arteries. The internal mammary vessels are most commonly left in situ proximally connected to the subclavian artery and anastomosed distally to the target coronary. When the GSV or radial arteries are used, they are free grafts, requiring anastomosis proximally to the aorta for inflow. Internal mammary arterial patency rates approach 90% at 10 years; GSV patency is reported 70% to 80% at 5 years and 40% to 60% at 10 years.[9] Because of the difference in the native architecture of the venous conduit, there is a higher rate of neointimal hyperplasia and atherosclerosis, leading to earlier stenosis. Radial artery grafts have greater than 80% patency at 5 years.[9]

At the completion of the procedure, the patient is slowly weaned off CPB, and the heart restarts the work of maintaining cardiac output (CO). CPB causes a number of physiologic changes that are evident immediately after its discontinuation and into the postoperative period. Circulating the patient's blood through the extracorporeal circuit activates coagulation, complement, fibrinolytic, and cytokine cascades. This can result in a clinically significant systemic inflammatory response syndrome (SIRS) and/or coagulopathy.[6] The nonpulsatile and relatively hypotensive nature of the CPB circuit leads to activation of the body's natural sympathetic system, which can lead to an increased incidence of postoperative arrhythmias.

CABG can be performed without the use of CPB, thereby decreasing or eliminating the physiologic alterations of the bypass circuit. Off-pump CABG (OPCAB) is performed with special instruments that stabilize the beating heart and allow the surgeon a small area of motionless myocardium to complete the required vascular anastomoses. OPCAB has documented benefits, including decreased hospital costs, length of stay, myocardial dysfunction, stroke, renal dysfunction, transfusion requirements, and gastrointestinal dysfunction.[6,10–14] OPCAB techniques are used mainly by surgeons experienced with this modality. Good candidates are those patients with good cardiac function, no significant valve disease, and good target vessels. Some high-risk patients with many systemic comorbidities may do poorly with the physiologic stresses of CPB and may be candidates for OPCAB.

INITIAL CRITICAL CARE MANAGEMENT

Management of postsurgical patients begins at the time of transfer from the operating room to the ICU. To ensure this safe transit, a team of transporters that includes a member of the surgical team and anesthesia should be present to treat life-threatening situations. Before leaving the operating room, a systematic review of the patient's physiologic status should be performed. Specifically, all monitoring devices are checked, and the patient's vital signs must be appropriate for transport. Significant bleeding, hypothermia, and acidosis should be corrected before leaving the operating room.

The patient is transported with continuous electrocardiogram (ECG) tracings, invasive blood pressure monitoring, and pulse oximetry. The transport team must be equipped with battery-operated infusion pumps to have uninterrupted delivery of the required cardiovascular medications until arrival in the ICU. Sudden changes in cardiac rate, rhythm, and systemic blood pressure can occur quickly, and the transporting team must be prepared to correct them en route. The transporting team must have additional emergency medications readily available. Mechanical breaths are given via bag-mask ventilation from a portable and full oxygen tank.

Upon arrival at the ICU, the team of transporters work together with the accepting ICU staff to provide a seamless transfer of care. The endotracheal tube is immediately connected to the awaiting mechanical ventilator. Cardiovascular medication dosages and rates are confirmed by the ICU staff and, ideally, continued on the same pumps used in transport to avoid any errors. Immediate pump exchange of infusions is made if needed based on pretransfer communication of medications between the operating room and the ICU nurse. The patient's thoracic drainage tubes are immediately connected to wall suction to evacuate any residual fluid that has collected during transport.

The patient is connected to continuous ECG, invasive and noninvasive blood pressure, pulse oximetry, and the appropriate pulmonary arterial catheter tracings. Immediately after the safe transfer from the operating room to the ICU monitors, a thorough physical examination is performed for vital signs, lateralizing neurologic findings, cardiac murmurs, breath sounds, abdominal distension, quality and quantity of urine and chest tube output, and evidence of extremity malperfusion by examining for color, palpable pulses, and tactile temperature. A 12-lead ECG is obtained upon arrival for postoperative baseline and daily thereafter to evaluate for myocardial ischemia. A portable chest X-ray is checked for placement of the endotracheal tube, the positions of the thoracic drainage tubes, the presence of hemo/pneumothorax, the width of the

mediastinum, and pulmonary vascular congestion. A full set of laboratory values is obtained: arterial blood gas, basic metabolic panel, complete blood count, serum magnesium and phosphorous, serum lactic acid, and a full coagulation profile consisting of prothrombin time, activated thromboplastin time, and international normalized ratio (INR).

Diagnosis and treatment of postoperative abnormalities should involve an algorithmic and systems-based approach. **Figure 8.1** illustrates the algorithm for management of low output state after CABG.

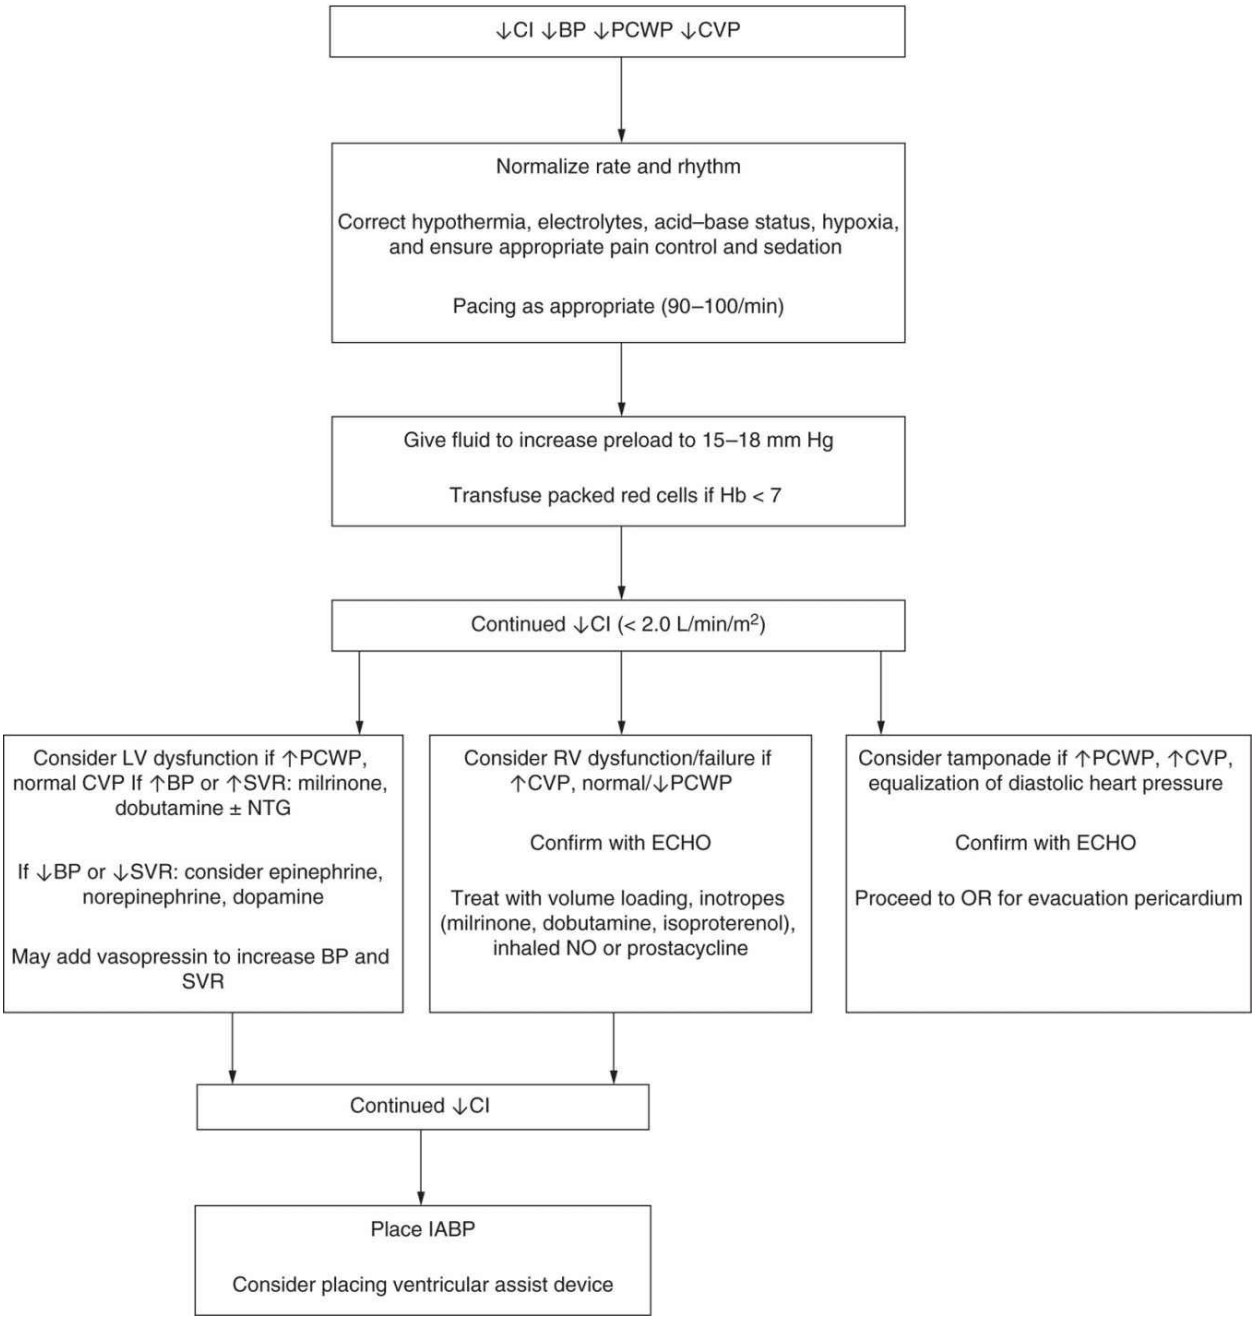

FIGURE 8.1 Algorithm for management of low output state after CABG. BP, blood pressure; CABG, coronary artery bypass surgery; CVP, central venous pressure; ECHO, echocardiogram; Hb, hemoglobin; IABP, intra-aortic balloon pump; LV, left ventricular; PCWP, pulmonary capillary wedge pressure; RV, right ventricle; SVR, systemic vascular resistance.

SYSTEMS MANAGEMENT

CARDIOVASCULAR

Postoperative cardiovascular issues can generally be divided into cardiac rate, rhythm, preload, afterload, contractility, or a combination of these. As discussed earlier, the use of a PA catheter can be omitted in patients with normal preoperative cardiac function; however, its use can provide a significant amount of information and guide management in the intensive care setting. When the PA catheter is not used, non-invasive hemodynamic monitoring, close physical examination, and clinical parameters such as urine output can be used to ensure adequate postoperative end-organ perfusion.

Rate

Rate disturbances are common in the immediate postoperative setting. Tachycardia can be caused by any number of physiologic disturbances such as CPB-induced sympathetic activation, pain, hypothermia, anemia, systemic hypoxemia, or pathologic postoperative conditions such as myocardial ischemia, tamponade, pneumothorax, or postpericardiotomy inflammation. Sinus tachycardia, although not inherently dangerous, contributes significantly to myocardial oxygen demand and should be avoided when possible in the immediate postoperative setting. Treatable causes of tachycardia should be addressed promptly. When secondary to sympathetic activation, atrioventricular (AV) nodal blockade with beta-blockers are considered first-line therapy; however, the use of beta-blockers in the immediate postoperative period is complicated by the depression of myocardial contractility. Postoperative myocardial depression usually dissipates within the first 12 to 24 hours of surgery, and beta-blockers are usually begun on postoperative day 1, with or without the presence of sinus tachycardia.

Asymptomatic bradycardia with or without conduction blockade and without changes to end-organ perfusion may not need to be treated urgently. However, when CO is inadequate, epicardial pacing may be accomplished via temporary ventricular and/or atrial wires placed routinely during the completion of the procedure. Transcutaneous pacing pads can be considered in an expedited fashion when urgent pacing is required in those patients without wires. Transvenous pacing wires can also be placed. When pacing is required, AV sequential pacing for AV nodal blockade or atrial pacing for sinus bradycardia is preferred to ventricular pacing alone to preserve the output of atrial systole, which increases preload and can contribute up to 30% of CO.

Rhythm

Rhythm disturbances, similarly, can be caused by the wide range of etiologies previously discussed, with the addition of electrolyte abnormalities (specifically potassium, magnesium, and calcium), acid–base disturbances, and myocardial irritation from indwelling catheters.

Atrial fibrillation (AF) is the most common post-CABG arrhythmia, occurring in up to 40% of patients. It usually occurs within the first 5 days of surgery but has a peak incidence at postoperative day 2. Risk factors associated with the development of AF include advanced age, history of paroxysmal AF, chronic obstructive pulmonary disease, the use of CPB, and longer intraoperative CPB times.[15, 16] Pharmacologic rate control and cardioversion are the two principles of treatment in new-onset AF. When AF is associated with rapid ventricular response, rate control is employed early to avoid a prolonged increase to myocardial oxygen demand, as is associated with other tachyarrhythmias. Beta-blockers are first-line therapy for acute rate control while corrections of the potential etiologies of the AF are explored.[17, 18]

In the absence of an identifiable and treatable cause of the AF in a stable patient, pharmacologic cardioversion may be performed with intravenous amiodarone. Administered as a bolus followed by continuous infusion, amiodarone acts both as a cardioverting agent with its Class III antiarrhythmic properties and as a sympatholytic and AV nodal blocker with its intrinsic beta receptor-blocking properties. Calcium channel blockers and digoxin are not typically used as first-line treatments in this setting.[19] Electrical cardioversion is reserved for patients with AF with rapid ventricular response with associated hemodynamic compromise. With significant hypotension or evidence of end-organ malperfusion associated with the onset of rapid AF, synchronized electrical cardioversion should be performed immediately. When AF persists, systemic anticoagulation with a heparin infusion should be initiated within 48 hours and bridged to therapeutic warfarin therapy with a target INR of 2.0 to 3.0.[18, 20]

Preload

Preload is the left ventricular end-diastolic volume (LVEDV), contributing to left ventricular (LV) myocyte stretch just prior to contraction. According to Starling’s law, increasing preload is associated with a predictable increase in LV contractility until a critical point is reached where further increases in preload lead to overdistension of the LV and a decrease in contractility. It is therefore

necessary to optimize preload to achieve the best CO. The most accurate measure of preload is by direct measurement of the left ventricular end diastolic pressure (LVEDP); this can be accomplished only via transarterial catheterization of the LV. Estimates of LVEDP can be made by measuring pulmonary artery wedge pressure (PAWP), pulmonary arterial diastolic pressure, or central venous pressure (CVP). In general, the further away the measurement from the LV, the less accurate the estimate of the LVEDP. In the postoperative period, however, these measurements can provide easy and rapid estimates of intracardiac volume status.

PAWP is measured after inflating the distally located PA catheter balloon in a segmental PA. This value approximates left atrial pressure, which in turn estimates LV pressure with the open mitral valve. Similarly, pulmonary arterial diastolic pressure, also measured by the PA catheter, estimates transmitted LA pressure. The PA diastolic pressure is, in general, slightly higher than the PAWP; it can be calibrated to the PAWP and trended in real time without having to frequently inflate the PA catheter balloon and risking PA rupture. Both PAWP and PA diastolic pressure are inaccurate in the setting of significant pulmonary hypertension or severe mitral valve disease. CVP provides the least accurate estimate of LVEDP; however, it is readily measured with a central venous catheter. CVP is an inaccurate estimation of LVEDP with right heart dysfunction, pulmonic or tricuspid valve disease. Trends, rather than direct measurements, are the most important aspect of these measurements. Fluctuations in pressure measurements mimic the changes in the LVEDP, and adjustments to postoperative resuscitation can be guided by those values.[6, 21]

Preload will be decreased when there is inadequate circulating volume. Active bleeding may be evident via increased chest tube output. More commonly, a postbypass inflammatory state results in a systemic response that includes capillary leakage and third-spacing of intravascular volume. Management is aimed at replacing lost volume, typically with colloid infusions. If there is active bleeding, packed red blood cells may be transfused to maintain adequate tissue oxygenation, as measured by the mixed venous calibration. A thick, stiffened left ventricle typical of patients with long-standing hypertension has poor compliance, and diastolic filling will be compromised. Patients with significant LV hypertrophy may require even higher filling pressures to maintain an adequate preload and normal CO.

Preload can also be compromised in the setting of cardiac tamponade. Postoperative bleeding into the pericardium increases the transmural pressure of

the cardiac chambers and compromises venous return to the right heart to restrict filling. Beck Triad (hypotension, distended neck veins, and distant/muffled heart sounds) is the classic finding in tamponade. **Table 8.3** lists the findings in acute tamponade. The diagnosis of tamponade may be subtle, however. The acute or gradual increase in CVP or PA pressures associated with hypotension may be an indication of tamponade without other physical examination findings. One can observe a trend toward equalization of the CVP, right atrial pressure, right ventricular diastolic pressure, PA diastolic pressure, and PAWP. A portable chest X-ray may show increased widening of the mediastinal silhouette, and echocardiography may demonstrate pericardial fluid with compression of the right heart and distension of the IVC. Diagnosis is critical and time-sensitive; treatment should be sought emergently. Evacuation of the pericardial blood is accomplished with resternotomy because this purely mechanical problem will be unresponsive to noninvasive treatments.[6]

TABLE 8.3 Findings of Acute Tamponade

Tachycardia and/or hypotension
Distended neck veins and elevated CVP (only if the patient is not hypovolemic)
Equalization of pressures including CVP, RA mean, RV diastolic, PA diastolic, and PA wedge (usually within 5 mm Hg)
Low voltage ECG tracings or electrical alternans
CXR findings including widening of the mediastinum or cardiac silhouette
TEE findings of RA or RV compression and IVC distension

CVP; central venous pressure; CXR, chest X-ray; ECG, electrocardiogram; IVC, inferior vena cava; PA, pulmonary artery; RA, right atrium; RV, right ventricle; TEE, transesophageal echocardiogram.

Afterload

Afterload is the pressure, or wall tension, generated by the left ventricle to overcome systemic vascular resistance (SVR) to produce adequate ejection of blood; the normal SVR range is 900 to 1200 dynes · seconds/m^5.[6, 21] Increased SVR in the postoperative period may occur secondary to increased sympathetic output after CPB, altered baroreceptor activity, hypothermia, pain, or anxiety. Patients with preoperative hypertension, diabetes, peripheral vascular disease, and chronic kidney disease are at higher risk for postoperative hypertension. The goal postoperatively is to achieve a pressure adequate for good organ perfusion, although not placing too much stress on the cardiac and vascular suture lines. This is especially true in older or frail patients with poor tissue strength. Systolic blood pressure is usually maintained between 90 and 130 mm Hg with a mean

arterial pressure of less than 90 mm Hg. A higher blood pressure may be needed in patients with significant peripheral arterial disease to maintain end-organ perfusion. Conversely, a high SVR may restrict flow through the systemic microvasculature, thereby decreasing organ perfusion. An elevated SVR places increased stress on the heart by increased LV wall tension and afterload, increasing myocardial oxygen demand and possibly worsening postoperative myocardial function.[6]

Postoperative sedatives such as propofol decrease SVR and blood pressure. Initially after arrival in the ICU, it is important that medications are both rapid onset and quickly cleared in the case of sudden hemodynamic changes.

Sodium nitroprusside lowers both SVR and pulmonary vascular resistance by relaxing arterial smooth muscle and can be used in the setting with an elevated SVR and systemic pressure. Nitroprusside is metabolized to cyanide and may therefore become toxic with prolonged use. Its toxicity is increased with liver dysfunction.

Nitroglycerin is commonly used in the setting of systemic hypertension following CABG. This venodilator increases venous compliance and reduces preload. It should be avoided in states of hypovolemia because it will significantly reduce ventricular filling and may induce a significant reflex tachycardia that will increase myocardial oxygen demand.

Short-acting beta-blockers can also be used for hypertension. However, negative inotropes are generally avoided in the immediate postoperative period. Dihydropyridine calcium channel blocking agents such as nicardipine are almost purely peripheral vasodilators and can be used to treat an elevated SVR. Caution should be exercised because this class of medication has a half-life that is significantly longer than that of nitroprusside and nitroglycerin.

A *low* SVR is also troublesome because it may cause a reflex tachycardia and an increase in CO to maintain peripheral perfusion. Decreased vasomotor tone as a result of SIRS following CPB is the most common cause of a decreased SVR. Other causes include peripheral vasodilation, sepsis, adrenocortical insufficiency, or anaphylaxis. Treatments include maintaining adequate preload, ensuring sufficient CO, and utilizing peripheral vasoconstrictors as needed. Norepinephrine is a first-line agent that may be supplemented with vasopressin or phenylephrine as needed. Epinephrine may also be used in the setting of a patient that requires both vasoconstricting and inotropic effects to maintain perfusion.

Contractility

Myocardial contractility is the intrinsic force of contraction and is generally estimated by left ventricular ejection fraction (LVEF). Patients with poor myocardial contractile function preoperatively have higher risks from surgical intervention. Those with a normal LVEF may also emerge from CABG with depressed myocardial contractility caused by ischemia-reperfusion injury, cardioplegic arrest, myocardial edema, or ischemia.

Intraoperatively, LVEF is recorded with TEE and is compared to the known preoperative values. Postoperatively, contractility may be estimated by measuring the CO using a PA catheter. Utilizing the principle of thermodilution, a small volume of cold saline is injected into the right atrial port, where it mixes with blood. The change in temperature is sensed by a probe at the tip of the catheter located distally in the pulmonary arterial tree. Cardiac output is estimated by the change in temperature of blood over time between the site of injection of cold saline and the tip of the pulmonary artery catheter. The faster the decrease in temperature, the higher the CO and vice versa. Other less invasive systems exist for estimating CO, including a FloTrac® sensor, which utilizes arterial line pressure measurements and waveforms to estimate the CO based on standardized values of SVR for the patient's height, weight, and age.

Post-CABG myocardial dysfunction is usually transient, especially in patients with normal preoperative function, and usually resolves within 12 to 48 hours. Normal CO is 4.0 to 6.0 L/min, but varies depending on the patient's size. The cardiac index (CI) is a measure of the CO, standardized to the patient's body surface area. The CI, measured in L/min/m^2, is a more effective measure of the patient's contractile function. An adequate CI should be greater than 2.0 L/min/m^2. With adequate preload and afterload, a depressed CI requires inotropic medications to augment myocardial contractility.[6]

Epinephrine is a strong alpha and beta-adrenergic agonist and can be simultaneously used as a positive inotrope and vasopressor. Dobutamine is a strong beta agonist and weak alpha agonist. Both exert strong inotropic effects and are titrated to achieve an adequate CO. Their use may be limited because of the intrinsic arrhythmogenic properties of the medications. Higher doses used to achieve an adequate CO may cause tachyarrhythmias that increase myocardial oxygen demand. Epinephrine causes fewer tachyarrhythmias at higher concentrations than does dobutamine, although both are acceptable for use in the immediate postoperative period.

Milrinone is a phosphodiesterase inhibitor that increases myocardial contractility while relaxing peripheral and pulmonary arterial smooth muscle. It is an ideal drug for an adequately volume-loaded patient with depressed myocardial contractility and an elevated SVR or pulmonary hypertension. Milrinone has a significantly longer half-life than epinephrine, and its use can have effects lasting for hours after it has been discontinued.

Other positive inotropes such as dopamine and isoproterenol exist, and their use varies depending on the clinical situation. Any medication used to treat impaired myocardial contractile function must be weighed against other systemic effects that they will induce on the critical care patient. In severe postoperative cardiogenic shock, placement of an intra-aortic balloon pump may be indicated to decrease afterload, increase coronary perfusion, and improve CO.

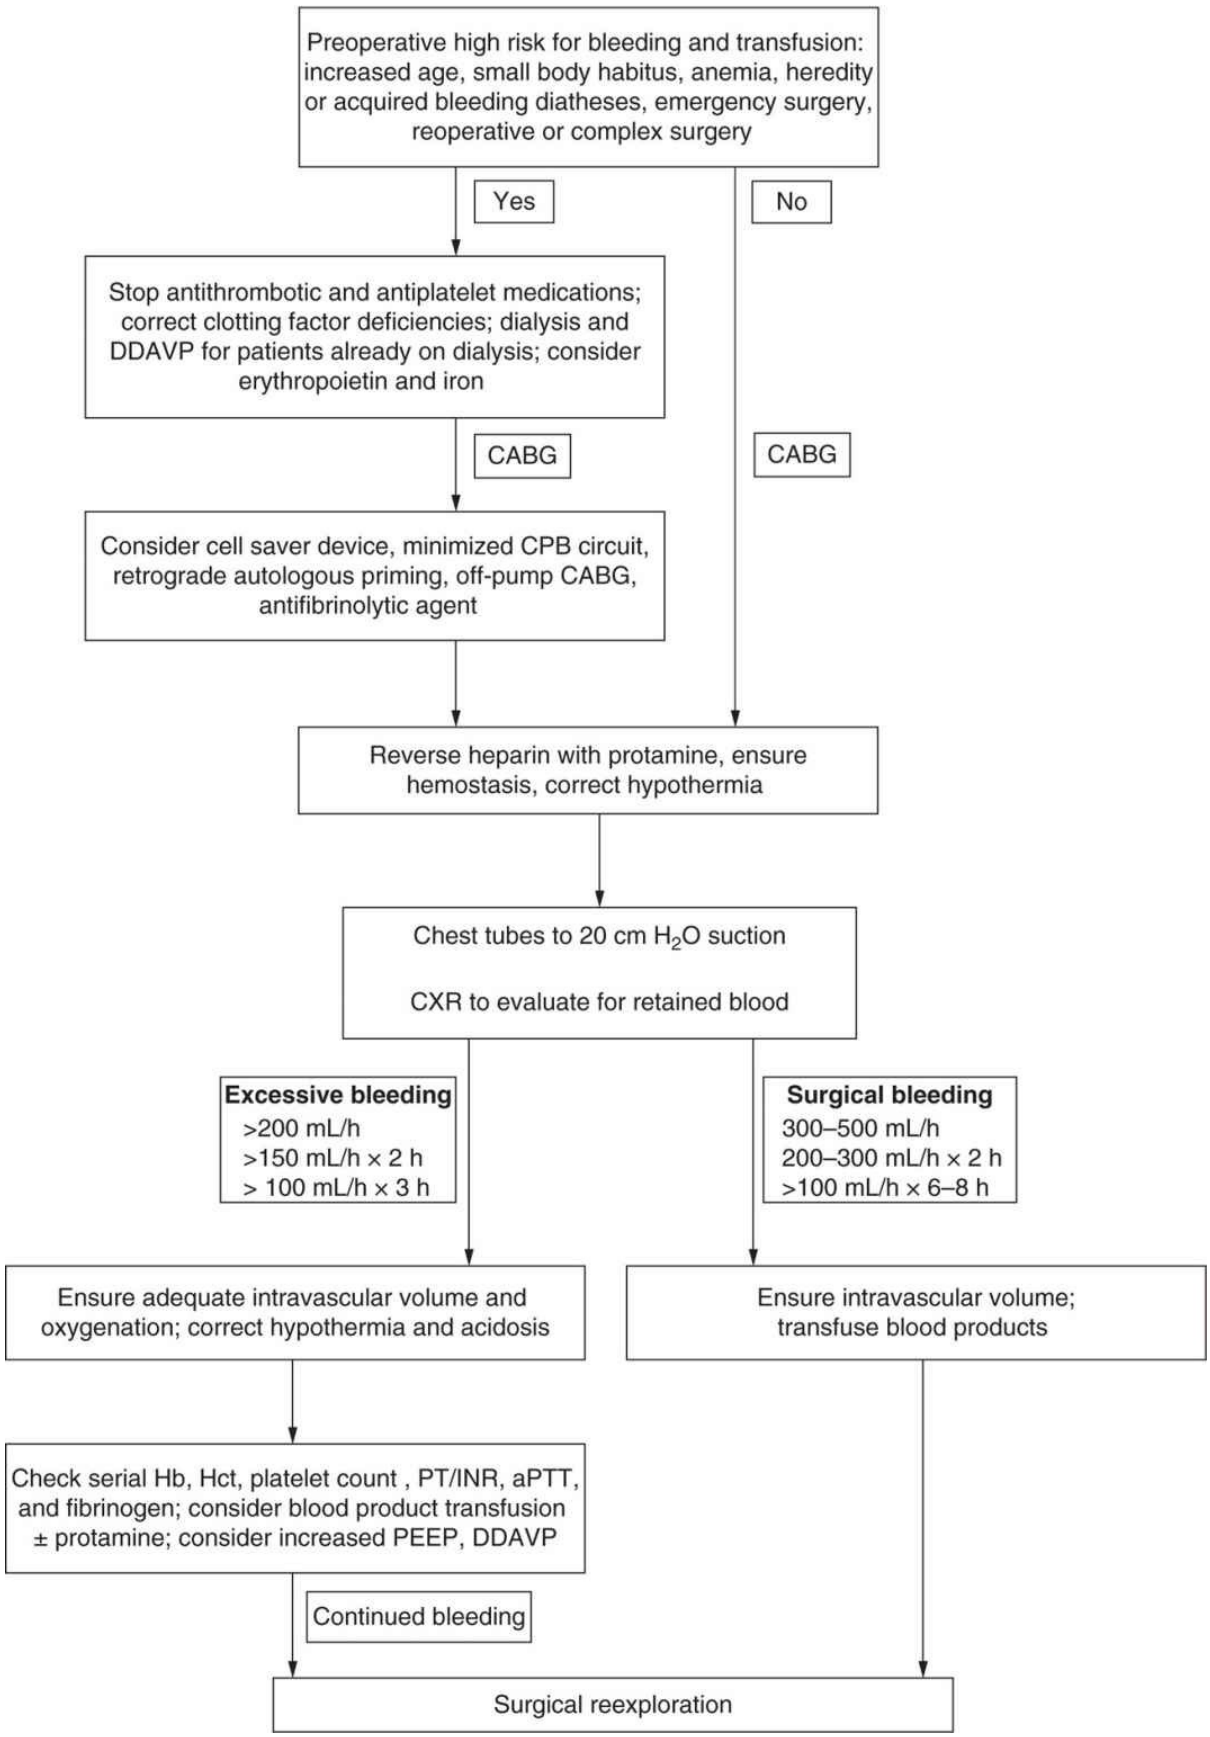
Although LV dysfunction is more commonly associated with a postoperative decrease in CI, right ventricular dysfunction may play an important role. Preexisting right heart failure, inadequate right ventricular protection during CPB, right ventricular infarction, and pulmonary hypertension may contribute to postoperative right heart dysfunction, which may present as a decreased CO. Common findings include elevated right ventricular filling pressures associated with relatively low or normal LV filling pressure. Echocardiography may demonstrate a hypokinetic and dilated right ventricle and/or new-onset tricuspid regurgitation.

Management of right heart failure is similar to that of left heart failure. The goal is to optimize preload for adequate myocardial stretch, provide inotropic support, and minimize afterload, which in this case is the pulmonary arterial vasculature. Milrinone can provide good inotropic support with pulmonary vasodilation in this setting. Dobutamine, isoproterenol, nitric oxide, prostacyclin, and sildenafil citrate may also be used as adjuncts in the ICU setting to improve RV function and decrease pulmonary hypertension.[22, 23]

BLEEDING AND HEMATOLOGIC DISTURBANCES

Bleeding in the immediate postoperative period is not uncommon post-CABG. Multiple reasons for this exist: preoperative antiplatelet agents or anticoagulants, disturbances to the coagulation cascade, hepatic dysfunction, CPB-associated platelet dysfunction, and hypothermia. The volume of hourly bleeding should trend downward from the time of sternal closure. A guideline for acceptable postoperative bleeding is 2 mL/kg for the first 3 hours, followed by 1 mL/kg for the next 3 hours, and then by 0.5 mL/kg up to postoperative hour twelve. We

define surgical bleeding mandating re-exploration vs. excessive bleeding with initial conservative measures as illustrated in **Figure 8.2**. Up to 4% of postoperative bleeding in CABG patients requires re-exploration.[24–26] Persistent hemorrhage is quickly communicated to the attending surgeon.



Preoperative high risk for bleeding and transfusion: increased age, small body habitus, anemia, heredity or acquired bleeding diatheses, emergency surgery, reoperative or complex surgery
Yes
No
Stop antithrombotic and antiplatelet medications; correct clotting factor deficiencies; dialysis and DDAVP for patients already on dialysis; consider erythropoietin and iron
CABG
CABG
Consider cell saver device, minimized CPB circuit, retrograde autologous priming, off-pump CABG, antifibrinolytic agent
Reverse heparin with protamine, ensure hemostasis, correct hypothermia
Chest tubes to 20 cm H_2O suction
CXR to evaluate for retained blood
Excessive bleeding
>200 mL/h
>150 mL/h × 2 h
> 100 mL/h × 3 h
Surgical bleeding
300–500 mL/h
200–300 mL/h × 2 h
>100 mL/h × 6–8 h
Ensure adequate intravascular volume and oxygenation; correct hypothermia and acidosis
Ensure intravascular volume; transfuse blood products
Check serial Hb, Hct, platelet count , PT/INR, aPTT, and fibrinogen; consider blood product transfusion ± protamine; consider increased PEEP, DDAVP
Continued bleeding
Surgical reexploration

FIGURE 8.2 Algorithm for the management of postoperative bleeding. aPPT, activated partial thromboplastin time; CABG, coronary artery bypass surgery; CPB, cardiopulmonary bypass; CXR, chest X-ray; DDAVP, desmopressin; INR, international normalized ratio; Hb, hemoglobin; Hct, hematocrit; PEEP, positive end-expiratory pressure; PT, prothrombin time.

The quality and quantity of chest tube drainage are examined in the bleeding patient. Fresh, bright red blood with brisk flow may indicate arterial surgical bleeding and require re-exploration. Slow draining, dark red blood may be evidence of venous bleeding or oozing from raw surfaces and may be controlled with improved coagulation, warming to normothermia, clotting factors, or watchful waiting.

Frequent laboratory tests of serum hemoglobin, hematocrit, platelet count, prothrombin time, activated partial thromboplastin time (aPTT), and INR are indicated. Although no specific transfusion trigger exists, packed red blood cell transfusions are generally initiated to maintain hemoglobin of at least 7 mg/dL. In patients with relatively more systemic oxygen demand, such as those with a lower threshold for end-organ ischemia, hemoglobin levels are general kept higher, around 8 to 10 mg/dL. In the coagulopathic patient with an elevated INR, fresh frozen plasma (FFP) may be transfused if the INR is greater than 1.5. An elevated aPTT, greater than 1.5 times baseline, may be an indication of residual circulating heparin, and additional protamine may be infused in doses of 50 to 100 mg. Checking the intraoperative anesthesia record is important because the total amount of infused protamine should not exceed 1.3 mg/100 units of heparin given for CPB.[27]

Postoperative platelet dysfunction may be a result of CPB, uremia from chronic kidney disease, or antiplatelet medications. Platelet concentrations should be maintained at 100,000/μL if ongoing coagulopathy and bleeding are present. Desmopressin (DDAVP) may also be used as an adjunct to postoperative bleeding that is thought to originate in platelet dysfunction. It causes a release of von Willebrand factor from vascular endothelium and promotes the adherence of platelets to collagen. Its routine prophylactic use to treat CPB-induced platelet dysfunction is not recommended; it may be used in excessive hemorrhage or when bleeding is secondary to uremia or known von Willebrand disease, type I or II.[26]

Cryoprecipitate, which contains factors VII, VIII, fibrinogen, and von Willebrand factor, may also be used as an adjunct to the bleeding patient receiving packed red blood cells, FFP, and platelets to account for dilution of

these factors. When massive volumes of blood product are being transfused, the ratios of packed red blood cell, FFP, and cryoprecipitate should be relatively equal.[26, 28]

Increasing intrathoracic pressure may be beneficial by effectively tamponading slowly bleeding surfaces, particularly from the chest wall. This is accomplished by increasing positive end-expiratory pressure (PEEP) on the ventilator, usually from 5 up to 8 to 10 mm Hg. The intravascular fluid status of the patient is important because this increase in PEEP reduces venous return to the heart and may cause hypotension.

Persistent hemorrhage, particularly in the setting of hemodynamic compromise with increased vasopressor requirements and normalized coagulopathy, may be an indication for return to the operating room for re-exploration.

PULMONARY

During transfer to the ICU, patients are manually bag-ventilated on 100% oxygen; they are transitioned to mechanical ventilation immediately after arrival. After arrival, a volume-controlled mode is used to maintain set minute ventilation. This mode of delivery can be programmed via assist-control ventilation or synchronized intermittent mandatory ventilation (SIMV); with the patient fully sedated, SIMV will perform as assist-control mode. The fraction of inspired oxygen is titrated down from 100% to 40% as tolerated by the patient to maintain hemoglobin saturation above 95%. Tidal volumes are set according to the patient's weight, and both tidal volume and respiratory rate should be adjusted as needed to maintain adequate ventilation after examination of the first arterial blood gas.

Most patients will be ready for extubation within 6 hours of arrival in the ICU. Risk factors for prolonged mechanical ventilation include advanced age, tobacco smoking, COPD, female gender, renal failure, emergency surgery, persistent cardiogenic shock, and cerebrovascular accidents (CVA).[29, 30]

Hemodynamically stable patients who are fully awake, alert, and following commands can proceed to ventilator weaning. Several protocols exist to ensure safe weaning from mechanical ventilation, and all rely on the patient's ability to breathe spontaneously and ventilate adequately. Initiating a spontaneous breathing trial (SBT) with zero mechanically delivered breaths, a PEEP of 5 cm H_2O, and little pressure support will allow the patient to assume the work of

breathing. During the SBT, diaphoresis, agitation, hypoxemia, use of accessory respiratory muscles, or hemodynamic instability are sufficient evidence that the patient is not ready for extubation. After 30 minutes, if the patient does not exhibit signs of physiologic distress, an arterial blood gas is measured to evaluate for adequacy of ventilation and oxygenation. If the pH ≥ 7.32, Pa_{O_2} ≥ 60 mm Hg, and P_{CO_2} ≤ 45 mm Hg, the patient meets the criteria for extubation in the right clinical setting.[6]

The patient is transitioned from mechanical ventilation to supplemental oxygen via facemask delivering humidified air. This should be progressively weaned to nasal cannula as tolerated by the patient to maintain a hemoglobin saturation above 92%. Pulmonary toilet, pain control, and mobilization are critical in the immediate postoperative period to prevent atelectasis and effusions that can delay the patient's progress. Incentive spirometry is taught to each patient and recommended frequently throughout the ICU stay.

If clinically indicated, high-flow oxygen via nasal cannula or continuous positive airway pressure via mask can be used to decrease the work of breathing for the patient and improve oxygenation. This is particularly true in obese patients or those with known preoperative pulmonary dysfunction.

RENAL

Management of fluids following CABG can be divided into two phases: (1) volume loading and (2) diuresis. Initially, maintaining an adequate preload is critical to CO, and infusion of significant volumes of intravenous fluids may be required. A urinary catheter with a temperature probe is inserted before the start of surgery and is left in place for precise hourly measurements of urine output that confirm good organ perfusion. Urine output should be maintained at 0.5 mL/kg/h; oliguria may be evidence of inadequate end-organ perfusion, and addressing problems with preload, afterload, and/or contractile function is mandatory.

Up to 8% of patients will develop acute kidney injury (AKI), and up to 0.7% will require dialysis after CABG. The presence of AKI increases the risk of perioperative mortality to 14%, and that rate is doubled for those requiring dialysis.[27, 31]

Within the first 24 to 48 hours, the CPB-associated SIRS response improves, and loss of fluid to the extravascular space secondary to capillary leak will reverse. Oncotic pressure will draw fluid into the intravascular space, and the

total body fluid volume will begin to decrease as urine output increases. In some cases, urine output alone is insufficient to remove the excess fluid. CPB can both activate the renin–angiotensin–aldosterone system and stimulate antidiuretic hormone release, both reducing fluid excretion. After the volume loading phase, when managing preload is no longer a concern, typically on the first or second postoperative day, the patient may be started on furosemide or other loop diuretic to aid in volume unloading.

GASTROINTESTINAL

Enteral feeding of the post-CABG patient should be done as soon as it is safe. For patients extubated immediately postoperatively, liquids and then solid food are started on postoperative day 1. For patients who require longer periods of mechanical ventilation, adequate caloric intake is ensured with an orogastric or nasogastric tube placed at the time of surgery. For longer-term enteral nutrition, a soft Dobhoff feeding tube should be inserted.

Gastrointestinal complications occur in 1% to 3% of CABG patients, and, although rare, they increase morbidity and mortality. The most common ones include paralytic ileus (gastric, small bowel, or colonic in origin), upper gastrointestinal bleeding, mesenteric ischemia attributed to diffuse hypoperfusion or acute vascular occlusion, and acute acalculous cholecystitis.

Paralytic ileus of the small bowel or colon may present with abdominal cramping, distension, nausea with bilious emesis, and obstipation. Its cause in the post-CABG patient is usually secondary to the use of opioid analgesics; however, CPB-associated SIRS may play a role. Treatment is largely supportive and requires bowel rest; discontinuation of opioid medications; and maintenance of adequate electrolyte levels, intravenous hydration, and early mobilization. Nasogastric decompression is indicated in the setting of persistent nausea and emesis and should be maintained until evidence of bowel function returns.[32–34]

Upper gastrointestinal bleeding may occur from previously undiagnosed gastroduodenal lesions, stress ulcers, or diffuse gastritis secondary to hypoperfusion. Epigastric pain associated with nausea and bloody or “coffee-ground” emesis should immediately prompt further investigation with esophagogastroduodenoscopy EGD. Other findings include melena and increasing blood urea nitrogen (BUN) with a normal serum creatinine with decreasing serum hemoglobin. In all high-risk patients postoperatively, the use of acid-reducing medications is initiated to reduce the incidence of bleeding

caused by stress gastritis.[35–37]

Mesenteric ischemia can be a life-threatening disease that requires urgent work-up. In post-CABG patients, especially those suffering from decreased CO, systemic hypoperfusion may lead to diffuse ischemia. This may be exacerbated in patients with known mesenteric arterial occlusive disease. Presenting symptoms may include vague abdominal pain, abdominal distension, obstipation, or hematochezia, as the endothelium necroses and begins to slough. Acute thrombosis or embolism to a major mesenteric vessel may also produce ischemia. In this case, the onset of pain may be more acute and intense with a patient in more distress than clinical examination would indicate. In both cases, elevations of white blood cell count and serum lactic acid occur as the ischemic bowel transitions to anaerobic metabolism. In a hemodynamically stable patient, a suspicion for mesenteric ischemia should be worked up with computed tomography (CT) angiography. In a rapidly deteriorating patient with a high suspicion for mesenteric ischemia, surgical exploration of the abdomen, possibly with on-table mesenteric angiography and bowel resection, should be planned.

Acalculous cholecystitis is a classic disease of the ICU patient with poor CO and compromised foregut perfusion. Symptoms may include acute onset of right upper quadrant pain with tenderness, fever, rigors, nausea, and emesis. Laboratory studies may be normal or demonstrate a new leukocytosis and hyperbilirubinemia or mild transaminitis. Diagnosis is usually made with right upper quadrant abdominal sonography, specifically looking for thickening of the gallbladder wall, pericholecystic fluid, and usually the absence of gallstones. Patients with acalculous cholecystitis may be treated with antibiotics alone. If the patient begins to clinically deteriorate, and fails nonoperative management, the placement of a percutaneous cholecystostomy tube will usually treat the obstruction without the need for further immediate surgical intervention.[38, 39]

NEUROLOGIC

The post-CABG patient is at significant risk for neurologic insults. Clinically significant postoperative CVA following CABG are estimated at 1% to 2%. Risk factors include increasing age, diabetes, previous CVA, carotid artery occlusive disease, significantly calcified aorta, aortic or mitral valve, prolonged CPB time, and AF.[40, 41]

CVA can be divided grossly into embolic or hemorrhagic stroke, global hypoperfusion, or hypoxemia. Clinically evident strokes are usually identified

after the patient is wakened from anesthesia and a full neurologic examination is completed. Inability to fully regain consciousness once sedation is weaned, hemiplegia or other lateralizing deficits, dysarthria, and visual field abnormalities may be apparent. Immediate noncontrast CT of the head should be obtained in any patient for whom suspicion for CVA exists.

Confusion and agitation are also common neurologic disturbances that occur in the postoperative setting. Although gross agitation is usually clear to all, subtle signs of confusion may be apparent only to a patient's family or nurse who cares for the patient from day to day. A mental status examination should be performed to assess the patient's orientation. If the patient is a threat to himself or others, emergency sedation or 1:1 observation may be indicated.

In all cases, a full assessment of the potential causes of the change in mental status is performed. Etiologies of confusion include narcotic medications, CVA, hypoxemia or hypercapnia, alcohol withdrawal, metabolic derangements such as hypoglycemia, elevated BUN, ammonia or acidosis, and seizure activity. Treatment is aimed at correction of the underlying cause. When none can be reliably identified, noncontrast head CT and/or electroencephalogram may be required. Neurology consultation is always obtained.

Patient and Family Information for: CORONARY ARTERY BYPASS SURGERY

BACKGROUND

CABG is a surgical procedure performed for patients who have blockages in the arteries that deliver oxygenated blood to their heart muscle. These blockages are caused by atherosclerosis, which occurs as a result of risk factors: smoking, hypertension, high cholesterol, diabetes mellitus, and family history.

Not all patients require surgery for these blockages; some can be treated with medications and others with minimally invasive procedures called stents. Surgery is recommended for those patients with a blockage in the main artery to their heart (left main artery) or multiple blockages in a patient with diabetes or decreased heart function. Some complex lesions also require surgical bypass.

Patients can be seen as outpatients to schedule their procedure. Others arrive in the hospital with a small or large heart attack, and it is recommended that they have surgery urgently to prevent complete blockage of the heart arteries that would result in a major heart attack and permanent loss of heart muscle function.

PROCEDURE

CABG surgery is performed with the patient asleep under general anesthesia. Most surgeries require between 3 and 6 hours, depending on the number of grafts that need to be placed. Although there are three main arteries to the heart, the branches of these arteries may be large and supply a significant amount of muscle. For that reason, patients may require between 1 and 6 grafts, depending

on the number of specific blockages and their specific anatomy.

The basis of the surgery is to use a vessel, or conduit, to bring new blood supply to the heart. The actual lesion itself is not removed. Rather, blood is rerouted from an area of high blood flow (such as the aorta), past the blockage, to an area of lesser blood flow. This procedure is often performed with the patient on a heart–lung machine, or CPB circuit. This device takes over the work of the heart and lungs while the surgeon is performing the operation. At the completion of the surgery, the patient is weaned off the machine, and the heart resumes beating on its own, pumping blood to the lungs and body.

CRITICAL CARE MANAGEMENT

Most patients are brought straight to the ICU after surgery. The first 48 hours are the most critical time after heart surgery. The patient is monitored closely for any changes in their blood pressure, heart rate, and organ function. Once they are awake after anesthesia and strong enough, they are removed from the ventilator and are able to breathe on their own.

In the ICU, the patients are watched closely for any signs of bleeding, irregular heart rates, and organ dysfunction. They are encouraged to deep breathe and cough to keep their lungs expanded. Pain control is very important for this process, and although they initially receive strong intravenous medications, they are slowly transitioned to oral medications as their pain improves. Respiratory therapists work with the patients immediately after arrival and throughout their hospital stay.

Another important part of recovery is mobilizing the patient after surgery. This helps lung function, bowel function, and overall strength. Deconditioning after heart surgery can be severe, and physical therapy is necessary to prevent this. Physical therapists work with all patients from the first day after surgery and continue to help them as they take a few steps, walk in the hallways, climb stairs, and mobilize on their own.

RECOVERY

Most patients are in the ICU for 24 to 48 hours after CABG surgery, barring any complications. The patient is then moved to a step-down monitored room in

preparation for discharge. In uncomplicated cases, families can expect their loved ones to return home within 5 to 7 days after surgery.

Medications Used in the Management of Acute Coronary Syndrome

The pharmacologic management of an acute coronary syndrome (ACS) has evolved dramatically over the past three decades into a heavily evidence-based discipline. Contemporary treatment strategies have become more targeted, focusing on the unique pathophysiologic underpinnings of this disorder. Additionally, new therapeutic approaches are rigorously tested and proven in large clinical trials before becoming standard therapy. As our armamentarium of new therapeutics continues to grow, our diagnostic and management strategies will necessarily change over time. As such, practitioners caring for patients with ACS must become life-long students of this exciting and dynamic field in order to provide the best care for their patients in the years to come.

Appropriate medical therapy is indicated for all patients presenting with or suspected of having ACS. The goals of initial medical therapy are fourfold: to relieve pain, to halt the progression of disease, to reduce morbidity, and to improve survival. Because the term *ACS* encompasses a spectrum of severity with a common pathophysiology, the difficulty in the pharmacologic management comes in determining where in the spectrum a particular patient falls and balancing the risks and benefits in treating that patient to achieve the desired goals.

Once the diagnosis of ACS is established, the patient should quickly be

stratified by risk into one of several treatment strategies. Medical therapy should be immediately started in a rational manner to achieve the initial goals of treatment, namely, to interrupt platelet activation/aggregation and thrombus formation and to relieve pain. Patients diagnosed with an ST-segment elevation myocardial infraction (STEMI) should be emergently stratified to primary percutaneous coronary intervention (PCI) or fibrinolytic therapy, whereas those with unstable angina (UA)/non–ST-segment elevation myocardial infarction (NSTEMI) should be risk stratified into either an early invasive or an initial conservative approach. Regardless of what treatment strategy is initiated, patients should be continuously evaluated for high-risk features of disease, adverse hemodynamic consequences, and treatment failure. Such features often mandate deviation from the initial management strategy to a more aggressive one. Importantly, as a patient transitions from one treatment strategy to another, the pharmacologic approach can vary substantially.

In general, the pharmacologic approach to managing ACS should be prioritized with an emphasis on rapid treatment with medications known to provide morbidity and mortality benefit. Guidelines for treatment are useful; however, they cannot address every possible nuance experienced in clinical practice. Health care providers must have a thorough understanding of their institutional capabilities and preferences, as well as familiarity with the drugs, doses, indications, and side effects in order to provide patients with optimal benefit and minimal harm.

ANTI-ISCHEMIC AND ANALGESIC THERAPY

β-ADRENERGIC BLOCKERS

Rationale: β-Blockers are used to inhibit the actions of catecholamines on the β_1-adrenergic receptors located in the myocardium. Inhibition of these receptors leads to a reduction in myocardial contractility, atrioventricular (AV) node conduction, sinus node rate, and an overall reduction in systolic blood pressure. The net effect of these actions results in a decrease in cardiac work and myocardial oxygen demand. Additionally, β-blockers increase diastolic pressure-time, which may be important in increasing coronary blood flow. In patients with ACS undergoing PCI, a large meta-analysis showed a significant reduction in mortality at 30 days and 6 months for patients who received β-blocker therapy.[1] However, the COMMIT trial failed to demonstrate a mortality benefit with the

early use of β-blockers in patients with myocardial infarction.[2] This finding has been attributed to injudicious use of β-blockers in patients with heart failure or other risk factors for cardiogenic shock and has been instructive in the most recent guidelines involving recommendations for β-blocker usage in ACS. In contrast to the early aggressive use of β-blockers for acute myocardial infraction (MI), the CAPRICORN trial demonstrated a reduction in all-cause mortality, cardiovascular mortality, and nonfatal MI with β-blockers when 1959 patients with acute MI and left ventricular (LV) dysfunction were randomized to receive to low-dose carvedilol versus placebo and treated with a more gradual uptitration strategy.[3]

Indications: ACS (without contraindications), stable angina, compensated chronic heart failure.

Dosing: Multiple preparations available including intravenous (IV) and oral, β_1 selective and nonselective, short and long acting (**Table 9.1**).

TABLE 9.1 β-Blockers Used in ACS

DRUGS	SELECTIVITY	DOSE	COMMENT
Metoprolol tartrate	β_1	50–200 mg twice daily	Often initiated with 12.5–25 mg every 6–8 h
Metoprolol succinate	β_1	12.5–200 mg daily	Short-acting tartrate preferred for ACS; however, mortality benefit shown for stable patients with CHF
Carvedilol	β_1, β_2, α_1	3.125–25 mg twice daily	Started low and titrate up; mortality benefit for LV dysfunction
Bisoprolol	β_1	1.25–5 mg twice daily	
Atenolol	β_1	25–200 mg daily	
Labetalol	β_1, β_2, α_1	200–600 mg twice daily	
Propranolol	β_1, β_2	20–80 mg twice daily	
Esmolol	β_1	50–300 μg/kg/min	

ACS, acute coronary syndrome; CHF, congestive heart failure; LV, left ventricular.

Side effects: Hypotension, bradycardia, AV block, acute exacerbation of heart failure, bronchospasm, paradoxical hypertension (HTN) in setting of active cocaine use.

Contraindications: High-grade AV block, active bronchoconstriction, hypotension, bradycardia, severe LV dysfunction or heart failure (rales, S3 gallop), or in patients with myocardial infarction at high risk for cardiogenic shock (older age, female sex, relative hypotension, high Killip class, reflexive tachycardia).

Recommendations: The acute use of β-blockers in ACS is recommended in all patients without contraindications, especially in patients with ongoing angina and HTN. Short-acting, β_1 selective agents are typically used to minimize side effects and allow for dose titration. The common practice used to be a regimen of metoprolol 5 mg IV, repeated every 5 minutes, up to a total of 15 mg. Oral therapy can be started at metoprolol 25 to 50 mg every 6 hours, or bisoprolol 1.25 mg every 12 hours, and titrated to achieve the desired heart rate or blood pressure. Frequent heart rate and blood pressure checks, continuous electrocardiography (ECG) monitoring, and routine auscultation for rales and bronchospasm should be performed (preferably in an intensive care unit setting). Once stabilized, patients should receive maintenance doses of up to 100 mg metoprolol twice daily or bisoprolol 2.5 to 5 mg twice daily. In patients with LV dysfunction, β-blockers with proven mortality benefit such as bisoprolol, carvedilol, and metoprolol succinate should be utilized for long-term management.

CALCIUM CHANNEL BLOCKERS

Rationale: Calcium channel blockers (CCBs) inhibit myocardial and vascular smooth muscle contraction by reducing transmembrane inward calcium flux. In ACS, CCBs are useful in decreasing myocardial oxygen demand (by decreasing afterload, contractility, and heart rate) and in coronary vasodilatation. Meta-analyses of UA/NSTEMI trials involving CCBs have suggested no overall benefit in death or nonfatal MI.[4] Retrospective studies of verapamil and diltiazem have shown increased mortality in patients with LV dysfunction.[5, 6] Additionally, a trial using nifedipine was stopped early because of concern for harm when taken without concomitant β-blockers.[7]

Indications: In ACS, considered second-line therapy in β-blocker-intolerant patients for relief of angina, blood pressure control, and rate control of

supraventricular arrhythmias. CCBs are considered adjuncts to β-blockers and nitrates for the relief of ischemic symptoms. They are generally the preferred treatment for patients with cocaine-induced myocardial ischemia or variant angina.

Dosing: Multiple preparations both IV and oral, short and long acting (**Table 9.2**).

TABLE 9.2 Calcium Channel Blockers Used in ACS

DRUG	DOSE	DURATION OF ACTION	COMMENT
Nondihydropyridines			
Diltiazem	Immediate release: 30–90 mg every 6 h	Short	Avoid with known or suspected LV dysfunction
	Slow release: 120–360 mg 3 times daily	Long	
Verapamil	Immediate release: 80–160 mg every 8 h	Short	Avoid with known or suspected LV dysfunction
	Slow release: 120–480 mg daily	Long	
Dihydropyridines			
Amlodipine	5–10 mg daily	Long	
Felodipine	5–10 mg daily	Long	
Nisoldipine	20–40 mg daily	Short	

ACS, acute coronary syndrome; LV, left ventricular.

Side effects: Hypotension, bradycardia, myocardial depression (diltiazem and verapamil), flushing, edema, headache.

Contraindications: Hypotension, AV conduction abnormalities, LV dysfunction or congestive heart failure (CHF) (especially diltiazem and verapamil).

Recommendations: In patients with contraindications to β-blockers or in those whom β-blockers and nitrates have failed to achieve relief of ischemia or rate control with supraventricular arrhythmias, CCBs can be used to further reduce blood pressure and chest pain. Caution should be exercised when CCBs and β-

blockers are used concomitantly because of depressed AV nodal conduction. Diltiazem and verapamil should be avoided in patients with LV dysfunction. Use of dihydropyridines such as amlodipine and felodipine appear to be safe with LV dysfunction, although their benefit remains undefined in the treatment of ACS; nifedipine should be avoided altogether.

NITRATES

Rationale: Despite a paucity of rigorous clinical trial data, nitrates continue to remain important in the treatment of HTN and chest pain in patients with ACS. Nitrates cause a reduction of myocardial oxygen demand while enhancing myocardial oxygen delivery and affect both peripheral and coronary vascular beds. Nitroglycerin (NTG) increases venous capacitance, thereby decreasing preload and reducing ventricular wall tension. Furthermore, NTG promotes the dilation of the coronary arteries, and possibly has a mild inhibitory effect on platelet aggregation (although the clinical significance of this is not known).

Indications: Angina, HTN, CHF, variant angina.

Dosing: NTG is available in multiple preparations including sublingual tablets and spray, transdermal, and intravenously (**Table 9.3**).

TABLE 9.3 Nitrate Preparations Used in ACS

COMPOUND	ROUTE	DOSE	DURATION OF EFFECT
Nitroglycerin	Sublingual tablets	0.3–0.6 up to 1.5 mg	1 to 7 min
	Spray	0.4 mg as needed	Similar to sublingual tablets, however, has a longer shelf life
	Transdermal	0.2–0.8 mg/h every 12 h	8 to 12 h with intermittent therapy; efficacy improved with 12 h off period
	Intravenous	5–200 μg/min	Tolerance in 7 to 8 h
Isosorbide dinitrate	Oral	5–80 mg, every 8–12 h	Up to 8 h
	Oral, slow release	40 mg, every 12–24 h	Up to 8 h
Isosorbide mononitrate	Oral	20 mg twice daily	12 to 24 h

	Oral, slow release	60–240 mg daily

ACS, acute coronary syndrome.

Side effects: Headaches, hypotension, and tachyphylaxis are common with NTG usage.

Contraindications: NTG is contraindicated after the use of phosphodiesterase inhibitors used for the treatment of erectile dysfunction such as sildenafil, tadalafil, and vardenafil as concominant use can induce profound hypotension. Additionally, nitrates should be avoided in patients suspected of having a right ventricular infarct because its usage can result in severe hypotension even with low doses.

Recommendations: NTG use is typically initiated with three 0.4-mg sublingual NTG tablets taken 5 minutes apart with the concomitant administration of either an oral or IV β-blocker. For patients with ongoing chest pain, HTN, or decompensated heart failure, it is appropriate to switch to IV NTG. This is given at 10 μg/min through continuous infusion via nonabsorbing tubing and can be up titrated by 10 μg/min every 3 to 5 minutes to achieve symptomatic relief or desired blood pressure response. Although there is no published maximal ceiling dose, 200 μg/min is typically used because there is unlikely to be measurable clinical benefit beyond this rate. For blood pressure titrations, NTG should be titrated to less than 110 mm Hg in previously normotensive patients or to greater than 25% lower than the starting Mean Arterial Pressure (MAP) in hypertensive patients. NTG should generally be avoided in patients with starting systolic blood pressures of less than 90 mm Hg, in patients with marked bradycardia or tachycardia, or in patients who present with systolic blood pressures 30 mm Hg or more below their baseline. After a patient has been stable or chest pain free for 12 to 24 hours, it is prudent to attempt weaning IV NTG or transitioning to an oral preparation if still indicated.

MORPHINE

Rationale: Although there is a lack of randomized clinical trials, morphine sulfate provides analgesic and anxiolytic effects that might partially counteract the adrenergic drive associated with ACS. Additionally, it causes mild venodilation, a modest reduction in heart rate via increased vagal tone, and decreased blood pressure, which lowers myocardial oxygen demand.

Dosing: Morphine sulfate 1 to 5 mg IV PRN.

Side effects: Nausea, vomiting, respiratory depression, hypotension.

Recommendations: Morphine should be considered for anginal relief in patients not sufficiently controlled with nitrates, β-blockers, or CCBs and is often given in preparation for further invasive testing.

ANCILLARY THERAPIES

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND ANGIOTENSIN II RECEPTOR BLOCKERS

Rationale: Inhibition of the renin–angiotensin–aldosterone system has salutary effects on blood pressure, afterload reduction, and LV remodeling associated with myocardial infarction (MI)-induced LV dysfunction. Angiotensin-converting-enzyme (ACE) inhibitors have a proven track record in multiple clinical trials for decreasing mortality, particularly when started within 24 hours to 16 days after myocardial infarction in patients with depressed ejection fractions, heart failure, and diabetes mellitus.[8–12] Patients with higher risk gained greater benefit. Additionally, the VALIANT trial demonstrated that valsartan was as effective as captopril in the reduction of death following MI in patients with demonstrable LV dysfunction or clinical heart failure.[13] Therefore, in addition to their proven clinical role in stable CHF, angiotensin receptor blockers (ARBs) appear to also offer benefit in the ACS setting.

Indications: ACS with concurrent pulmonary congestion or LVEF ≤ 40%, in absence of contraindications. ARBs should be given to patients intolerant of ACE inhibitors.

Dosing: Multiple preparations both short and long acting. IV forms are not recommended for ACS (**Table 9.4**).

TABLE 9.4 ACE Inhibitors and ARBs Used in ACS

ACE Inhibitors				
Drug	***Starting dose***	***Typical dose***	***Maximum dose***	***Comments***
Benazepril	10 mg	20–40 mg	80 mg	May use bid dosing
Captopril	6.25–12 mg bid–tid	25–50 mg bid–tid	450 mg daily	Target dose in HF: 50 mg tid
Enalapril	2.5–5 mg daily–bid	10–40 mg	40 mg	Target dose in HF: 10 mg bid

Fosinopril	10 mg	20–40 mg	80 mg	
Lisinopril	2.5–5 mg	10–40 mg	80 mg	Target dose in HF: 20 mg daily
Moexipril	7.5 mg	7.5–30 mg	30 mg	
Perindopril	4 mg	4–8 mg	16 mg	
Quinapril	10 mg	20–80 mg	80 mg	Target dose in HF: 20 mg daily
Ramipril	2.5 mg	2.5–20 mg	20 mg	
Trandolapril	1 mg	2–4 mg	8 mg	Reduce dose in hepatic dysfunction
ARBs				
Candesartan	8–16 mg	16–32 mg	32 mg	
Eprosartan	600 mg	600–800 mg	800 mg	
Irbesartan	75–150 mg	150–300 mg	300 mg	
Losartan	25–50 mg	50–100 mg	100 mg	Reduce dose in hepatic dysfunction
Valsartan	20 mg	160 mg	320 mg	
Olmesartan	20 mg	20–40 mg	40 mg	
Telmisartan	20–40 mg	40–80 mg	80 mg	

ACE, angiotensin-converting-enzyme; ACS, acute coronary syndrome; ARBs, angiotensin receptor blocker; HF, heart failure.

Side effects: Hypotension, hyperkalemia, angioedema and cough (ACE inhibitors).

Contraindications: Hemodynamic instability, renal failure, hyperkalemia.

Recommendations: Typically initiated early, within the first 24 hours of hospital stay, in patients without contraindications. Use of short-acting formulations (ie, captopril 6.25 mg q8h) allows for dose titration. Once stable, once-daily dosing can be initiated. IV ACE inhibitors should be avoided in the management of ACS.

ALDOSTERONE RECEPTOR ANTAGONISTS

Rationale: Aldosterone receptor antagonists have been shown to prevent deleterious ventricular remodeling after acute MI, decrease the rate of death, and

reduce hospitalizations in patients with chronic severe heart failure. The EPHESUS trial further expanded the beneficial role in renin–angiotensin–aldosterone blockade by demonstrating a reduction in morbidity and mortality for patients presenting with acute MI complicated by heart failure and LV dysfunction (LVEF ≤ 40%) when treated with eplerenone.[14]

Indications: ACS with concurrent pulmonary congestion or LVEF ≤ 40%, in absence of contraindications.

Dosing: Eplerenone 25 mg daily with gradual uptitration to a maximum of 50 mg daily. Frequent monitoring of electrolytes, especially potassium and creatinine, is essential.

Side effects: Hypotension, hyperkalemia, renal dysfunction.

Contraindications: Hemodynamic instability, renal failure, hyperkalemia.

Recommendations: Given the totality of evidence to date, ACE inhibitors and ARBs remain preferred first-line therapy agents for renin–angiotensin–aldosterone blockade for patients with ACS and concurrent LV dysfunction. However, the addition of an aldosterone receptor blocker such as eplerenone may be considered in patients already receiving optimal medical treatment in the absence of contraindications.

HMG-COA REDUCTASE INHIBITORS (STATINS)

Rationale: Statins have been widely studied both in primary and secondary prevention for chronic coronary artery disease (CAD). The “pleiotropic” effects of statins include not only their well-established ability to lower the levels of low-density lipoprotein (LDL), but also their anti-inflammatory, antioxidant, and antithrombotic properties. The first clinical trial to demonstrate benefit of statins given early (24 to 96 hours) after ACS was MIRACL study—compared with placebo, atorvastatin given for 16 weeks reduced the composite end point of death, nonfatal MI, cardiac arrest with resuscitation, or recurrent symptomatic myocardial ischemia with objective evidence and requiring emergency rehospitalization by 16% (95% CI: 0.7 to 1.0, $P = 0.048$).[15] Also in the setting of ACS, PROVE IT-TIMI 22 showed a significant 16% reduction in the hazard ratio for death, MI, UA, revascularization and stroke in patients treated with intensive lipid-lowering therapy (atorvastatin 80 mg) compared with standard therapy (pravastatin 40 mg) and followed for 18 to 36 months.[16]

Indications: STEMI and UA/NSTEMI.

Dosing: Multiple agents; however, atorvastatin was the most studied for ACS.

They are typically given at 40 to 80 mg po daily (**Table 9.5**).

TABLE 9.5	Statins Used in ACS
DRUG	**DOSE**
Atorvastatin	10–80 mg daily
Fluvastatin	20–80 mg daily
Lovastatin	10–80 mg daily
Pravastatin	10–80 mg daily
Rosuvastatin	5–40 mg daily
Simvastatin	10–80 mg daily

Side effects: Dyspepsia, rash/pruritis, myalgias, hepatotoxicity, rhabdomyolysis (rare).

Contraindications: Caution should be exercised when used with cytochrome P450 inhibitors and in the setting of elevated transaminases.

Recommendations: Statins at high doses should be considered early in the course of patients presenting with ACS, irrespective of the baseline LDL-cholesterol levels. Statins should be considered standard therapy for secondary prevention in the absence of contraindications.

ANTIPLATELET MEDICATIONS

ASPIRIN (ASA)

Rationale: Aspirin is a potent, irreversible platelet COX-1 inhibitor that inhibits the production of thromboxane A_2 and results in decreased platelet aggregation at the site of intimal injury and thrombus formation. Although it is a relatively weak inhibitor of overall platelet aggregation, ASA confers a significant reduction in mortality.[17–21]

Indications: ACS (diagnosed or suspected), chronic CAD.

Dosing: Initial dosing should be 162 to 325 mg given orally as a nonenteric coated, chewable tablet to allow for rapid buccal absorption. If active nausea or vomiting, a 300-mg rectal suppository should be promptly administered. The maintenance dose of ASA is conventionally the lowest available dose, which

ranges from 75 to 100 mg/d in different countries (81 mg/d in North America).

Side effects: Nausea, vomiting, dyspepsia, gastrointestinal (GI)/genitourinary (GU) bleeding.

Contraindications: The only contraindication is patients with true ASA allergy (anaphylaxis, hives, nasal polyps, bronchospasm). Such patients should be given a thienopyridine such as clopidogrel, with strong consideration given for ASA desensitization treatment.

Recommendations: Aspirin 325 mg should be administered to all persons as soon as ACS is diagnosed or suspected, typically in the ambulance or the emergency department. In general, therapy with ASA should be continued indefinitely after the first presentation with ACS at a low dose of 75 to 81 mg daily.

$P2Y_{12}$ ADENOSINE DIPHOSPHATE RECEPTOR INHIBITORS

$P2Y_{12}$ inhibitors are inhibitors of adenosine diphosphate (ADP)-induced platelet aggregation and dual antiplatelet therapy (DAPT) of $P2Y_{12}$ inhibitors (thienopyridines and nonthienopyridines) along with ASA have become a cornerstone in the pharmacologic management of patients with ACSs and after coronary stent placement. The first thienopyridine introduced and used after coronary stenting was ticlopidine. Since the introduction of other agents of this group, ticlopidine use has been largely decreased mainly due to unfavorable side-effect profile including GI effects, neutropenia, and thrombotic thrombocytopenic purpura (TTP) in addition to long onset of action and frequent dosing. Therefore, ticlopidine is no longer recommended in the treatment of ACS. During the last two decades, another three oral $P2Y_{12}$ inhibitors have received the Food and Drug Administration (FDA) approval in the United States for use in ACS: clopidogrel, prasugrel, ticagrelor, and another IV agent introduced recently, cangrelor. Each of these drugs work by inhibiting the $P2Y_{12}$ ADP receptor on platelets, with ticagrelor being the only oral drug with reversible inhibition. They differ importantly with respect to their onset of action, side-effect profile, and overall potency. Evidence for the beneficial use of $P2Y_{12}$ inhibitors comes from multiple, large-scale randomized trials. Because DAPT with $P2Y_{12}$ inhibitors exert more robust platelet inhibition than ASA alone, the risk of subsequent bleeding is higher and therefore appropriate $P2Y_{12}$ inhibitors selection should be tailored to a patient's individual bleeding risk.

Clopidogrel

Rationale: Clopidogrel is an irreversible $P2Y_{12}$ receptor inhibitor, the most studied thienopyridine, and the most used until the introduction of ticagrelor. As the maximal therapeutic platelet inhibition of clopidogrel takes 3 to 7 days to reach, the administration of a loading dose of 300 to 600 mg, resulting in substantial inhibition within approximately 2 hours, has been used in ACS studies. In the CURE trial, patients with UA or NSTEMI were found to have a lower rate of cardiovascular death, nonfatal MI, or stroke when treated with ASA and clopidogrel than ASA alone (9.3% vs 11.4%, $P < 0.001$); however, this came at the expense of major bleeding, particularly in patients who subsequently underwent coronary artery bypass graft (CABG).[22] In STEMI patients, the COMMIT-CCS-2 study demonstrated a significant reduction in the composite end point of death, reinfarction, and stroke (9.2% clopidogrel vs 10.1% placebo, $P = 0.002$) in 45,852 patients treated with clopidogrel, 93% of whom had ST elevation.[23] The addition of clopidogrel to fibrinolytic therapy was proven beneficial in the CLARITY-TIMI 28 trial where 3491 patients with STEMI had a significant reduction in occluded infarct artery on angiography, death, or recurrent MI when treated with clopidogrel (15% clopidogrel vs 21.7% placebo, $P < 0.001$).[24] This was felt to be driven by the prevention of infarct-related reocclusion. Randomized controlled trials of clopidogrel versus placebo, added to ASA, in primary PCI for patients with STEMI has not been conducted and its efficacy in that setting has been assumed on the basis of the results of studies of patients with ACS undergoing elective PCI and patients with STEMI treated with fibrinolysis before PCI. On this background, the HORIZONS-AMI trial evaluated two loading doses, 600 versus 300 mg, of clopidogrel in STEMI patients undergoing primary PCI. The higher loading dose resulted in 28% reduction of 30 days' composite of mortality, reinfarction, and stent thrombosis without significantly increasing the rate of major bleeding.[25] The larger CURRENT-OASIS 7 trial has evaluated high dose of clopidogrel, 600 mg loading and 150 mg daily for a week with regular 75-mg daily dose thereafter, to regular loading and maintenance dose among 25,086 patients with ACS. A prespecified analysis of 17,263 individuals who underwent PCI revealed a reduction of cardiovascular events at 30 days, especially to be noticed a 46% reduction in the occurrence definite stent thrombosis with the high-dose regimen of clopidogrel compared with the regular dose.[26]

Indications: STEMI, UA/NSTEMI, alternative to ASA in patients with true

ASA intolerance.

Dosing: Loading dose 300 to 600 mg followed by 75 mg daily. When combined with fibrinolytics, a 300-mg loading dose should be used for patients under 75 years of age and no loading dose for patients over 75 years of age.

Side effects: Bleeding, GI intolerance, rash, TTP (rare).

Contraindications: High risk for intracranial/GI/GU bleeding, anticipated CABG within 5 days, high suspicion for diminished clopidogrel response (eg, CYP2C19 variant, stent thrombosis).

Special note on clopidogrel responsiveness: It has become increasingly recognized that there is considerable interindividual variability in platelet inhibition from clopidogrel, often leading to adverse clinical events. This is thought to be primarily related to genetic polymorphisms involving the metabolism of clopidogrel and other drugs by the hepatic CYP450 system, specifically the CYP2C19 isoenzyme, and has led to an FDA warning for the use of clopidogrel. Although genetic and platelet function testing are available, routine use is not specifically recommended at this time. However, patients deemed to be at moderate to high risk (previous history of stent thrombosis, recurrent ischemic events, planned complex interventions) should be considered for platelet function testing or alternative antiplatelet strategies including prasugrel or ticagrelor, two agents that do not appear to have these limitations.

Recommendations: Clopidogrel with loading dose of 300 to 600 mg followed by 75 mg daily alongside with ASA is indicated early in the treatment of UA/NSTEMI (both early invasive and initial conservative strategy), although it is reasonable to use ticagrelor in preference to clopidogrel in patients who are treated with an early invasive strategy. Clopidogrel should be continued for up to 12 months, with treatment beyond that time considered in specific patients. Halting clopidogrel and DAPT may be required in some clinical circumstances earlier than 12 months after the index event, such as with the occurrence of bleeding, the need for noncardiac surgery or if anticoagulant therapy for atrial fibrillation becomes indicated. With no clear answers from randomized controlled trials, it is important to utilize clinical judgment as to the length of DAPT duration for the scenarios mentioned here, taking into consideration the bleeding risk on the one hand and the risk of stent thrombosis on the other (based on clinical and anatomic findings of each patient and the stent type).

Because of the increased bleeding associated with CABG, clopidogrel should be held for at least 5 days and up to 7 days before elective CABG. In patients with a high likelihood of needing bypass, some centers opt to delay clopidogrel

loading until coronary anatomy has been defined if angiography can be done in a timely manner. If a loading dose is given and a patient is subsequently found to need urgent surgical revascularization, centers with experienced surgeons can often operate with an acceptable incremental bleeding risk.

For patients with STEMI, when fibrinolysis is planned, clopidogrel alongside with ASA is recommended with a 300-mg loading dose for patients <75 years. However, no loading dose is currently recommended for patients ≥75 years. For patients planned for primary PCI, a loading dose of 600 mg with 75 mg daily thereafter is recommended, but it is reasonable to use ticagrelor or prasugrel in preference to clopidogrel in this setting.

Prasugrel

Rationale: Prasugrel is a newer irreversible $P2Y_{12}$ ADP receptor inhibitor that offers distinct advantages over clopidogrel. Like clopidogrel, prasugrel is a pro-drug that requires hepatic metabolism to its active metabolite. However, its metabolism is not affected by the CYP2C19 allele and does not appear to have the same interpatient variability found with clopidogrel. Additionally, its pharmacodynamic properties result in more rapid and consistent platelet inhibition when compared with clopidogrel. The TRITON-TIMI 38 study is the largest trial to date for prasugrel evaluation, comparing it to clopidogrel in patients with ACS scheduled to undergo PCI. Prasugrel was found to significantly reduce the combined rates of death, nonfatal MI, and stroke when compared with clopidogrel (9.9% prasugrel vs 12.1% clopidogrel, $P < 0.001$). Additionally, significant reductions in MI, urgent target vessel revascularization, and stent thrombosis were shown. However, the benefit of prasugrel came at the expense of significantly increased major bleeding, including fatal bleeding.[27] Patients with prior stroke or transient ischemic attack (TIA) had worse outcome with prasugrel, and bleeding rates were noted to be particularly high in patients with body weight <60 kg or age >75 years.

Indications: STEMI when fibrinolysis is not planned and UA/NSTEMI.

Dosing: Loading dose of 60 mg followed by 10 mg daily.

Side effects: Bleeding.

Contraindications: Age ≥75 years, body weight <60 kg (or use maintenance dose of 5 mg daily), history of stroke/TIA, high risk for intracranial/GI/GU bleeding, active bleeding, CABG planned within 5 to 7 days.

Recommendations: Prasugrel is currently recommended for the treatment of STEMI in patients undergoing primary PCI. For patients undergoing nonprimary

PCI, prasugrel should not be given if the patient has received a fibrinolytic. For UA/NSTEMI, prasugrel is a reasonable alternative thienopyridine in patients without the aforementioned contraindications and in whom clopidogrel would otherwise be indicated, especially after coronary stent placement. It must be noted that in TRITON-TIMI 38, patients with UA/NSTEMI treated with prasugrel were given the loading dose only *after* coronary anatomy was defined. Injudicious upstream loading in patients at high risk for surgical disease before knowledge of coronary anatomy may lead to excessive bleeding. This drawback and the introduction of ticagrelor have turned prasugrel to be less preferred in the setting of UA/NSTEMI. Additionally, prasugrel has not been studied in the early conservative management strategy.

Ticagrelor

Rationale: Ticagrelor is a nonthienopyridine reversible $P2Y_{12}$ ADP receptor inhibitor. Like prasugrel, it offers several potential advantages over clopidogrel, namely, it provides more rapid and consistent platelet inhibition. Additionally, because it is a reversible inhibitor, its antiplatelet effects dissipate more rapidly than other thienopyridines. The PLATO trial compared ticagrelor with clopidogrel in the treatment of patients presenting with ACS both with and without STEMI (n = 18,624). Ticagrelor was associated with a significant reduction in the primary composite end point of death, MI, and stroke compared with clopidogrel (9.8% vs 11.7%, $P < 0.001$). There was no significant difference in the rates of major bleeding between the two groups; however, the ticagrelor group did have a higher incidence of major bleeding not related to CABG, including more intracranial bleeding.[28] A substudy of PLATO trial including only patients planned for invasive strategy has reached the same results.[29] The PEGASUS-TIMI 54 trial examined the benefit and safety of extended treatment with ticagrelor among patients with previous MI. Comparing two doses of ticagrelor, 90 mg twice daily and 60 mg twice daily, with placebo for a median follow-up of 33 months revealed a significant reduction in the composite end point of cardiovascular death, MI, or stroke with the expense of increased risk of bleeding.[30]

Indications: STEMI when fibrinolysis is not planned and UA/NSTEMI (both early invasive or initial conservative strategy).

Dosing: Initial loading dose of 180 mg followed by 90 mg twice daily.

Side effects: Bleeding, dyspnea, ventricular pauses.

Contraindications: High risk for intracranial/GI/GU bleeding, active bleeding.

Recommendations: Ticagrelor is indicated in STEMI when percutaneous intervention is planned. As it has not been studied in conjunction with fibrinolytic agents, ticagrelor is not indicated when these agents are planned to be given or immediately after being given as in rescue PCI—in these circumstance clopidogrel is more appropriate. Ticagrelor is indicated for the treatment of UA/NSTEMI whether they planned for invasive strategy or conservative/medical management. Particularly advantageous is ticagrelor's reversible pharmacokinetic properties and short half-life, which make upstream loading possible irrespective of the patient's risk for surgical CAD.

Cangrelor

Rationale: Cangrelor is an IV nonthienopyridine blocker of the ADP activated $P2Y_{12}$ receptor. The rapid onset of action and the rapid return of platelets function after cessation of its infusion are thought to be its clinical advantage. The CHAMPION PHOENIX trial of 11,145 patients compared bolus and infusion of cangrelor to clopidogrel 300 or 600 mg in patients undergoing elective or urgent PCI. Cangrelor reduced the occurrence of primary end point (composite of death, MI, ischemia-driven revascularization, and stent thrombosis at 48 hours) by 22% to 4.7% in the cangrelor group versus 5.9% in the clopidogrel (95% CI: 0.66 to 0.93, $P = 0.005$). To be noted, the secondary end point of stent thrombosis at 48 hours was reduced to 0.8% with cangrelor in comparison with 1.4% with clopidogrel (95% CI: 0.43 to 0.90, $P = 0.01$).[31]

Indications: As adjunct to PCI in patients who have not been treated with $P2Y_{12}$ receptor inhibitors and who are not being given a glycoprotein IIb/IIIa inhibitors (GIPs).

Dosing: Cangrelor is given as 30 μg/kg bolus followed by 4 μg/kg/min infusion at the time of PCI for 2 hours up to a maximum of 4 hours.

Side effects: Bleeding, worsening renal function, hypersensitivity.

Contraindications: Significant active bleeding, hypersensitivity reaction.

Recommendations: Cangrelor is recommended as adjunct to PCI in patients who have not been treated with oral $P2Y_{12}$ receptor inhibitors at the time of PCI and who are not being given a GIP.

PLATELET GP IIB/IIIA RECEPTOR ANTAGONISTS

GPIs decrease platelet aggregation and thrombus formation by inhibiting the

ability of fibrinogen to cross-link platelets. Three GPI medications that are currently approved for use in the United States include abciximab, eptifibatide, and tirofiban. The benefit of GPI medications seems to be predominantly in patients managed invasively with PCI and with high-risk clinical features (positive troponins, diabetics). However, in the modern era of DAPT with aspirin plus a $P2Y_{12}$ inhibitor, the benefit of upstream use before PCI in the ACS population has become less apparent. For UA/NSTEMI patients, the *EARLY-ACS* trial compared routine upstream use of eptifibatide in addition to standard DAPT versus delayed use at the time of angiography. No significant reduction in ischemic complications was observed with early upstream use of GPI, even though eptifibatide was used in only approximately 25% of patients in the "delayed" arm.[32] Similarly, the *ACUITY Timing* trial failed to show benefit of the strategy of upstream GPI inhibitors when compared with provisional use at the time of PCI. For patients treated with upstream use, increased major bleeding was observed at 30 days.[33] As such, the routine *upstream* use of GPI is not recommended in NSTEMI.[34] Accordingly, in NSTEMI, guidelines recommend DAPT with aspirin plus *either* a $P2Y_{12}$ inhibitor or GPI, but not *routine* triple antiplatelet therapy with all three class of agents. GPIs should be used in addition to aspirin, especially at the time of PCI if there was no adequate pretreatment with ADP receptor blockers. If adequate pretreatment with an ADP receptor blockers was given, the administration of GPI at the time of PCI is according to class 2a recommendation.

For patients with STEMI, the FINESSE and BRAVE-3 studies showed no benefit with regard to infarct size or ischemic events in patients treated upstream with abciximab, as compared with administering GPI during primary PCI.[35, 36] According to STEMI 2012 European guidelines.[37] in primary PCI patients:

1. GPIs should be considered for bailout therapy if there is angiographic evidence of massive thrombus, slow or no-reflow, or a thrombotic complication as a class 2a recommendation.
2. Routine use of a GP IIb/IIIa inhibitor as an adjunct to primary PCI performed with unfractionated heparin (UFH) may be considered in patients without contraindications as a class 2b recommendation.
3. Upstream use of a GPI (vs in-lab use) may be considered in high-risk patients undergoing transfer for primary PCI as a class 2b recommendation.

Additionally, the 2013 STEMI guidelines of ACC/AHA[38] emphasizes the

following points:

1. It is reasonable to administer GPI at the time of primary PCI in the cath-lab in selected STEMI patients treated with UFH irrespective of the pretreatment of ADP receptor blockers—a 2a recommendation. It is possible to consider intracoronary abciximab—a 2b recommendation.
2. Upstream administration of GPI in planed primary PCI—as a class 2b recommendation.

Many of these trials predated the routine use of P2Y12 inhibitors. Although the relative efficacy of prasugrel and ticagrelor in the trials appeared consistent among patients receiving and not receiving GIPs, the efficacy and safety of GPIs on top of these P2Y12 inhibitors have not been prospectively addressed.[27, 28] In patients treated with prasugrel or ticagrelor, GPIs should be limited to bail out situations *or* thrombotic complications during PCI. All GPIs should be used in conjunction with ASA and heparin or enoxaparin. Benefit must be weighed against increased incidence of bleeding, especially in patients at a higher risk for this adverse outcome such as elderly patients.

Abciximab

Rationale: Abciximab is a Fab fragment of a humanized murine antibody that inhibits the GP IIb/IIIa receptor, endothelial cell vitronectin receptors, and leukocyte MAC-1 receptors. Although it has a short half-life, its binding to GP IIb/IIIa receptors can persist for weeks although platelet aggregation gradually returns to normal 24 to 48 hours after discontinuation of the infusion. The role of abciximab in ACS was first established with the EPIC trial, which demonstrated a significant reduction in the rate of death, MI, or emergent revascularization in the group treated with a bolus and infusion of the drug before undergoing PCI.[39] In the contemporary era, the ISAR-REACT 2 trial demonstrated a significant reduction in death, MI, or urgent revascularization in high-risk (troponin positive) UA/NSTEMI patients treated with abciximab who underwent PCI (8.9% abciximab vs 11.9% placebo, $P = 0.03$).[40] However, for UA/NSTEMI patients who are risk-stratified to the early conservative strategy, the GUSTO IV-ACS trial showed abciximab to be of no additional benefit.[41]

Indications: UA/NSTEMI as adjunct to PCI in bailout situations or thrombotic complications during PCI, STEMI during primary PCI.

Dosing: 0.25 mg/kg 10 to 60 minutes before PCI followed by 0.125

μg/kg/min for 12 hours (maximum rate 10 μg/min).

Side effects: Bleeding, thrombocytopenia, hypersensitivity reactions.

Contraindications: Prior hypersensitivity, high risk for intracranial/GI/GU bleeding.

Recommendations: Abciximab should not be used in the treatment of UA/NSTEMI when PCI is not planned. For STEMI, it should be initiated at the time of primary PCI.

Eptifibatide

Rationale: A heptapeptide antagonist that reversibly inhibits GP IIb/IIIa. In the PURSUIT trial, patients with UA/NSTEMI treated with eptifibatide in addition to ASA and heparin had reduced rates of death and nonfatal MI at 96 hours and 6 months, particularly in those who underwent PCI.[42]

Indication: UA/NSTEMI treated with PCI with high-risk features. STEMI during primary PCI.

Dosing: Upstream ACS: Loading dose 180 μg/kg bolus followed by 2 μg/kg/min for 96 hours. If CrCl ≤ 50 mL/min, dose should be reduced to 1 μg/kg/min.

Primary PCI: Loading dose of 180 μg/kg bolus twice, separated by 10 minutes, followed by 2 μg/kg/min for 18 to 24 hours. If CrCl ≤ 50 mL/min, dose should be reduced to 1 μg/kg/min.

Side effects: Bleeding, thrombocytopenia (rarely severe).

Contraindications: Renal dialysis, severe thrombocytopenia, high risk for intracranial/GI/GU bleeding.

Recommendations: Eptifibatide use is acceptable in the management of UA/NSTEMI for patients as adjunct to PCI in bailout situations or thrombotic complications during PCI, or in addition to other standard antiplatelet medications for patients with high-risk features or recurrent ischemia. Daily monitoring of hemoglobin and platelets is recommended. For STEMI, eptifibatide should be initiated at the time of primary PCI.

Tirofiban

Rationale: Tirofiban is a nonpeptide antagonist that reversibly inhibits GP IIb/IIIa receptor. When combined with UFH, it has been shown to reduce death, MI, and refractory ischemia up to 30 days in patients with high-risk presentations (ischemic ECG features, elevated cardiac biomarkers).[43]

Dosing: High dose—25 µg/kg bolus, followed by 0.15 µg/kg/min infusion for 18 to 24 hours; standard dose—0.4 µg/kg/min for 30 minutes, then 0.1 µg/kg/min for 96 hours. Dose should be reduced by half for patients with CrCl < 30 mL/min.

Side effects: Bleeding, thrombocytopenia (rarely severe).

Contraindications: High risk for intracranial/GI/GU bleeding, severe thrombocytopenia.

Recommendations: Typically, its addition to other standard antiplatelet medications is reserved for patients with high-risk features or recurrent ischemia. Most contemporary trials utilize the high-dose regimen for patients undergoing PCI due to more robust platelet inhibition. Daily monitoring of hemoglobin and platelets is recommended.

ANTICOAGULANTS

UNFRACTIONATED HEPARIN

Rationale: Heparin accelerates the action of circulating antithrombin, which leads to inactivation of factor IIa (thrombin), factor IXa, and factor Xa. Ultimately, this prevents further clot propagation but not lysis of existing thrombus. A meta-analysis involving six trials showed a nonsignificant relative risk reduction of 33% ($P = 0.06$) in death or MI when combined with ASA.[44]

Indications: ACS (both STEMI and UA/NSTEMI).

Dosing: Weight-based nomogram preferred to fixed-dose regimens. Bolus: 60 U/kg (max 4000 U) with initial infusion at 12 U/kg/h (max 1000 U/h). The activated partial thromboplastin time (aPTT) should be monitored q6h until dosing is therapeutic (aPTT 50 to 70).

Side effects: Mild thrombocytopenia, bleeding, heparin-induced thrombocytopenia (HIT).

Contraindications: Severe thrombocytopenia, previously documented HIT.

Recommendations: UFH is recommended early in the management of STEMI and UA/NSTEMI (for both conservative and early invasive strategies) and during PCI. A weight-based dosing regimen should be utilized with frequent monitoring of aPTT, hemoglobin, and platelets. For conservative management strategy, UFH should be continued for at least 48 hours or until discharge (up to 8 days). For CABG or PCI, it should be continued up until the time of procedure (holding according to institutional practices).

LOW-MOLECULAR-WEIGHT HEPARIN: ENOXAPARIN

Rationale: Enoxaparin is a low-molecular-weight heparin (LMWH) that is more selective than UFH at inhibition of factor Xa. When compared with UFH, LMWHs have decreased binding to plasma proteins and endothelial cells, dose-independent clearance, a longer half-life, and more sustained and predictable anticoagulation. Multiple clinical trials have shown a reduction in death, MI, and recurrent angina up to 40 days when compared with UFH.[45–47] For patients with STEMI treated with fibrinolysis, the ExTRACT TIMI 25 study showed that enoxaparin was superior to UFH with regard to death, nonfatal reinfarction, and urgent revascularization but with increased rates of major bleeding.[48]

Advantages over UFH: More predictable anticoagulation, more cost-effective (less monitoring), less occurrence of HIT, twice-daily subcutaneous (SC) dosing, better reduction of nonfatal MI, death, or recurrent angina.

Disadvantages compared with UFH: Unable to give in setting of severe renal impairment, not reversible with protamine, increased major bleeding,[49] inability to reliably monitor ACT (Activated Clotting Time) during PCI.

Indications: UA/NSTEMI and STEMI.

Dosing: Enoxaparin 30 mg IV × 1 may be given early and then 1 mg/kg q12h for 2 to 8 days. It should be avoided in patients with CrCl < 30 (or reduction to q24h should be considered). Unclear dosing strategy for morbidly obese patients; however, often an anti-Xa level is measured, with a commonly accepted therapeutic target of 0.5 to 1.0 anti-Xa units/mL. For patients >75 years, no IV bolus should be given and dose at 0.75 mg/kg q12h.

Side effects: Bleeding, HIT (rare), injection-site complications.

Contraindications: CrCl < 30 mL/min.

Recommendations: In patients with UA/NSTEMI, use of enoxaparin is considered an acceptable alternative to UFH, especially in those being managed conservatively. Duration of treatment is at least 48 hours and typically until discharge (up to 8 days). If CABG is pursued, enoxaparin should be discontinued 12 to 24 hours prior and bridged with UFH according to institutional practice. Although there are limited data for the use of dalteparin for this indication, enoxaparin remains the preferred LMWH. For STEMI patients treated with fibrinolysis, enoxaparin has proven efficacy, albeit at increased risk for bleeding, and can be used throughout the index hospitalization up to 8 days.

DIRECT THROMBIN INHIBITORS: BIVALIRUDIN

Rationale: Direct thrombin inhibitors (DTIs) bind reversibly to thrombin and inhibit clot-bound thrombin more effectively than does UFH. Bivalirudin is a synthetic derivative of hirudin (older DTI no longer used clinically) with a shorter half-life. The ACUITY trial studied UA/NSTEMI patients undergoing PCI and showed noninferiority of bivalirudin monotherapy as compared with UFH or LMWH plus GPI with respect to ischemia (9% vs 8%, $P = 0.45$), but importantly a significant reduction in major bleeding (4% vs 7%, $P < 0.0001$).[50] The HORIZONS-AMI trial showed that STEMI patients undergoing primary PCI treated with bivalirudin alone compared with UFH plus GPI had significantly reduced 30-day rates of death from cardiac causes (1.8% vs 2.9%, $P = 0.03$) and a lower rate of major bleeding (4.9% vs 8.3%, $P < 0.001$).[51] When followed out to 1 year, patients classified as high risk had a decreased mortality (8.4% vs 15.9%, $P = 0.01$) and a decreased rate of recurrent MI (3.6% vs 7.9%, $P = 0.04$).[52] Yet, a recently published meta-analysis of 13 randomized controlled trials, involving 24,605 patients with ACS treated with PCI revealed a significant reduction in the rate of major bleeding with bivalirudin compared with UFH with routine use of GPIs, but not when provisional use of GPIs with UFH was attempted. Additionally, there was a significant increase in the rate of 30 days' definite stent thrombosis largely driven by a 4-fold increase in acute (<24 hours) stent thrombosis regardless of routine or provisional use of GPIs with UFH.[53]

Indications: UA/NSTEMI (early invasive strategy only); STEMI undergoing primary PCI.

Dosing: Bolus 0.75 mg/kg followed by infusion of 1.75 mg/kg/h up to 4 hours. Then it should be decreased to 0.2 mg/kg/h for up to 20 hours.

Side effects: Bleeding.

Contraindications: Dosing adjustments for renal impairment.

Recommendations: Bivalirudin is an acceptable alternative for treatment of UA/NSTEMI in patients undergoing early invasive strategy when used with $P2Y_{12}$ inhibitor given upstream of PCI. It is not recommended for UA/NSTEMI patients being treated with an initial conservative strategy. For STEMI, bivalirudin can be used during primary PCI with or without prior treatment with UFH.

FACTOR XA INHIBITORS: FONDAPARINUX

Rationale: Fondaparinux is a synthetic pentasaccharide that selectively binds to

and potentiates antithrombin thereby promoting factor Xa inhibition. Its dose-independent clearance and long half-life allow for once-daily administration and predictable and sustained anticoagulation effects. The OASIS 5 study compared fondaparinux with enoxaparin in the treatment of UA/NSTEMI. Patients treated with fondaparinux had similar rates of death, MI, and refractory ischemia at 9 days, but significantly less major bleeding. At 180 days, fondaparinux was associated with a significant reduction in all major end points.[54] However, there was an increased incidence of catheter-associated thrombus formation during PCI, which led to the open-labeled use of UFH. The OASIS 6 study found that patients with STEMI treated with fondaparinux and fibrinolysis had reduced mortality and reduced rates of reinfarction without increased bleeding or strokes,[55] although again there was evidence of increased thrombotic complications during coronary intervention. These adverse events have turned fondaparinux to be contraindicated as a sole anticoagulant to support PCI in ACS.[38]

Indications: UA/NSTEMI and STEMI.

Dosing: Initial dose of 2.5 mg IV followed by 2.5 mg SC injection daily (maximum antifactor Xa activity is reached in 3 hours).

Side effects: Bleeding, rash/pruritus at injection site, mild elevation of aminotransferases, thrombocytopenia.

Contraindications: CrCl < 30 mL/min, caution if body weight < 50 kg.

Recommendations: Fondaparinux is an alternative anticoagulant for the treatment of UA/NSTEMI patients being managed conservatively and should be continued for up to 8 days. Its use is preferred in the treatment of those with an increased bleeding risk. In the event of PCI, co-administration of UFH or bivalirudin is recommended to decrease the incidence of catheter-associated thrombosis. Fondaparinux should be avoided in patients with planned CABG within 24 hours owing to its long half-life. For STEMI, fondaparinux is an acceptable alternative to UFH in patients undergoing fibrinolysis and should be continued for up to 8 days. The incidence of catheter-associated thrombosis has limited its use for primary PCI and therefore fondaparinux should not be used in this setting.

WARFARIN

Rationale: Warfarin exerts its anticoagulant effect by inhibiting the hepatic synthesis of the vitamin K–dependent coagulation factors II, VII, IX, and X as

well as the anticoagulant proteins C and S. Although older, small studies found limited benefit when used in the post-MI setting, the role of warfarin for ACS in the modern era is primarily relegated to the treatment of LV thrombus, atrial fibrillation, or mechanical heart valves. Given the role of DAPT for ACS, the addition of warfarin ("triple antithrombotic therapy") for other indications introduces a greater overall risk of bleeding and can often be challenging to manage in clinical practice.

Indications: Atrial fibrillation, LV thrombus, mechanical heart valve, venous thromboembolism (VTE).

Dosing: 2 to 5 mg po daily should be started and adjusted according to international normalized ratio (INR). Standard nomograms or genotype-specific dosing strategies are available. Starting lower dose in elderly or debilitated patients should be considered. Target INR varies with indication.

Side effects: Bleeding, hypersensitivity reactions, skin/tissue necrosis (rarely).

Contraindications: Active bleeding or unacceptable bleeding risk, unsupervised patient with high nonadherence risk, pregnancy.

Recommendations: The use of warfarin during or after ACS is predominately guided by expert opinion with limited evidence in the current literature. Warfarin should generally be started or continued in high-risk patients with a clear indication for its use (atrial fibrillation, LV thrombus, mechanical heart valve, or VTE). When used in combination with aspirin and a thienopyridine, the benefit of warfarin should outweigh the incremental risk of bleeding, and it should be given for the minimal time necessary to achieve the desired protection. Patients on triple antithrombotic therapy should be closely monitored for bleeding with strict attention paid to maintaining a therapeutic INR.

NEW ORAL ANTICOAGULANTS

During the last decade, the oral DTI Dabigatran and the direct factor Xa inhibitors Rivaroxaban, Apixaban, and Edoxaban have gained widespread use to reduce the thromboembolic risk in nonvalvular atrial fibrillation (NVAF) and in VTE with superior efficacy and safety profile, as a group, over warfarin.[56] Therefore, they are used in patients with ACS mainly for above-mentioned indications, NVAF, and VTE. As with warfarin, the addition of one of these agents to DAPT after coronary syndrome and PCI is associated with increased risk of bleeding. For the meantime, no large randomized clinical trials to examine different protocols and combinations of these agents have been completed. Therefore, as with warfarin, triple antithrombotic therapy should be

given for the minimal time necessary, with reduced dosage of new oral anticoagulants (NOACs) and with addition of proton pump inhibitors. Additionally, when triple therapy is needed, it is a common practice to prefer clopidogrel to ticagrelor and prasugrel.[57] As the clearance of these agents is partly renal, they are not given with severe impairment of renal function (CrCl < 15 mL/min).

Except for their common use in NVAF and VTE, clinical trials have shown some reduction in ischemic events when NOACs were given to patients after ACS but with the expense of increased bleeding events.[58]

Indications: NVAF, VTE.

Dosing: Dabigatran 110 to 150 twice daily, rivaroxaban 20 mg once daily (15 mg for CrCl 15 to 49 mL/min) (15 mg twice daily for 21 days as a loading dose for VTE), apixaban 5 mg twice daily (2.5 mg twice daily when two of the following exists: Serum Creatinine > 1.5 mg%, age > 80, weight < 60 kg).

Side effects: Bleeding.

Contraindications: Active bleeding or unacceptable bleeding risk, advanced renal failure, pregnancy.

Recommendations: NVAF, VTE.

FIBRINOLYTICS

All fibrinolytic agents are plasminogen activators and work by catalyzing the cleavage of endogenous plasminogen to generate plasmin. Their thrombolytic action is derived from the ability of plasmin to degrade the fibrin matrix of the thrombus. Although contemporary practice favors the use of a catheter-based reperfusion strategy when available, fibrinolytic reperfusion still remains an important component in the treatment of STEMI in the United States and worldwide. The mortality benefit of fibrinolytic therapy is well proven and, when compared with control, fibrinolysis has been estimated to confer a significant 18% relative reduction in 35-day mortality.[59] Similar to primary PCI, fibrinolytic reperfusion offers the greatest benefit when given early, ideally within the 30 minutes of diagnosis. As a thrombus becomes more organized over time, the efficacy of fibrinolytic therapy decreases. Patients at higher risk for adverse consequences (anterior MI, diabetes, hypotension, left bundle branch block) seem to derive the most benefit when pharmacologic reperfusion is initiated early in the course.

Fibrinolytic agents differ substantially with regard to their antigenicity, specificity for clot-bound fibrin, dosing, and cost. There is no preferred fibrinolytic agent currently recommended by ACC/AHA guidelines. Instead, the choice of fibrinolytic agent should be selected on the basis of physician familiarity, timely availability, and, in the case of streptokinase, past exposure. The most feared and catastrophic adverse consequence of fibrinolytic therapy is intracranial hemorrhage, which is estimated to occur in 0.5% to 0.7% of patients. As such, the absolute contraindications for fibrinolytic therapy include patients with increased risk for intracerebral hemorrhage (ICH) (prior hemorrhagic stroke, prior ischemic stroke within 3 months, intracranial neoplasm or vascular lesions, or closed-head injury within 3 months). Fibrinolytic reperfusion is contraindicated in the treatment of UA/NSTEMI.

Concominant use of anticoagulants in patients treated with fibrinolytics: All patients receiving fibrinolytic reperfusion should receive anticoagulant therapy for a minimum of 48 hours and preferably for the duration of the hospitalization, up to 8 days. UFH, enoxaparin, and fondaparinux have established efficacy when used with fibrinolytics and are the recommended anticoagulants. UFH should be dosed according to recommended ACS weight-based dosing guidelines. However, use for greater than 48 hours is discouraged due to the increased risk of developing HIT and therefore should be changed to enoxaparin or fondaparinux. Enoxaparin should be dosed with specific attention to age, weight, and CrCl. In patients <75 years with normal creatinine, an initial 30-mg IV bolus is given followed by 1-mg/kg SC every 12 hours. If ≥75 years, the IV bolus is eliminated and 0.75 mg/kg SC every 12 hours is given. For all patients with CrCl < 30 mL/min, 1 mg/kg SC daily should be given. Fondaparinux is dosed with an initial 2.5-mg IV followed by 2.5-mg SC daily. It should be avoided in patients with creatinine less than 3.0 mg/dL.

STREPTOKINASE

Rationale: Streptokinase (SK) is a first-generation non–fibrin-specific lytic that exerts its effects both on clot-bound and circulating plasminogen. Although inexpensive by comparison, SK is limited by the possible development of neutralizing antibody titers in previously treated patients. Additionally, SK results in systemic fibrinolysis.

Indication: STEMI.

Dosing: 1.5 million IU over 60 minutes.

Side effects: Bleeding, bronchospasm, anaphylaxis, hypotension, angioedema,

periorbital swelling, fever, urticaria.

Contraindications: See **Table 9.6**.

TABLE 9.6 Contraindications for the Use of Fibrinolytic Agents in STEMI

ABSOLUTE CONTRAINDICATIONS
Any prior ICH
Known intracranial neoplasm or cerebral vascular lesion
Ischemic stroke within 3 mo (EXCEPT acute ischemic stroke within 3 h)
Suspected aortic dissection
Active bleeding or bleeding diathesis (excluding menopause) such as active peptic ulcer
Significant closed-head or facial trauma within 3 mo
RELATIVE CONTRAINDICATIONS
Severe, uncontrolled HTN on presentation (SBP > 180 mm Hg or DBP > 110 mm Hg)
History of ischemic stroke > 3 months, dementia, or intracranial pathology not specified above
Traumatic or prolonged (>10 min) CPR
Noncompressible vascular punctures
Pregnancy
Recent (2–4 wk) internal bleeding
Major surgery within past 3 weeks

Adapted from Antman EM, Anbe DT, Armstrong PW, et al. ACC/AHA guidelines for the management of the patients with ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction). *J Am Coll Cardiol.* 2004;44:E1-E211.
CPR, cardiopulmonary resuscitation; DPB, diastolic blood pressure; ICH, intracerebral hemorrhage; HTN, hypertension; SBP, systolic blood pressure; STEMI, ST-elevation myocardial infarction.

ALTEPLASE (RTPA)

Rationale: A second-generation fibrinolytic considered to be more specific for clot-bound fibrin. Compared with SK, alteplase was shown to confer a significant 30-day mortality reduction (15%) when administered with UFH.[60] However, alteplase is associated with a slightly higher risk of ICH than SK.

Indications: STEMI.

Dosing: Accelerated protocol—(for patients > 67 kg) 15 mg IV bolus, then 50 mg over 30 minutes, then 35 mg over 60 minutes (total dose = 100 mg). For patients ≤ 67 kg, 15 mg IV bolus, then 0.75 mg/kg (50 mg maximum) over 30 minutes, then 0.5 mg/kg (35 mg maximum) over 60 minutes (total dose < 100 mg).

Side effects: Bleeding, hypotension, nausea/vomiting.

Contraindications: See **Table 9.6**.

RETEPLASE (RPA)

Rationale: rPA is a third-generation fibrinolytic similar to alteplase but with less high-affinity fibrin binding and increased potency. Although no increased mortality was shown over alteplase in GUSTO III, its ability to be given as a double bolus may confer a theoretical advantage related to it by timely administration and less dosing errors.

Indications: STEMI.

Dosing: 10 units IV bolus followed by a second 10 units IV bolus in 30 minutes.

Side effects: Bleeding.

Contraindications: See **Table 9.6**.

TENECTEPLASE (TNK)

Rationale: TNK is a third-generation fibrinolytic that, compared with alteplase, has increased fibrin specificity, decreased clearance, and decreased inhibition from plasminogen activator 1. The ASSENT 2 trial showed similar 30-day mortality rates when compared with alteplase, however fewer mild-to-moderate systemic bleeding complications and need for blood transfusions.[61]

Indications: STEMI.

Dosing: Single 30-to-50-mg IV bolus given over 5 seconds, dosed by weight. For <60 kg, 30 mg should be given; for 60 to 70 kg, 35 mg; for 70 to 80 kg, 40 mg; for 80 to 90 kg, 45 mg; for ≥ 90 kg, 50 mg.

Side effects: Bleeding, hypotension.

Contraindications: See **Table 9.6**.

atient and Family Information for: MEDICATIONS USED IN THE MANAGEMENT OF ACS

The medicines used to treat heart attacks in the modern-era stem from decades of laboratory and clinical trial research. As more and more is learned about CAD, the drugs used to treat heart attack victims will hopefully become even more safe and effective. Today, medical therapy forms the cornerstone of heart attack care. Early after diagnosis, much emphasis is placed on controlling chest pain, interrupting further heart damage, and maintaining a safe blood pressure and heart rate. Powerful blood thinners, pain medications, blood pressure–and cholesterol-lowering drugs, catheterization procedures, and sometimes even bypass surgery are used to varying degrees in the early treatment of heart attacks. Alongside these therapies, other medicines may be added to treat cardiac arrhythmias, CHF, diabetes, or tobacco addiction. The decisions underlying which medicines are used to treat a specific patient are complex and often change depending on one's age, cardiac risk factors, medical history, and type of heart attack encountered.

The following sections are divided into various classes and types of medications routinely used in the treatment of heart attacks. Many of the medicines described are also used to treat other conditions, both related and unrelated to the heart. The rationale behind each medication's use, both generic and commonly used trade names, potential side effects, and important details are provided. It is important to emphasize that the following pages should be used only as a general guide. Specific details about each drug, doses, and potential interactions with other medications should always be discussed with a physician and pharmacist.

TREATING THE PAIN OF A HEART ATTACK

A heart attack results from the interruption of blood flow to the muscle of the heart, most commonly by a small blood clot known as a thrombus. As heart muscle is dependent on the oxygen and nutrients carried by the blood, it quickly becomes starved in a process known as ischemia. Ischemia in most patients results in chest pain or angina. It is classically described as a chest pressure or tightness, often moving to the shoulder, neck, jaw, or arms. Other symptoms may include nausea, vomiting, or shortness of breath. For patients who have experienced chest pain or pressure in the past, the discomfort associated with a heart attack is usually more intense, more frequent, and even occurring at rest. In some patients, particularly diabetics and the elderly, symptoms may be more subtle and present only as mild stomach pain or indigestion, occasional palpitations, or even no symptoms at all. The onset of chest pain is often the first sign of a heart attack, and it provides warning that the heart muscle is threatened. While the primary goal in treating all heart attacks is to restore blood flow within the jeopardized coronary artery, the adequate treatment of pain is of paramount importance to all patients.

Medications used to specifically treat the pain of a heart attack are called “antianginals” and include nitrates, β-blockers, and CCBs. For pain unrelieved with these classes of drugs, various forms of narcotic medications, known as opioids, are commonly used.

NITRATES

Names: NTG (*Minitran, Nitro-Bid, Nitro-Dur, Nitro-Time, Nitrolingual, NitroQuick, Nitrostat*)

Related medications: Isosorbide mononitrate (*Imdur, Ismo, Monoket*), isosorbide dinitrate (*Isordil, Dilatrate-SR, Isochron*)

NTG is one of the most commonly used medicines for the treatment of chest pain. It is a “vasodilator” and primarily works by dilating, or expanding, the size of coronary arteries. The net effect is that more blood can get to the heart muscle. Even in patients with a completely blocked coronary artery, NTG is useful because it recruits blood flow to other, less diseased arteries. NTG lowers blood pressure, a property that is helpful in relieving pain and decreasing the amount of strain placed on the heart. NTG can be administered in a variety of forms, a feature that makes it particularly useful when treating someone with

ongoing nausea and vomiting. When given as permanent medication, people treated with nitrates develop a situation called “tolerance,” which means that the influence of nitrates decreases by time. On the other hand, when kept for only s.o.s. use as in heart attacks, nitrates retain their above-mentioned benefits.

Preparations: Sublingual (dissolved under the tongue), translingual (sprayed into the mouth), oral, transcutaneous (absorbed through the skin), and IV.

Side effects: Headache (most common), flushing, dizziness, lightheadedness, nausea, vomiting, blurred vision, swelling.

Important information: The patients who use medications to treat erectile dysfunction such as sildenafil (*Viagra*), tadalafil (*Cialis*), or vardenafil (*Levitra*) should not use NTG because combined use may result in a severe, rapid reduction in blood pressure or even death. The prior or ongoing use of any of these medications should immediately be reported to a physician.

β-BLOCKERS

Names: Metoprolol (*Lopressor, Toprol-XL*), carvedilol (*Coreg*), bisoprolol (*Zebeta*), atenolol (*Tenormin*), labetalol (*Trandate*), propranolol (*Inderal*), esmolol (*Brevibloc*)

β-Blockers are a class of blood pressure medications commonly used in the treatment of heart attacks, abnormal heart rhythms, and CHF. They work to relieve angina by both lowering blood pressure and reducing the heart rate. When the heart is forced to pump blood against a high blood pressure or beat at a fast rate, it requires greater amounts of oxygen and thus greater coronary blood flow. During exercise and especially during a heart attack, blood flow to the heart muscle is jeopardized and unable to meet the demands required. By lowering both the blood pressure and heart rate, β-blockers are useful at reducing this strain on the heart and often result in reduced levels of chest pain.

Preparations: Oral, IV.

Side effects: Dizziness, fatigue, lightheadedness, change in sexual ability or desire, depression, diarrhea, slow heartbeat.

Important information: Some patients with asthma, emphysema, bronchitis, or related diseases of the lungs may experience excessive wheezing or shortness of breath while taking β-blockers. Such reactions should be reported to a physician. Additionally, abruptly discontinuing β-blockers has been reported sometimes to result in worsening of chest pain.

CALCIUM CHANNEL BLOCKERS

Names: Diltiazem (*Cardizem, Cartia, Dilacor, Dilt, Diltia, Diltzac, Taztia, Tiazac*), verapamil (*Calan, Covera, Isoptin, Verelan*), amlodipine (*Norvasc*), felodipine (*Plendil*), nisoldipine (*Sular*), lercanidipine (*Zanidep*)

CCBs, a class of blood pressure medications, are also used to treat angina and abnormal heart rhythms. CCB have various effects, with part of them working similar to β-blockers, reducing the heart rate and blood pressure, thus reducing strain on the heart. Yet, it is a common practice to avoid this group of medications in heart attacks because they can result in significant decrease in heart contractility and may aggravate heart failure. On the other side, patients with a combination of heart attack and elevated blood pressure may gain benefit from CCB treatment.

Preparations: Oral, IV.

Side effects: Dizziness, lightheadedness, headache, nausea or vomiting, constipation, swelling, slow heartbeat.

NARCOTICS (OPIOIDS)

Names: Morphine (*Avinza, MS Contin, Roxanol*), fentanyl (*Sublimaze*), oxycodone (*OxyContin, OxyFast, Percocet, Endocet, Magnacet*), hydrocodone (*Lortab, Norco, Vicodin, Zydone*), hydromorphone (*Dilaudid*), meperidine (*Demerol*)

Narcotics such as morphine do not specifically treat angina. Rather, they act more generally to block pain signals in the body from reaching the brain. Narcotics are often prescribed for heart attack patients when other antianginal medications have failed to completely control pain. Additionally, they have several beneficial side effects, one of which is to help slow the heart rate. Like β-blockers and CCBs, this helps to reduce the work load exerted on the heart thereby reducing strain on the heart. Narcotics come in many different preparations, but in the context of heart attacks narcotics are used mainly intravenously; by this route, they provide the most rapid relief of symptoms needed at the initial phase of management.

Preparations: Oral, IV, transdermal (through the skin).

Side effects: Nausea, vomiting, constipation, dizziness, flushing, slow heartbeat, shallow breathing.

ANTIPLATELET MEDICATIONS

Platelets are specialized blood cells that constantly survey the body for areas of injury. In blood vessels, and in the coronary arteries in particular, platelets are responsible for identifying damaged areas of vessel wall and then sealing off these areas before further harm ensues. Unfortunately, other adverse processes, such as cholesterol deposits and thickening of arterial wall, may cause activation of platelets as these small cells recognize these arterial wall changes as damage to be sealed. When this occurs, platelets quickly change their shape, become sticky, and along with other platelets form a small blood clot—thrombus. Unfortunately, this small blood clot may often grow large enough to completely or incompletely impede flow through the entire artery. This, most simply, is the cause of a heart attack. Antiplatelet drugs are special medications that interfere with the ability of platelets to form clots, particularly large obstructive clots. Antiplatelet medications work particularly well at reducing heart attacks caused by blood clots in the coronary arteries. However, because they block the natural actions of platelets throughout the body, they can also increase the risk of unintended bleeding.

ASPIRIN

Names: Aspirin (*Bayer Aspirin*, *Ecotrin*, *Anacin*)

Aspirin is one of the oldest, most widely used, cheap, and effective antiplatelet medicines around. Even today, it remains an essential component in the treatment of heart attacks both during hospitalization and after discharge. With very few exceptions, aspirin therapy should be taken for life in individuals who suffer a heart attack.

Preparations: Oral, rectal.

Side effects: Upset stomach, heartburn, stomach bleeding, easy bruising.

Important information: Because aspirin remains such an important medicine in the treatment and prevention of heart attacks, patients should take it daily. This is especially important if a stent is used in the treatment of one’s heart disease. Although a true aspirin allergy exists, fortunately, it is rare and most side effects from aspirin can be overcome with the use of coated formulations and certain medicines to reduce stomach acid. Consultation with a cardiologist is recommended before stopping aspirin, even temporarily, for situations such as elective surgery.

$P2Y_{12}$ INHIBITOR

Names: Clopidogrel (*Plavix*), prasugrel (*Effient*), ticagrelor (*Brilinta*)

These medications each work as potent antiplatelet medications, most commonly taken in addition to aspirin, and work to greatly reduce the body's ability to form blood clots in the coronary arteries and elsewhere. Studies of patients with heart attacks have consistently proven that these drugs, when added to aspirin, help reduce the incidence of future heart attacks and prolong one's lifespan. In addition to their role in the treatment of heart attacks, they are critically important in patients who have been treated with coronary stents.

Preparations: Oral.

Side effects: Easy bruising or bleeding, nausea, dizziness.

Important information: Like with aspirin, patients prescribed medications from this class should strive to take them exactly as requested by a physician. In patients with coronary stents, this becomes of even greater importance because the abrupt discontinuation can result in new blood clots forming within the stent itself. Although such events are rare, they often lead to a second heart attack and can be fatal. As with aspirin, consultation with a cardiologist is recommended prior to electively stopping these medications for upcoming surgeries. Patients should avoid missing doses or running out before a prescription can be renewed.

PLATELET GLYCOPROTEIN IIB/IIIA RECEPTOR ANTAGONISTS

Names: Abciximab (*Reopro*), eptifibatide (*Integrilin*), tirofiban (*Aggrastat*)

Glycoprotein IIb/IIIa receptor antagonists are molecules named for the specific platelet receptor they bind. As with other antiplatelet medications, they work to decrease the ability of platelets to form clots within the coronary arteries. However, this class of medications is only given intravenously. Although these drugs are often used in addition to aspirin for the early treatment of heart attacks, they are most commonly used during coronary intervention during catheterization, including stent placements. Their highly potent platelet-blocking effects make them particularly well suited to prevent clot formation within stents, thereby increasing stent durability. Like with other antiplatelet medications, drugs from this class have been proven in thousands of patients who had heart attack to prolong life and reduce future heart attacks.

Preparation: IV.

Side effects: Easy bruising or bleeding, nausea, stomach aches.

ANTICOAGULANTS

A blood clot, or thrombus, is not only formed by platelets. Within the circulating blood exists a multitude of microscopic proteins that work alongside platelets to assist in the formation of blood clots at sites of vessel injury. When damage is detected, these proteins form long, thin threads call fibrin. In turn, these fibrin threads create a mesh-like plug that helps to stabilize blood clots. Whereas antiplatelet medications block the actions of platelets, anticoagulants block the body's ability to form fibrin. Because they work to prevent blood clot formation, they too are often referred to as "blood thinners."

HEPARIN AND RELATED MEDICATIONS

Names: Heparin

Related medications: Enoxaparin (*Lovenox*), bivalirudin (*Angiomax*), fondaparinux (*Arixtra*), dalteparin (*Fragmin*)

Heparin and its related medicines comprise a central role in the treatment of heart attacks. They are given early in the course of a heart attack and sometimes continued throughout the duration of a hospital stay. In addition to preventing blood clots associated with heart attacks, heparin or similar drugs are routinely used in the prevention of clots associated with other disorders. Typical uses may include the prevention of blood clots in the legs (deep vein thrombosis), those associated with mechanical heart valves, and those that may form with certain abnormal heart rhythms.

Preparations: IV, SC (under the skin) injections.

Side effects: Easy bruising or bleeding, pain at injection site, abnormal blood counts (especially platelets), rash.

Important information: A rare condition known as HIT can occur in some patients who have had previous exposure to heparin. This condition causes a dramatic drop in platelets and can lead to both excessive bleeding and clotting. Patients with a history of HIT should promptly notify their physicians during any hospital admission or office visit.

WARFARIN

Names: Warfarin (*Coumadin, Jantoven*)

Related medications: Dabigatran (*Pradaxa*)

Warfarin is an orally given blood thinner that has been used for decades to treat a multitude of conditions associated with blood clotting. Inherited clotting disorders, mechanical heart valves, abnormal heart rhythms, and prior blood

clots in the legs or lungs are all common reasons for warfarin to be prescribed. Although it is rarely used to specifically treat or prevent heart attacks, warfarin deserves special mention because it is often used in addition to the antiplatelet and anticoagulant medications commonly prescribed for patients who had heart attack. A unique and often frustrating feature of warfarin is that it requires frequent blood tests to monitor its activity.

Preparations: Oral.

Side effects: Easy bruising or bleeding, nausea, vomiting, altered sense of taste.

Important information: Each blood thinner added to a patient's list of medications introduces an incremental risk of unintended bleeding. In properly selected patients, these drug combinations can be safely followed but often require more aggressive monitoring and physician visits. It is not uncommon for warfarin dosing, even if stable for years, to need adjusting after the initiation of new medications. Patients should pay close attention to early signs of bleeding, especially bleeding related to the stomach or intestines, and report these to their physician.

NEW ORAL ANTICOAGULANTS (NOACS)

Names: Dabigatran (*Pradaxa*), Rivaroxaban (*Xarelto*), Apixaban (*Eliquis*)

This class of orally taken blood thinners was introduced during the last decade to treat several conditions that, until then, were treated by warfarin. There is no need to continuously monitor their activity by blood tests, and they have additional benefit in efficacy and safety over warfarin. Still, as blood thinners, they may increase the risk of unintended bleeding especially when taken with antiplatelet agents as in patients after heart attacks.

Preparations: Oral.

Side effects: Bleeding.

FIBRINOLYTICS OR "CLOT BUSTERS"

Names: Streptokinase (*Streptase*), alteplase (*Activase*), reteplase (*Retavase*), Tenecteplase (*TNKase*)

Fibrinolytics, also called "thrombolytics" or "clot busters," are a class of medications used to treat a specific type of heart attack where blood flow through a coronary artery is completely obstructed. Unlike antiplatelet and anticoagulant drugs, which prevent blood clots from forming or expanding,

fibrinolytics actually target and destroy clots that have already formed. These extremely potent medications work best when given very early in the course of a heart attack and typically are used in areas where a cardiac catheterization laboratory is not immediately available. Unfortunately, they have not proven to be useful in treating heart attacks caused by only partially obstructive clots.

Preparations: IV.

Side effects: Easy bruising or bleeding, stroke (rare).

OTHER IMPORTANT MEDICATIONS USED IN TREATING HEART ATTACKS

The immediate control of chest pain, addition of antiplatelet and anticoagulant medications, and often cardiac catheterization or use of fibrinolytics are crucially important during the early stages of a heart attack. These therapies are largely targeted at aborting further damage and salvaging heart muscle from permanent damage. Aggressive and early control of blood pressure, fluid volume, and cholesterol levels are equally important in achieving these goals. In many cases, additional blood pressure medications may be added to more closely control one's HTN. In other cases, they may be added simply for the unique and beneficial properties they provide to patients with heart disease.

ACE INHIBITORS AND ARB*S*

Names: **ACE inhibitors**—benazepril (*Lotensin*), captopril (*Capoten*), enalapril (*Vasotec*), fosinopril (*Monopril*), lisinopril (*Prinivil*, *Zestril*), moexipril (*Univasc*), perindopril (*Aceon*), quinapril (*Accupril*), ramipril (*Altace*), trandolapril (*Mavik*); **ARBs**—cadesartan (*Atacand*), eprosartan (*Teveten*), irbesartan (*Avapro*), losartan (*Cozaar*), olmesartan (*Benicar*), valsartan (*Diovan*), telmisartan (*Micardis*)

Medications from these two classes of blood pressure drugs are commonly used alongside other therapies to treat specific consequences of heart attacks, such as CHF, that is, a weakened heart muscle. Apart from being blood pressure–lowering drugs, these medications have shown to be beneficial in prolonging life, reducing the incidence of CHF, and protecting the kidneys in diabetic patients.

Preparations: Oral.

Side effects: Dizziness, lightheadedness, cough (ACE inhibitors), abnormal electrolyte levels, swelling.

DIURETICS

Names: furosemide (*Lasix*), bumetanide (*Bumex*), torsemide (*Demadex*), hydrochlorothiazide (*Esidrix, Microzide*), chlorothiazide (*Diuril*), metolazone (*Zaroxolyn*), amiloride (*Midamor*), triamterene (*Dyrenium*), spironolactone (*Aldactone*), eplerenone (*Inspra*).

Diuretics, commonly referred to as "water pills," are routinely used in the care of patients who had heart attack and who suffer from CHF or any condition characterized by increased fluid in the body, most often in the lower extremities or lungs. They work to remove excess fluid by stimulating urine production in the kidneys. Furosemide (*Lasix*) remains the most prescribed drug used in the hospital for this purpose. Some weaker diuretics are often added for their blood pressure–lowering properties, whereas others such as spironolactone (*Aldactone*) and eplerenone (*Inspra*) may be added in special circumstances characterized by severe CHF.

Preparations: Oral, IV.

Side effects: Dizziness, lightheadedness, dry mouth, thirst, hearing difficulty, abnormal electrolyte levels, and kidney function.

CHOLESTEROL-LOWERING MEDICATIONS

Names: atorvastatin (*Lipitor*), fluvastatin (*Lescol*), lovastatin (*Mevacor, Altoprev*), pravastatin (*Pravachol*), rosuvastatin (*Crestor*), simvastatin (*Zocor*)

Related medications: niacin (*Niaspan, Niacor*), gemfibrozil (*Lopid*), fenofibrate (*Tricor*), cholestyramine (*Questran*), colestipol (*Colestid*), colesevelam (*Welchol*), ezetimibe (*Zetia*)

Cholesterol-lowering medications, most notably the statins, have emerged as some of the most important drugs used in the treatment CAD in the past three decades. Stringent cholesterol control helps prevent both future heart attacks and strokes. Additionally, clinical trials have shown the benefits of statins, especially powerful agents as atorvastatin (*Lipitor*), simvastatin (*Zocor*), or rosuvastatin (*Crestor*), when given during the early phase of heart attack management. The related medications listed above are sometimes added to better control certain types of cholesterol or triglycerides abnormalities, most often in addition to statins.

Preparations: Oral.

Side effects: Muscle aches or pains, nausea, stomach aches, flushing or itching (niacin), insomnia (niacin), gas, diarrhea.

Pathway for the Management of Acute Heart Failure

EPIDEMIOLOGY AND IMPACT

Heart failure is a common and growing problem in the developed nations owing to an aging population. If the overall prevalence of heart failure among adults is 1% to 2%, it exceeds 10% in the elderly (over 70 years old).[1] Moreover, acute decompensated heart failure is among the most common causes of hospitalization among elderly patients. Besides being common and costly, heart failure hospitalization has important prognostic implications: it carries subsequent 1-year mortality risk close to 30%.[1] The current chapter is intended to outline a simple yet comprehensive approach to diagnosis and management of acute decompensated heart failure by synthesizing the evidence from multiple studies and major cardiology society recommendations.[1, 2] It is based on the initial acute heart failure management pathway published by our heart failure team (**Figure 10.1**).[3]

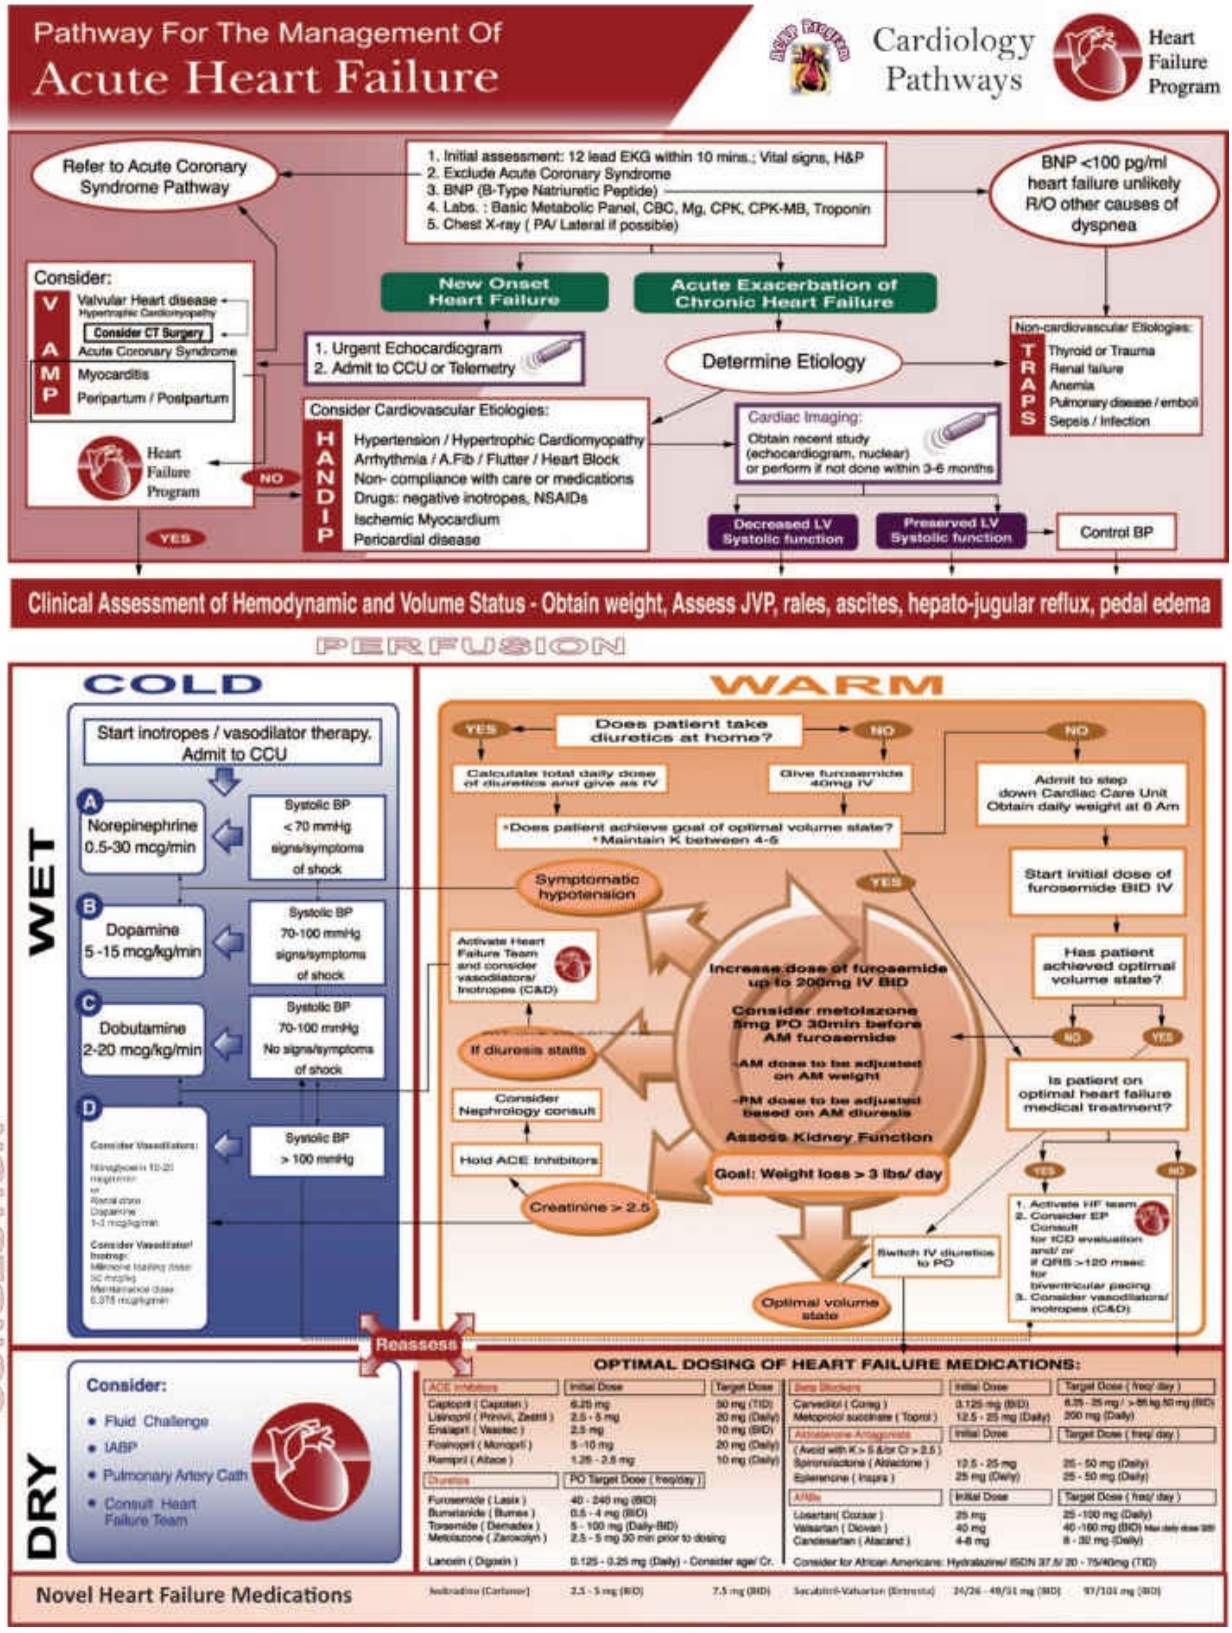

FIGURE 10.1 Pathway for the evaluation and management of acute decompensated heart failure. ACE, angiotensin converting enzyme; ARB, angiotensin receptor blocker; BNP, B-type natriuretic peptides; BP,

blood pressure; CBC, complete blood count; CCU, coronary care unit; CPK, creatine phosphokinase; CPK-MB, CPK-muscle and brain; CT, computed tomography; EKG, electrocardiogram; HANDIP, hypertension, arrhythmias, noncompliance with care, drugs, ischemic myocardium, and pericardial disease; IABP, intra-aortic balloon pump; IV, intravenous; JVP, jugular venous pressure; LV, left ventricular; NSAIDs, nonsteroidal anti-inflammatory drugs; PA, pulmonary artery; TRAPS, thyroid, renal failure, anemia, pulmonary disease, and sepsis; VAMP, valvular disease, acute coronary syndromes, myocarditis, and peripartum/postpartum cardiomyopathy.

DEFINITIONS

Acute decompensated heart failure refers to the acute onset of symptoms (predominantly dyspnea, congestion, and fatigue) due to elevated cardiac filling pressures and/or decreased cardiac output. It can be newly diagnosed heart failure or exacerbation of preexisting chronic heart failure condition. Despite major advances in confirmatory laboratory and diagnostic modalities, heart failure remains a clinical diagnosis of a constellation of signs and symptoms. Careful history taking and focused physical examination are the cornerstones of the diagnosis. The diagnosis is established by the combination of symptoms of heart failure (such as dyspnea and orthopnea), signs of fluid overload (such as jugular venous distention, pulmonary crackles, and peripheral edema), signs of hypoperfusion (such as cold extremities, confusion, and narrow pulse pressure), and objective evidence of structural heart disease (such as third heart sounds, cardiac murmurs, and echocardiographic findings). Acute decompensated heart failure is a continuum of clinical presentations ranging from mild dyspnea to florid pulmonary edema to cardiogenic shock; therefore, urgent evaluation and triage of suspected acute decompensated heart failure are warranted.

Although initially described for patients with myocardial infarction, the Forrester classification can be applied to all patients with acute decompensated heart failure to guide the management.[4] It assigns patients to groups on the basis of bedside estimation of fluid overload status (“wet,” meaning apparent signs of congestion) and perfusion state (“cold,” meaning low perfusion state). “Wet” signs include pulmonary congestion, jugular venous distention, congestive hepatomegaly, and peripheral edema. “Cold” signs include cold extremities, confusion, narrow pulse pressure, and oliguria. Most but not all patients in the “cold” category are hypotensive. Most patients with acute decompensated heart failure fall into the “wet” and “warm” category: They have evidence of pulmonary congestion/pulmonary edema with normal or high blood pressure. Patients with pulmonary edema and hypoperfusion are in or at risk for

cardiogenic shock, which typically signifies bad prognosis unless a reversible cause is rapidly identified and corrected (eg, reperfusion therapy in a patient with acute myocardial infarction or a corrective surgery in a patient with acute valvular dysfunction). Sometimes patients with cardiogenic shock (“cold” state) have no evidence of pulmonary congestion and systemic hypoperfusion dominates the clinical picture. Patients with acute right ventricular infarction are a classic example in this category.

ETIOLOGY AND PRECIPITATING FACTORS

There is a long list of possible heart failure etiologies, but in reality a few causes account for the majority of cases. From long-term heart failure management perspective, the causes can be broadly divided into heart failure with reduced left ventricular ejection fraction (LVEF) and heart failure with preserved LVEF. Recently, a new category of heart failure with mid-range ejection fraction of 40% to 49% has been proposed, which represents a “gray zone” between the traditional categories.[1, 2] Coronary artery disease is the most common cause of heart failure with reduced LVEF. Less common causes include myocardial diseases resulting in dilated cardiomyopathy that can be idiopathic, genetic, or associated with other conditions (such as infections, toxins, immune-mediated condition, peripartum, and so on). The prevalence of heart failure with preserved LVEF increases with age and overall accounts for approximately 50% of heart failure cases. The etiology of heart failure with preserved ejection fraction is complex and relates to important cardiovascular risk factors such as hypertension. Some valvular diseases (such as aortic stenosis and mitral regurgitation), hypertrophic cardiomyopathy, and restrictive cardiomyopathy also present as heart failure with preserved LVEF.

In any patient who presents with new-onset acute decompensated heart failure or chronic heart failure exacerbation, the precipitating cause should be identified and adequately addressed. Myocardial ischemia is a common precipitating factor and should be considered in the differential diagnosis. Valvular pathology can cause acute heart failure if it develops suddenly: Typical examples include flail mitral valve with chordal rupture or aortic valve perforation in infective endocarditis. Similarly, mechanical complication of myocardial infarction (such as papillary muscle rupture and ventricular septal rupture) can cause sudden profound hemodynamic deterioration. Myocarditis and postpartum

cardiomyopathy can present as acute heart failure. VAMP (valvular disease, acute coronary syndromes, myocarditis, and peripartum/postpartum cardiomyopathy) is a useful mnemonic in evaluating a patient with new-onset acute heart failure (**Figure 10.2**).[3] Severe hypertension is another common condition that is typically associated with preserved LVEF and better in-hospital outcomes. Both supraventricular and ventricular arrhythmias can precipitate heart failure. It is important to know that patients with diastolic dysfunction are highly dependent on preload for left ventricular filling. Certain arrhythmias such as atrial fibrillation decrease diastolic filling by increasing heart rate and eliminating atria kick, and therefore they can provoke florid heart failure in an otherwise stable patient. Interestingly, frequent ventricular premature beats and right ventricular pacing can create dyssynchrony contributing to heart failure. Medication and diet noncompliance is one of the most common factors that precipitate acute exacerbation in patients with chronic heart failure. HANDIP (hypertension, arrhythmias, noncompliance with care, drugs, ischemic myocardium, and pericardial disease) is another useful mnemonic in evaluating patients with heart failure exacerbation from cardiac causes (**Figure 10.2**).[3]

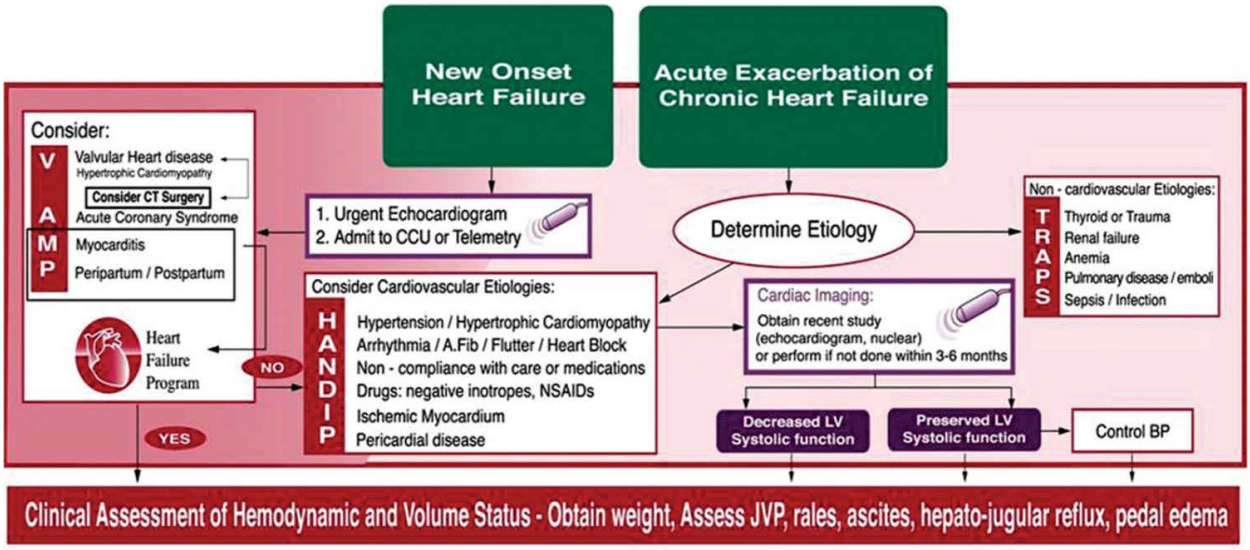

FIGURE 10.2 Differential diagnosis between new-onset heart failure and acute exacerbation of chronic heart failure, with timing of imaging and consideration of precipitating pathophysiology. BP, blood pressure; CCU, coronary care unit; CT, computed tomography; HANDIP, hypertension, arrhythmias, noncompliance with care, drugs, ischemic myocardium, and pericardial disease; JVP, jugular venous pressure; LV, left ventricular; NSAIDs, nonsteroidal anti-inflammatory drugs; TRAPS, thyroid, renal failure, anemia, pulmonary disease, and sepsis; VAMP, valvular disease, acute coronary syndromes, myocarditis, and peripartum/postpartum cardiomyopathy.

Noncardiac factors can precipitate heart failure in otherwise stable patients by creating high oxygen demand and inducing tachycardia (such as anemia, thyroid diseases, drugs, fever and infection, and pulmonary emboli), causing fluid overload (in-hospital intravenous fluid administration, renal failure, and nonsteroidal anti-inflammatory agents), or decreasing myocardial contractility (negative inotropes such as verapamil). TRAPS (thyroid, renal failure, anemia, pulmonary disease, and sepsis) is a mnemonic to help categorize noncardiac precipitants of heart failure exacerbation (**Figure 10.2**).[3]

DIAGNOSIS AND WORKUP

Once the history and physical examination findings consistent with heart failure are ascertained, further work-up is directed toward confirming the diagnosis, establishing the cause of the heart failure, addressing the precipitating factor(s), and identifying prognostic indicators. Physical examination should specifically focus on the degree of respiratory failure (tachypnea, accessory respiratory muscle use), vital signs, signs of fluid overload (pulmonary crackles, jugular venous distension and peripheral edema), and signs of hypoperfusion (cold extremities, confusion, feeble pulses). Cardiac assessment may provide important clues to the diagnosis (eg, a new murmur). Bedside rapid assessment of congestion status and systemic perfusion helps to assign the patient to one of the Forrester categories as described earlier. The essential set of initial tests includes electrocardiogram (ECG), laboratory work-up (complete blood count, electrolytes, renal function and liver function test, and coagulation profile), cardiac troponins, and chest X-ray. Thyroid function tests are recommended in patients with newly diagnosed acute decompensated heart failure. Up to one-third of patients with acute coronary syndrome have no chest pain upon presentation. Therefore, serial ECGs and cardiac biomarkers should be an essential part of the initial work-up. Of note, some repolarization abnormalities and QTc interval prolongation can be caused by acute heart failure per se, not necessarily myocardial ischemia. Similarly, small increase in cardiac biomarkers is often seen in acute decompensated heart failure. Other important findings on ECG include arrhythmias, conduction delays, and hypertrophy. Chest X-ray can confirm pulmonary congestion and can demonstrate some other relevant pathology (large pleural effusion, infiltrates, and cardiomegaly). Arterial blood gases provide information about oxygenation, ventilation, and acid–base status;

arterial blood gases should be considered in all patients with significant respiratory distress as well as low perfusion (“cold”) state.

B-type natriuretic peptides (BNP and pro-BNP) are released from myocardial cells in response to increase in the wall stress. Their levels are elevated in both heart failure with preserved LVEF and that with reduced LVEF, but on average they are lower in patients with heart failure with preserved LVEF. Measuring BNP level can supplement the evaluation of patients with suspected acute decompensated heart failure if used in the appropriate clinical context.[5] Low BNP levels (<100 pg/mL) have a high negative predictive value that makes the diagnosis of heart failure unlikely in a patient who presents to the emergency department with dyspnea. Values > 400 pg/mL are consistent with heart failure, whereas intermediate values (100 to 400 pg/mL) are in the gray zone. Studies showed linear correlation between the admission BNP levels in patients with acute decompensated heart failure and in-hospital mortality.[6] Of note, obese patients with heart failure have lower BNP levels, which should be factored in during clinical decision making. Sudden, “flash” pulmonary edema can sometimes be associated with falsely low BNP levels. At the same time, the positive predictive value of elevated BNP levels (especially gray-zone values) is not very high because they can be elevated in patients with atrial fibrillation, left ventricular hypertrophy, pulmonary hypertension, sepsis, renal dysfunction, and liver disease. For example, in a septic patient with persistent atrial fibrillation and possible heart failure, elevated BNP levels add little information to the clinical judgment. In the patients with preexisting chronic heart failure who come with acute exacerbation, one-time elevated BNP level conveys little information.

Echocardiography is an essential tool in evaluating patients with acute decompensated heart failure. The urgency of getting echocardiogram is determined by the clinical presentation. For example, in a patient suspected to have acute valvular pathology or an acute mechanical complication of myocardial infarction, a bedside echocardiogram can immediately confirm the diagnosis, whereas in a patient with known chronic heart failure, subacute symptoms, and medication noncompliance, the immediate test would add little information. In the acute settings, an echocardiogram helps to assess the presence and degree of systolic dysfunction, right ventricular size and function, and valvular and pericardial pathology. It can assess the diastolic dysfunction and give the estimate of right-sided pressures as well as left-sided filling pressures. Regional wall motion abnormalities and dyssynchrony can provide

clues to the possible causes of the symptoms. Determination of LVEF (heart failure with reduced LVEF vs preserved LVEF) is fundamental in long-term management of heart failure patients.

The routine insertion of a pulmonary artery catheter in patients with acute decompensated heart failure is *not* recommended because it has not been shown to improve major clinical outcomes.[7] It can be considered under specific circumstances to estimate left-sided filling pressures and cardiac output. Possible scenarios include complex patients with cardiac and pulmonary disease, persistent hypotension, worsening renal function, and so forth. The benefits of getting important hemodynamic information should be weighed in each individual patient against the complications of the invasive monitoring and limitations of the technique.

Coronary angiography is indicated in patients with acute decompensated heart failure believed to be precipitated by myocardial ischemia. Successful reperfusion in these settings has been shown to improve survival.

Comprehensive assessment of patients admitted for acute decompensated heart failure includes identification of prognostic indicators. The indicators of poor prognosis include clinical variables (age, poor functional status at baseline, low admission blood pressure, etc), Laboratory factors and ECG changes (wide QRS complex, certain arrhythmias, hyponatremia, positive cardiac biomarkers, marked elevation of BNP, etc), and imaging findings (low LVEF, restrictive mitral inflow pattern, abnormal RV function, etc).[1]

MANAGEMENT

The management of acute decompensated heart failure should be approached in systematic manner and tailored to each individual patient. **Figure 10.1** outlines the general approach to the management of acute decompensated heart failure. The following components of the therapy should be addressed: (1) oxygenation, (2) hemodynamics, (3) fluid overload, and (4) precipitating factors.

OXYGENATION

The range of respiratory distress varies along the spectrum of presentations in acute decompensated heart failure. Rapid assessment of oxygenation and respiratory status is an important initial step. Mild respiratory distress might

require oxygen supplementation via nasal cannula or a mask, with the goal of keeping the patient comfortable and maintaining oxygen saturation above 90% to 92%. Caution should be exercised in chronic CO_2 retainers because high-flow oxygen delivery in these patients can result in acute CO_2 retention and respiratory acidosis. Patients with significant respiratory distress need arterial blood gas analysis to assess oxygenation, ventilation, and acid–base status. Patients with pulmonary edema have been shown to benefit from noninvasive positive pressure ventilation, provided they do not have contraindications (eg, impaired level of consciousness, agitation, inability to protect airways, high risk of aspiration, etc). The benefits of noninvasive positive pressure ventilation result from improved V/Q mismatch and decreased cardiac preload. Meta-analyses of randomized clinical trials in patients with pulmonary edema suggest a decrease in the need of intubation and improvement in respiratory signs and symptoms.[8] Mortality benefit from noninvasive positive pressure ventilation in those patients has not been consistently demonstrated. Patients in significant respiratory distress and those who have contraindications to noninvasive positive pressure ventilation should be intubated and mechanical ventilation should be initiated.

HEMODYNAMICS

Rapid bedside assessment of hemodynamics as described earlier is important in initial management of acute decompensated heart failure. Most heart failure patients are in “warm” and “wet” category and need treatment with diuretics and vasodilators. Patients with borderline or low blood pressure, poor perfusion, and pulmonary edema (“cold” and “wet”) are in/at risk of cardiogenic shock and generally carry poor prognosis. Rapid correction of precipitating factors may improve their condition (eg, revascularization in acute coronary syndrome). Patients with borderline and low systolic blood pressure and poor perfusion (cold and clammy) and patients who are resistant to diuretic therapy experience symptomatic improvement from inotropic agents. Dobutamine, which is a β-adrenergic agonist, can be used in these settings. Phosphodiesterase inhibitors (such as milrinone) are potent inotropes and can also provide significant symptomatic relief. It is important to remember that inotropic agents should be used only as temporary measure and withdrawn as early as possible once adequate perfusion is restored and congestion has been relieved. Symptomatic relief provided by those agents comes at the expense of increased risk of

ischemia, arrhythmias, and myocardial damage. They have been shown to increase short-term and long-term mortality in patients with congestive heart failure.[1] Their use should be restricted to patients with known severe systolic left ventricular dysfunction. In addition, vasodilator effect of inotropic agents may cause hypotension. Vasopressor agents (preferably norepinephrine) can be used in these settings to maintain blood pressure. Finally, patients with hypotension and no signs of significant pulmonary congestion ("cold" and "dry" state) can receive a fluid challenge, if volume depletion and sepsis are a consideration. However, these patients are at risk of rapidly developing volume over load and edema. Careful monitoring is essential. In patients who develop symptomatic hypotension during aggressive diuresis, the diuretics should be held. Patients who are highly preload dependent (eg, severe aortic stenosis or severe concentric left ventricular hypertrophy and normal LVEF) are at a higher risk of hypotension with aggressive diuresis.

In patients with cardiogenic shock who do not have an adequate response to pharmacologic therapy, mechanical assist devices should be considered. These include intra-aortic balloon pump and ventricular assist devices. They can provide temporary hemodynamic support as a "bridge to decision" or bridge to longer-term intervention. The evidence behind using mechanical assist devices in these settings is limited and needs further study and validation.[1]

FLUID OVERLOAD

Symptoms of dyspnea in acute decompensated heart failure are attributed to elevated left-sided filling pressures. Most patients with decompensated heart failure are fluid overloaded owing to renal retention of sodium and water, whereas some patients with acute, especially precipitous, heart failure are normovolemic. Early diuresis and manipulation of preload are the most effective ways to bring symptomatic relief to those patients. Most patients with acute decompensated heart failure require intravenous loop diuretic therapy except "dry" patients and those with hypotension and shock. Patients with hypotension, severe acidosis, renal failure, and hyponatremia are less likely to respond to loop diuretics. The dosing of the intravenous loop diuretic (eg, furosemide) used in patients with acute decompensated heart failure should be based on the degree of fluid overload, renal function, and preadmission loop diuretic use (**Figure 10.3**). Interestingly, it has been shown that loop diuretics improve symptoms even before the diuretic effect by venodilation and a decrease in preload. Parameters

that need to be monitored during diuretic therapy include volume status, intake and output, blood pressure, electrolytes, and renal function. Patients with decreasing renal function upon diuresis (a form of “cardiorenal syndrome”) carry a worse prognosis. In patients who show suboptimal response to escalating doses of loop diuretics, the following options can be considered: addition of a thiazide diuretic, addition of mineralocorticoid receptor antagonist, inotropic therapy, and continuous infusion of a loop diuretic. In patients with renal dysfunction, metolazone added to loop diuretics might be used. Dopamine in low doses has been shown to improve renal perfusion, but the clinical implications of this finding were not supported in a large randomized clinical trial. Ultrafiltration is the last-resort therapy, especially in patients with severe renal dysfunction.

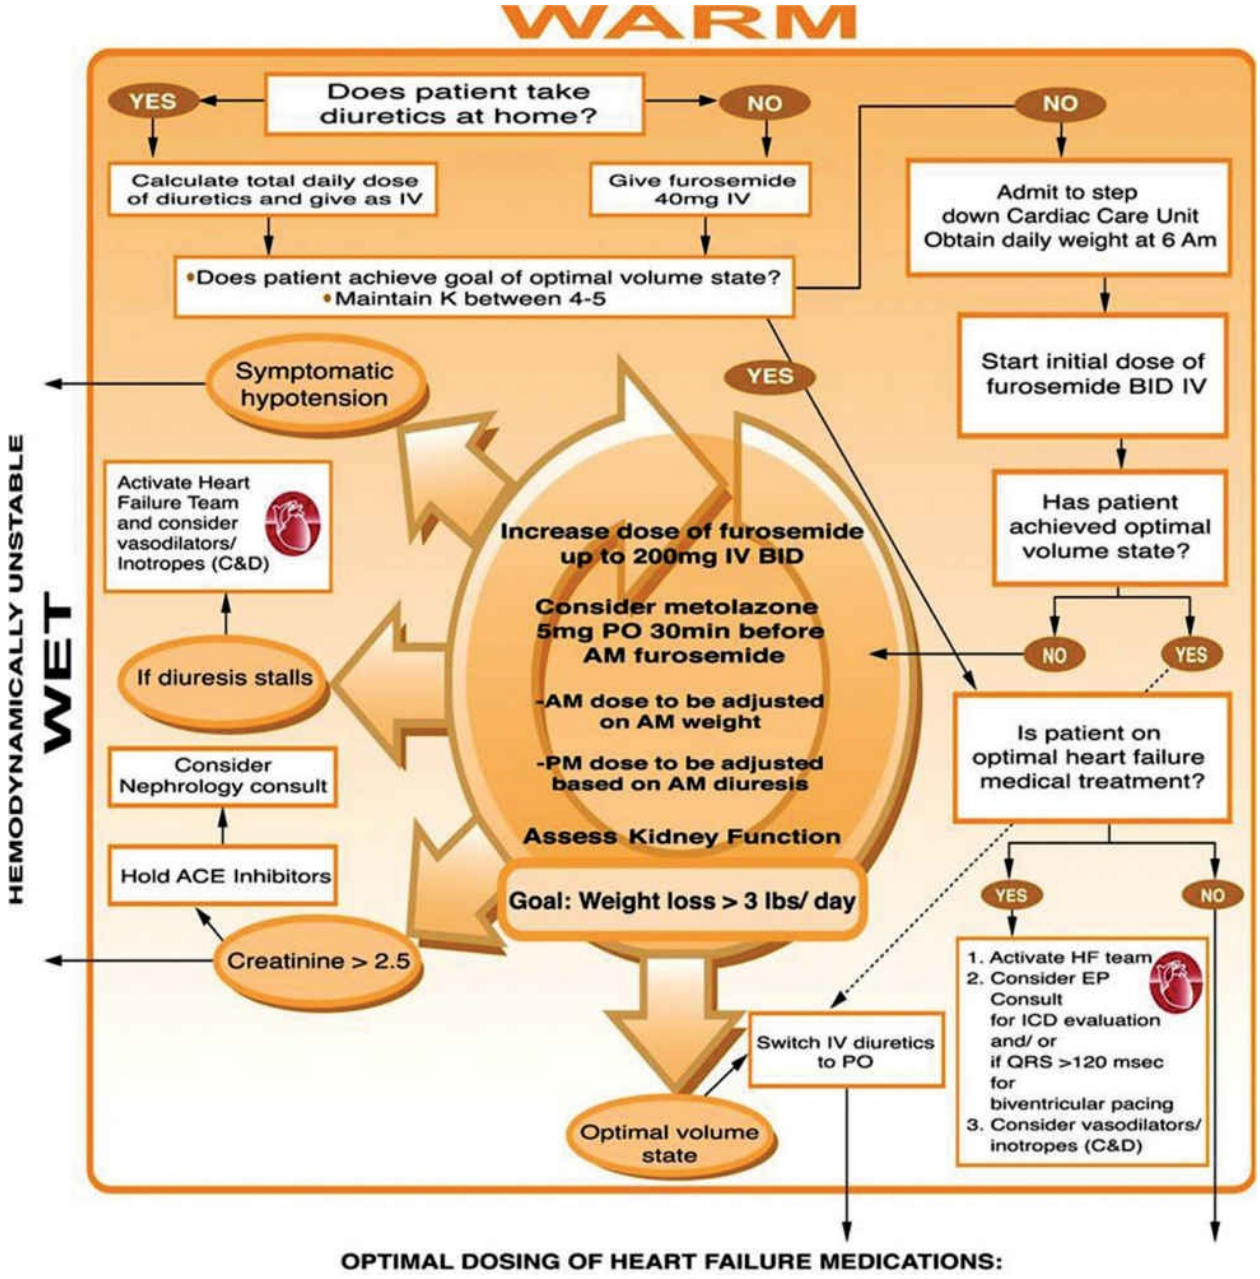

FIGURE 10.3 The "loop" concept of aggressive usage of loop diuretics to rapidly and safely diurese patients, shorten length of stay, and transition to oral therapy upon successful completion of diuresis. ACE, angiotensin converting enzyme; EP, electrophysiology; ICD, implantable cardioverter defibrillator.

Preload reduction brings significant symptomatic relief in patients with acute decompensated heart failure by decreasing left-sided filling pressures. It can be achieved by using venodilators such as nitroglycerine, isosorbide dinitrate, and nitroprusside. Nitroglycerin, typically in the form of intravenous infusion, can be used as add-on therapy to diuretics if systolic blood pressure is >110 mm Hg. In patients with systolic blood pressure <90 mm Hg, vasodilators should be

avoided, whereas in patients with systolic blood pressure of 90 to 110 mm Hg, they should be used with caution. Hypotension is the main side effect of nitroglycerine, especially in patients who are significantly preload dependent (eg, severe aortic stenosis, right ventricular infarction). Nitrates should be avoided in patients using phosphodiesterase inhibitors (eg, sildenafil). Headache is a common complaint, and tachyphylaxis develops with continuous use. Nitroprusside is a potent vasodilator that achieves significant afterload reduction along with preload reduction. This property is important in certain situations such as hypertensive emergencies and acute valvular pathology such as acute mitral regurgitation. Accumulation of cyanide is a potential side effect with continuous infusion. Nesiritide is an analog of brain natriuretic peptide. It produces vasodilation, reduces preload, and may bring symptomatic relief to patients with pulmonary congestion. However, a large randomized trial showed that nesiritide improves symptoms only marginally and does not improve the rates of death and rehospitalization. [9] Therefore, routine use of nesiritide is not recommended. Morphine reduces anxiety and sense of dyspnea and produces vasodilation in patients with pulmonary edema. However, retrospective studies raised some concerns regarding the use of morphine in these patients because of association with increased in-hospital mortality.[2] In patients with acute coronary syndrome and chest pain, morphine should not be withheld.

OTHER THERAPIES

Angiotensin-converting enzyme (ACE) inhibitors reduce morbidity and mortality in patients with chronic heart failure and decreased LVEF but their role in managing patients with acute decompensated heart failure is limited. They are generally avoided in these patients until they are stable due to the following concerns: ACE inhibitors can precipitate hypotension and worsening renal function in patients who are aggressively diuresed. Similarly, β-blockers are the mainstay of chronic heart failure treatment in patients with systolic left ventricular dysfunction, but they should be avoided in the settings of acute exacerbation. In patients who are already taking β-blockers, they can be cautiously resumed once the patients are stable. Thromboembolism prophylaxis should be ensured in all patients with acute decompensated heart failure.

PRECIPITANTS

Identifying the precipitating factors for acute decompensated heart failure should

be the part of the initial thought process. The common precipitating factors are described above, and some of them should be actively sought and corrected such as myocardial ischemia, hypertensive crisis, arrhythmias, and acute valvular pathology (see specific chapters on how to address those issues). Medication and diet noncompliance is a common precipitant, and it should be specifically inquired. Other precipitating factors such as infection, medications (eg, nonsteroidal antiinflammatory drugs), pulmonary disease, and so on could be more subtle and their identification requires a systematic approach to history taking, physical examination, and laboratory work-up.

END-STAGE HEART FAILURE

Patients with severe, "end-stage" heart failure that are resistant to optimal medical therapy often have symptoms at rest (NYHA functional class IV). They have frequent hospitalizations, long hospital stays, and poor quality of life. Options for those patients are limited to continuous inotrope infusion as palliative measure and mechanical support as "bridge" therapy to transplantation or as "destination" therapy. In addition, for refractory end-stage heart failure palliative and hospice care discussions should be initiated.[1, 2]

OPTIMAL DISCHARGE PLANNING

Optimal discharge planning involves patient education, proper follow-up, identification and correction of precipitants, and evidence-based therapy for heart failure. Patient education should include information about the nature of the disease, importance of diet and medication compliance, self-monitoring (eg, weight and edema), and early recognition of decompensation symptoms. Precipitating factors should be addressed, which in specific circumstances might include ischemic work-up, valvular disease surgery, long-term control of arrhythmias, control of hypertension, and the like. Chronic management of heart failure is based on the estimation of the LVEF. Patients with systolic left ventricular dysfunction should be placed on a β-blocker and an ACE inhibitor (or angiotensin receptor blocker) and optimal dosing of the agents should be achieved by slow uptitration during outpatient follow-up. Other therapies for those patients include aldosterone antagonists, hydralazine and isosorbide dinitrate combination, and digoxin (see Chapter 19 for specific drug discussion). Newer agents such as an angiotensin receptor-neprilysin inhibitor (sacubitril-

valsartan) and a selective sinus node inhibitor (ivabradine) have a role in the outpatient treatment of chronic systolic heart failure. Specifically, sacubitril-valsartan has been shown to be a superior agent compared with ACE inhibitor.[10, 11] Ivabradine can be considered to further lower heart rate in normal sinus rhythm despite patients' being on optimal doses of β-blockers or in patients intolerant of β-blockers.[12] The evidence for chronic management of diastolic heart failure is more limited; optimal volume control and treatment of hypertension seem to be the best strategy at this point.

Patient and Family Information for: THE MANAGEMENT OF ACUTE HEART FAILURE

DEFINITION AND CAUSES

Heart failure is a common problem in the United States, especially in the elderly population. It is one of the most common reasons for hospital admission. Heart failure is a clinical syndrome and not a specific disease. It can have many causes. It results from decreased pumping function of the heart and its inability to propagate adequate amounts of blood to the tissues. Acute heart failure is a serious, life-threatening condition; it can be the presentation of newly diagnosed illness or an exacerbation of a preexisting disease. Shortness of breath is the most common symptom of acute heart failure. It results from fluid accumulation in the lungs. Other manifestations of heart failure include cough, swelling of the legs, fatigue, tiredness, and poor appetite. Some patients experience nighttime episodes of breathlessness and find it difficult to sleep flat in bed. Patients with preexisting chronic heart failure often experience slow and progressive shortness of breath on exertion, leg swelling, and weight gain, all symptoms of fluid accumulation in the body before they present to the hospital with breathlessness at rest. Acute heart failure is not synonymous to “heart attack,” but it can sometimes be precipitated by heart attack. In that case, it is common for patients to have chest pain, chest discomfort, or pressure-like sensation in the chest. The severe form of acute heart failure is called “pulmonary edema”; it causes significant distress and breathing difficulty due to rapid build-up of the fluid in the lungs. Another extreme form of heart failure is called “cardiogenic shock”; it causes poor perfusion of the tissues due to significant impairment of heart function. The patients appear cold and clammy, their blood pressure is low, and

their thinking can be impaired. Those patients are at a high risk of dying and often need drastic measures to correct the underlying problem and support the circulation.

Heart failure is not a single disease; it is a manifestation of a big variety of structural heart disorders. The most common disorder that results in heart failure is coronary artery disease. Blockage of the blood vessels that supply the heart muscle can result in a significant heart muscle damage, causing the heart to fail. High blood pressure, if unrecognized or untreated, causes pathologic changes in the heart muscle over months to years and can eventually result in heart failure. The heart valve narrowing or leakage is a relatively common cause of heart failure. Diseases of the heart muscle, itself termed “cardiomyopathy,” manifest as heart failure. Some causes of cardiomyopathy are known (such as infection, alcohol, and illegal drugs) and some are genetically inherited. A well-described form of cardiomyopathy is associated with pregnancy. Sometimes, there is no obvious cause for the heart muscle weakness, and in medical literature, it is referred to as “idiopathic.” Besides the structural heart disease that results in heart failure, it is important to realize that a variety of conditions can provoke an acute exacerbation of heart failure. Those conditions are called “precipitating factors.” Precipitating factors superimposed on the underlying structural heart disease are responsible for acute onset of symptoms in otherwise stable patient. A “heart attack” or inadequate blood supply to the heart muscle called “ischemia” is a common precipitating factor. Poorly controlled blood pressure puts excessive strain on the heart and precipitates heart failure. Noncompliance with the diet and medications is among the most common precipitating factors for acute heart failure. Other conditions that can precipitate or worsen heart failure include infection, certain medications (including painkillers), low blood count, heart rhythm disturbances (called “arrhythmias”), kidney disease, etc.

DIAGNOSIS AND TREATMENT

The physician establishes the diagnosis of acute heart failure by taking history (asking questions about the patient’s symptoms), performing physical examination, and ordering appropriate tests. Besides confirming the diagnosis, the physician needs to determine what the underlying structural heart disease is that causes heart failure and what the precipitating factor for the current acute exacerbation is. Blood tests are commonly sent, and ECG and chest X-ray are

also typically performed. Ultrasound examination of the heart (also known as echocardiogram) helps to visualize cardiac chambers, and it is the most commonly used tool to evaluate the structure and function of the heart. Other tests are performed as deemed necessary by the physician. Cardiac catheterization is an invasive test that includes placing catheters into the heart chambers and major vessels to diagnose vessel blockage or get important pressure readings from various heart chambers. It is also used for interventions if vessel blockage seems to be causing patient's symptoms.

Treatment of heart failure has several important components. Patients are given oxygen by nasal prongs or a mask to ensure adequate oxygen delivery to the tissues. In patients with significant breathing difficulty, assisted ventilation via special mask is employed (commonly called "continuous positive airway pressure"). Occasionally, a breathing tube is placed in the airway and mechanical ventilation is initiated. In patients with low blood pressure and poor perfusion, medications are used to maintain blood pressure. In severe cases, medications that enhance heart muscle contractility are used; unfortunately, those medications are associated with significant adverse effects and therefore their use is limited to refractory cases. As explained above, fluid overload underlies many symptoms of heart failure; therefore, diuretic medications are commonly administered to increase water and sodium excretion from the body. Other medications that help to relieve the symptoms include vasodilators; these medications dilate the blood vessels in the body decreasing the workload on the heart. These are commonly administered as intravenous drips. Precipitating factors are also addressed. These could include controlling abnormal heart rhythm, lowering blood pressure, treating infection, etc.

FOLLOW-UP AND PREVENTION

Once the acute phase is over, the long-term management plan should be discussed in detail. Medications used to treat chronic heart failure are often different from those used to treat acute exacerbation. β-Blockers (such as metoprolol or carvedilol), ACE inhibitors (such as lisinopril and enalapril), sacubitril-valsartan, and spironolactone are commonly used in the treatment of chronic heart failure. They help to maintain heart function and prevent acute exacerbation. They have also been shown to decrease the risk of death in certain patients with heart failure. Proper education of the patient includes teaching

them about the appropriate medication regimen, necessity of taking the medications daily, and compliance with low-salt diet. Sodium contained in salt retains fluid in the body and causes heart failure exacerbations. Besides, it commonly elevates blood pressure, putting excessive stain on the heart. Patients should not only follow appropriate diet but also be able to recognize early signs and symptoms of heart failure such as exertional shortness of breath, fatigue, inability to lay flat in bed, awakening from sleep short of breath, using several pillows to elevate the head and thereby making breathing at night easier, gradual weight gain, and ankle swelling. Weight gain is commonly the first manifestation of fluid build-up in the body; therefore, the patients should know their “dry weight” and try to follow their weight regularly. Proper follow-up after discharge is necessary to ensure stability of clinical symptoms and proper adjustment of medication doses. Some of the medications (such as β-blockers) need to be titrated up slowly during follow-up visits to avoid adverse effects. In case of coronary artery disease and valvular heart disease, certain interventions or surgery can fix the problem. Implantations of certain devices such as a pacemaker or defibrillator might be beneficial in certain groups of patients.

Heart Failure with Reduced Ejection Fraction

INTRODUCTION

This chapter provides the basic definitions, pathophysiology, clinical presentation, and the basis of treatment in patients with heart failure (HF) with reduced ejection fraction (EF). From an epidemiologic standpoint, HF is a growing problem with a substantial impact affecting millions of patients worldwide. About 5.7 million adults in the United States have HF, and half of those affected will die within 5 years of diagnosis.[1] In fact, HF is the leading cause of hospitalization among patients over the age of 65 in the United States.[2] The economic burden of HF is reflected in costs estimated to be as much as $30.7 billion/year in the United States alone.[3] This total includes the cost of health care services, medications to treat HF, and missed days of work.

DEFINITION

HF has a broad definition with no single diagnostic test as a gold standard. Impaired contractility and reduced EF are not an adequate definition—at least half of the patients with HF have a preserved EF (impaired relaxation or

"diastolic" HF). According to current clinical guidelines, the broadest definition of HF is "a complex clinical syndrome that results from any structural or functional impairment of ventricular filling or ejection of blood."[4]

Older definitions include the "classic" definition by Braunwald—"A pathophysiological state in which an abnormality of cardiac function is responsible for the failure of the heart to pump blood at a rate commensurate with the requirements of the metabolizing tissues."[5] Another classic definition emphasizing HF pathophysiology proposed by Poole-Wilson is "a clinical syndrome caused by an abnormality of the heart and recognized by a characteristic pattern of hemodynamic, renal, neural and hormonal responses."[6]

Currently, "heart failure" replaced the older term "congestive heart failure" because many patients present with symptoms of dyspnea and exercise intolerance rather than overt volume overload.[4]

SUBGROUPS

HF can be divided into several well-known subgroups. Left-sided HF refers to pulmonary congestion as opposed to right-sided HF representing peripheral edema, pleural effusion, and ascites. Forward failure is used to describe low cardiac output and poor peripheral perfusion. In contrast, backward failure consists of peripheral edema, pulmonary edema, and splanchnic congestion (ascites, hepatomegaly, abdominal fullness).

CLASSIFICATION ACCORDING TO LEFT VENTRICULAR EJECTION FRACTION

EF is the percentage expressed by (left ventricular end-diastolic volume—end-systolic volume)/left ventricular end-diastolic volume. EF is considered as a load-independent factor that can identify patients with a primary defect in cardiac contractility—systolic function. Many HF trials selected patients according to reduced EF because it can be measured objectively by echocardiography, magnetic resonance imaging (MRI), or radionuclide imaging. However, as mentioned earlier, approximately half of the patients with HF have preserved EF—diastolic dysfunction. The etiology, comorbidities, demographics, and response to therapy differ between patients with reduced

ejection fraction (HFrEF) and preserved EF (HFpEF). Therefore, patients with HF are generally divided into these two categories.[7] It is important to understand that diastolic dysfunction (impairment of myocardial relaxation) may coexist in the setting of systolic dysfunction. Conversely, patients with diastolic dysfunction may have impaired systolic function not identified by the EF. That is why the terms HFrEF and HFpEF are more accurate rather than systolic and diastolic HF. In addition, an intermediate group with a left ventricular ejection fraction (LVEF) of 40% to 50% has been added recently to reflect this mixture of systolic and diastolic dysfunction.[4, 7]

ETIOLOGY

HF has a wide range of causes varying from common causes (coronary artery disease, hypertension) to rare infiltrative diseases (amyloidosis, Fabry disease). These etiologies are categorized phenotypically in **Figure 11.1**. The initial classification includes non-myocardial diseases—valvular disease, pericardial disease, and congenital heart disease. Pericardial disease mainly refers to constrictive pericarditis, which typically presents with right-sided HF, although many patients have dyspnea as well. Valvular heart disease often results in myocardial disease over time because of compensatory mechanisms such as hypertrophy (eg, aortic stenosis and left ventricular hypertrophy [LVH]) and dilation (aortic regurgitation and dilated left ventricle [LV]). Congenital heart disease represents a diverse category, often with myocardial changes, even after palliative or correctional surgery.

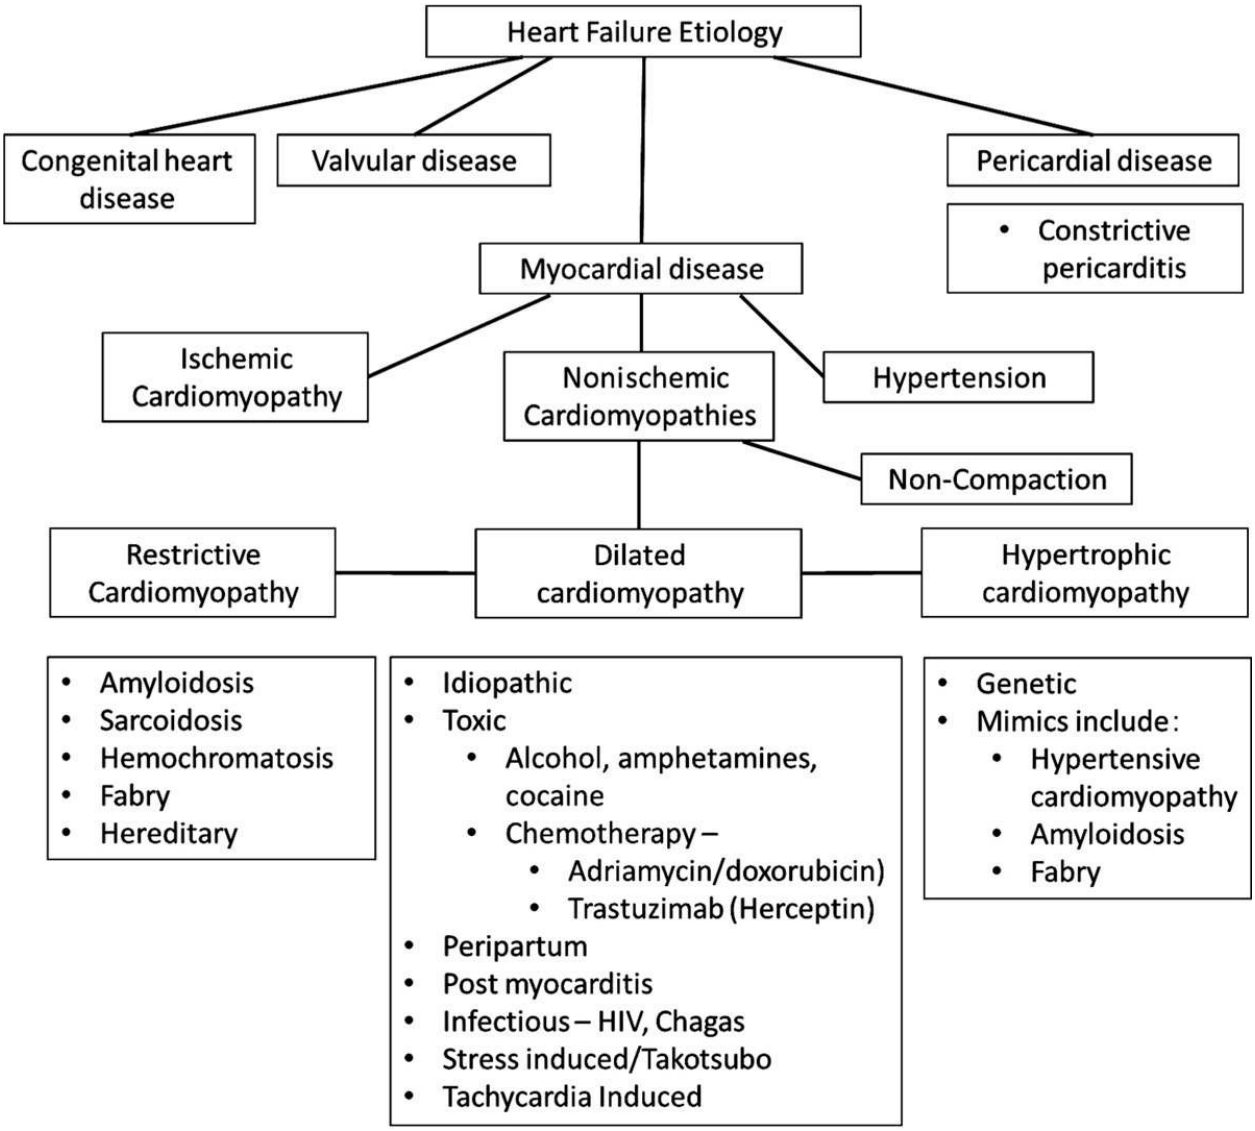

FIGURE 11.1 Heart failure etiologies.

Primary myocardial disease can be roughly divided to ischemic cardiomyopathy and nonischemic cardiomyopathies. Although hypertension is not a primary myocardial disease, it causes LVH over time (depending on treatment) and results in diastolic dysfunction. When blood pressure elevation is at extreme levels, systolic dysfunction may also occur (“afterload mismatch”)—reduced LVEF.

Coronary artery disease and myocardial infarction remain a leading cause of HFrEF even in the current era of timely reperfusion for ST-elevation myocardial infarction. Eventually, many patients post myocardial infarction will develop a global dilated cardiomyopathy after the initial insult (remodeling) or repeated

insults—ischemic cardiomyopathy. Some of these patients may present with HF without preceding angina (usually diabetics with "silent" ischemia). Nonischemic cardiomyopathies include a variety of myocardial diseases. These can be divided into dilated, restrictive, hypertrophic, and non compaction cardiomyopathies.

Dilated cardiomyopathy can be subdivided into several groups—genetic/idiopathic, post myocarditis, toxic, and peripartum cardiomyopathy. Alcohol is a common cause of toxic cardiomyopathy, often partially reversible after cessation of alcohol intake. Chemotherapy-induced cardiomyopathy is increasing in prevalence, especially due to the relatively high success rate in the treatment of leukemia/lymphoma, and the use of doxorubicin and Herceptin in breast cancer. This set the ground for a new subspecialty in itself—cardio-oncology.

PATHOPHYSIOLOGY

Several key pathophysiologic concepts are important to understand when dealing with HF.[8] Cardiac output is determined by heart rate (HR) × stroke volume (SV). One important consequence of this equation is that tachycardia is a proper response to increase cardiac output. Therefore, beta-blockers and HR–lowering therapy in patients with a fixed SV may be detrimental (eg, acute systolic HF, amyloidosis, aortic stenosis). The hazardous effects of tachycardia in the long term are discussed later.

SV is determined by three factors: preload, cardiac contractility (inotropic state), and afterload.

Preload is defined as the ventricular end-diastolic volume. The left ventricular preload is determined by venous return, atrial contraction (20%), and right ventricular function. An important relationship is the force–volume curve, more commonly known as the Frank-Starling curve. A useful analogy is visualizing the basic myocardial unit, the actin–myosin complex, as a spring **(Figure 11.2)**. If the spring is stretched (ie, filling the LV with volume—preload), it will contract with increased force. When the preload is excessive, the spring will reach a certain limit and may even generate a reduced force of contraction. The final end of the Frank–Starling curve is also explained by the right ventricle–left ventricle (RV–LV) interaction and septal displacement.

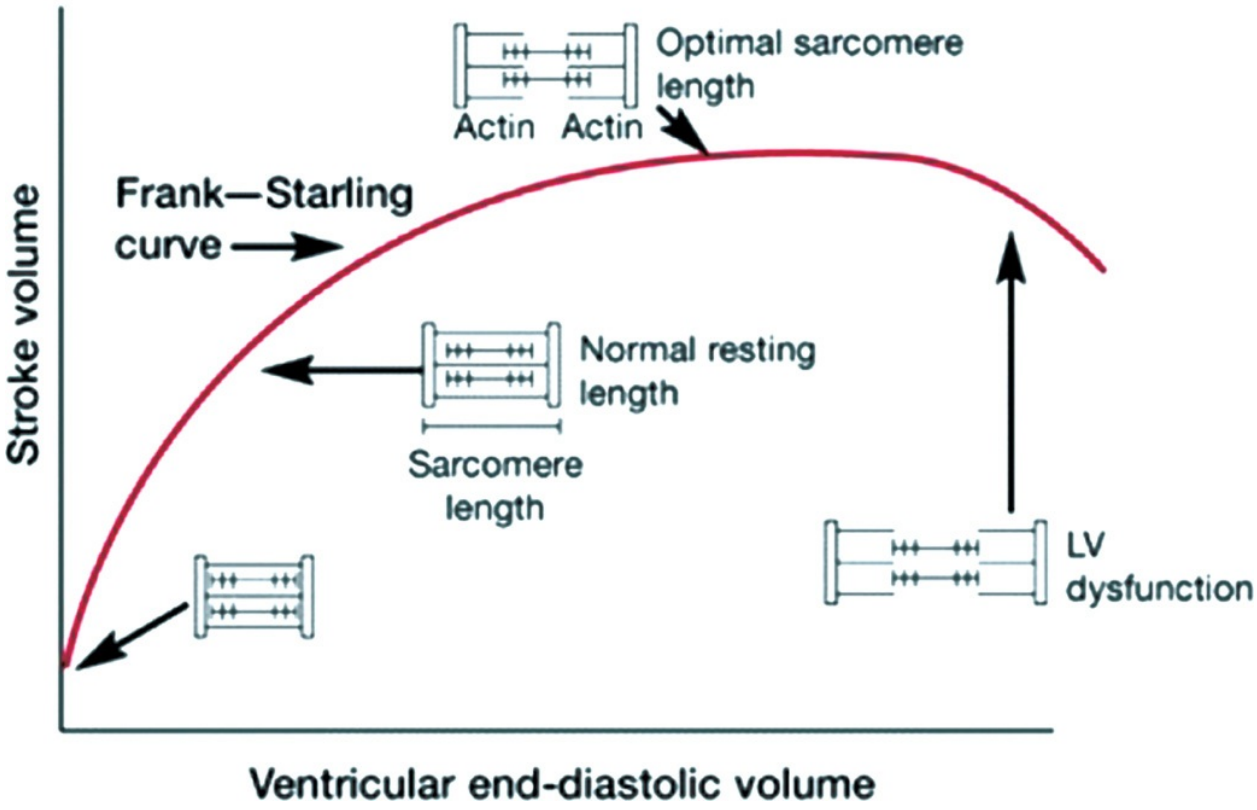

FIGURE 11.2 Relation between stroke volume and ventricular end-diastolic volume. LV, left ventricle.

Cardiac contractility is also known as the inotropic state. This is determined by the intrinsic ability of the myocardium to contract. Factors affecting the inotropic state are intracellular calcium, catecholamines, and pharmacologic agents at different levels (beta-adrenergic receptor, phosphodiesterase 3, NA/K exchanger, etc).

Afterload represents the resistance against which the heart ejects blood. This tension faced by the myocardium is determined by Laplace's law—$T = P*R/2D$, where P is the pressure faced by the LV, R is the radius of the ventricular chamber, and D is the wall thickness. Common situations of increased afterload are vasoconstriction, systemic hypertension, and aortic stenosis. Increased afterload results in reduced systolic function even in hearts with preserved cardiac contractility. This inverse relationship is markedly pronounced in patients with HFrEF **(Figure 11.3)**—patients with HFrEF are "afterload sensitive." This is why afterload reduction is such a crucial and important part of HF therapy.

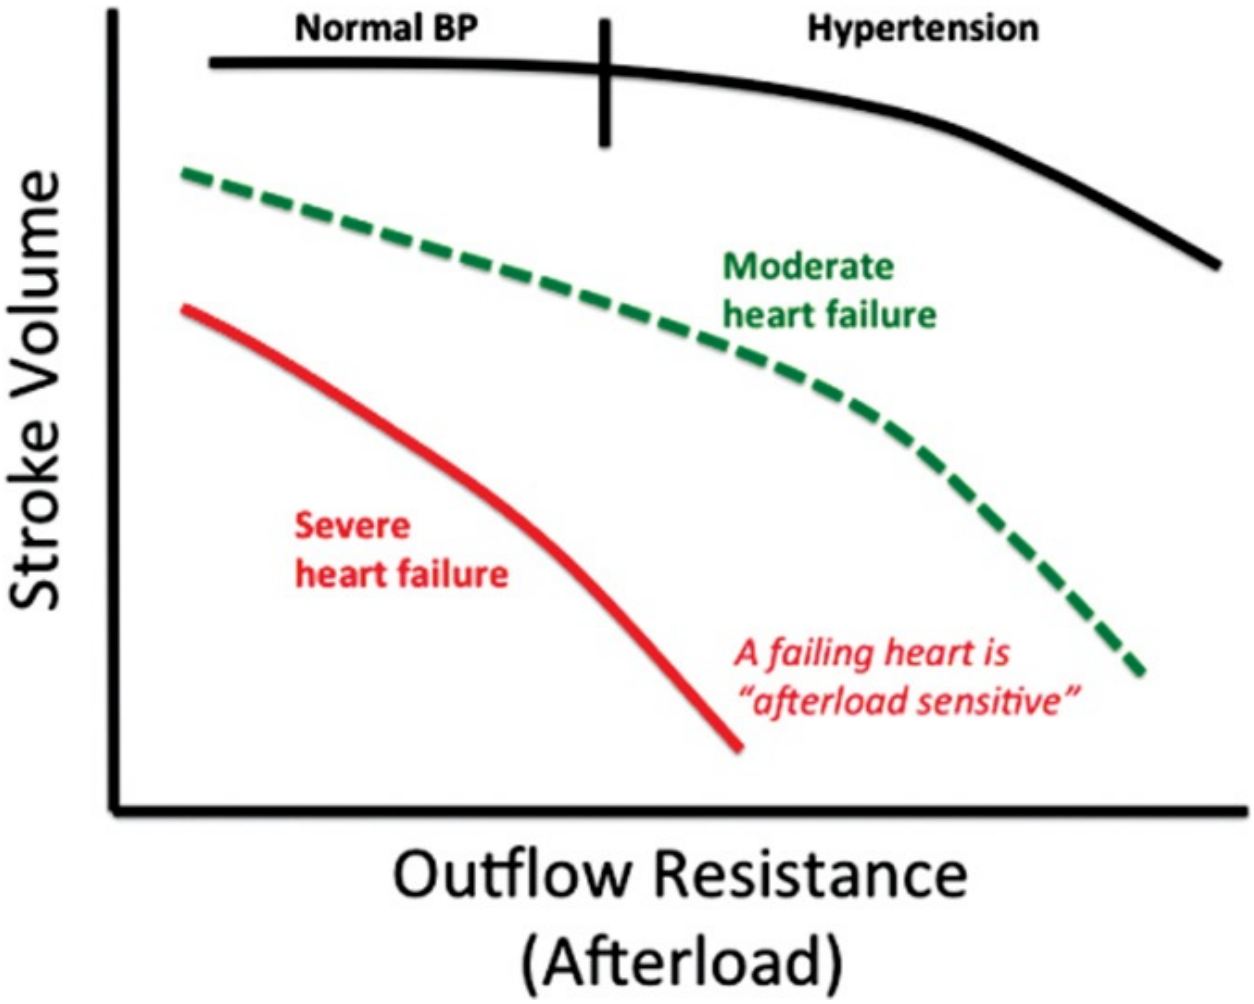

FIGURE 11.3 Relation between stroke volume and outflow resistance (afterload). BP, blood pressure.

REMODELING

Remodeling is a pathophysiologic concept describing the process in which an initial insult (eg, myocardial infarction, myocarditis) results in eccentric hypertrophy and LV enlargement. At first, LV enlargement increases SV and cardiac output allowing for initial compensation. However, the progressive ventricular enlargement (beyond the extent of the initial insult) results in thinning of the heart muscle and globally reduced contraction. This is analogous to a "bad remodeling" job done in the house. The official definition of remodeling is a "group of molecular, cellular and interstitial changes that clinically manifest as changes in size, shape and function of the heart resulting from cardiac injury," as published in an international consensus document.[9]

NEUROHORMONAL ACTIVATION AFTER MYOCARDIAL INSULT

The reduced SV in HFrEF along with elevated pressures lead to the activation of several neurohormonal pathways.

Activation of the sympathetic nervous system is an immediate consequence of any cardiac insult. Reduced cardiac output is sensed by baroreceptors, which in turn increase central nervous system sympathetic discharge and catecholamine production by the adrenal glands. Catecholamines act upon beta-receptors in the heart and alpha-receptors in the peripheral vasculature; resulting in tachycardia, increased venous return (preload), increased cardiac contractility (inotropic state), and peripheral vasoconstriction (which increases blood pressure and afterload). The sympathetic activation therefore increases cardiac output in the short term, allowing for compensation and meeting the body's metabolic demands. However, in the long term, catecholamines are detrimental with direct apoptotic effects on myocardial cells, pro-arrhythmia, and increase in afterload and cardiac work.

Another hormonal cascade activated post myocardial injury is the renin–angiotensin–aldosterone axis. Decreased cardiac output causes an increase in renin production, which in turn increases angiotensin production and vasoconstriction. In addition to vasoconstriction, angiotensin stimulates production of aldosterone. Aldosterone exerts its effect on the renal collecting ducts, promoting sodium reabsorption along with K and H secretion. Aldosterone also has a direct effect on myocardial cells, promoting apoptosis and fibrosis.

An inflammatory reaction occurs as well during HF, resulting in increased levels of cytokines such as tumor necrosis factor. In the long term, this is one of the causes of cardiac cachexia, similar to that in cancer patients.

In contrast to the deleterious "bad" neurohormones that cause salt and water retention and long-term damage to myocardial cells, there is a "positive" pathway providing natriuresis and vasodilation—the natriuretic peptides. These natriuretic peptides are secreted by the heart chambers and blood vessels. There are several natriuretic peptides; the most well known is the B-type natriuretic peptide (BNP) secreted mainly by the ventricles. Since natriuretic peptides are measurable, elevated BNP and N-terminal (NT)-pro-BNP levels provide a diagnosis of HF as well as an estimation of prognosis (extent of HF).

Myocardial energy metabolism is also modulated in HF—an "energy crisis."[10] Since free fatty acids require more O_2 and energy to derive adenosine triphosphate, glucose is a more efficient fuel for the failing heart. The implications of these energetic derangements are providing good nutritional support, in general, and appropriate glucose and insulin management during acute HF.

SYMPTOMS AND SIGNS OF HFrEF

Dyspnea is a cardinal manifestation of HF and may manifest in several forms. The basic underlying mechanism of dyspnea is increased hydrostatic pressure in the alveolar capillaries and transudation of fluids into the alveoli. Exertional dyspnea occurs because of the increased preload and cardiac demand. Dyspnea may also occur during the night, due to the supine position and increased preload. This is the mechanism of paroxysmal nocturnal dyspnea (PND) and orthopnea. PND is often described by patients as nightly rales or wheezing. Orthopnea is not as common as exertional dyspnea; but when it is described ("sleeping upright in a chair"), it is quite specific for HF rather than for other causes of dyspnea. A recently recognized symptom is bendopnea—dyspnea while bending over.[11] Bendopnea is quite common in HFrEF (especially in the patients with advanced HF), also due to increased preload. Many patients will complain of the inability to tie their shoe laces. Because the underlying cause of dyspnea in HF is increased hydrostatic pressure, it is not specific for HFrEF and is a common symptom of HFpEF as well. In addition, younger patients with a more compliant LV and atrium ("less stiff" compared to the aging fibrotic heart) may not necessarily complain of dyspnea. Dyspnea may also present as "cardiac asthma"—the alveolar fluid may cause bronchoconstriction and wheezing. This may sound exactly like asthma on clinical examination!

Patients with HFrEF may also manifest right-sided symptoms such as peripheral edema, abdominal fullness, or ascites. Often the liver/splanchnic congestion may cause right upper quadrant and epigastric pain, sometimes masquerading as cholecystitis (especially when the patient already has gallstones). Cachexia and unintended weight loss are late and ominous symptoms of advanced HF, usually marking the "point of no return" even with advanced therapies.

Important physical signs in patients with HFrEF include measurement of vital

signs (HR, blood pressure), estimation of jugular venous pressure (JVP), lung auscultation (crackles and wheezing), heart auscultation (S3), and lower extremity edema. JVP is an essential component, with a particular emphasis on the abdominojugular test (abdominal compression resulting in jugular venous distension), which correlates well with wedge pressure (not only occult right atrial pressures as previously thought).[12] Weight is another physical sign that reflects changes in body volume/fluids in the short term. In the long term, weight loss and cachexia are signs of advanced HF. In fact, obesity seems to have a "protective" effect in HF—hence the term "obesity paradox."

DIAGNOSTIC TESTS

The single most important test in HF is the echocardiogram. First, the echocardiogram provides us with the major distinction between HFrEF and HFpEF. Second, the echocardiogram allows for evaluation beyond LV function —including valvular disease (eg, mitral regurgitation, aortic stenosis), hemodynamics (estimation of pulmonary artery pressure, cardiac output), presence of thrombus, and RV function.

Natriuretic peptide measurement in HF is the equivalent of the troponin measurement in myocardial infarction. As mentioned earlier, the natriuretic peptide system is activated as part of the neurohormonal response in HF. BNP is released from the ventricles in response to increased wall stress, and reflects the degree of HF. During the late 1990s and early 2000s, the natriuretic peptides transformed from a basic science neurohormonal marker to a clinically relevant biomarker allowing for rapid diagnosis of dyspnea in the emergency room.[13] BNP is measured directly or as NT-pro-BNP, depending on the commercial kit used by the hospital biochemistry laboratory. In addition to ruling in or ruling out HF in patients with dyspnea, natriuretic peptides are also a useful marker of prognosis. Lastly, BNP may be used to guide therapy, suggesting that several measurements of BNP during the HF hospitalization are warranted.

The electrocardiogram (ECG) is a basic cardiac test and contributes in the diagnosis and management of HF. Although most patients with HF will have a pathologic ECG, it does not always provide specific information. However, the ECG can help support possible etiologies—such as low voltage in amyloidosis, Q waves with or without ST elevation in myocardial infarction, and LVH in patients with hypertension, hypertrophic cardiomyopathy or aortic stenosis. Left

bundle branch block (LBBB) is also important, because this is the main indication of biventricular pacing (cardiac resynchronization therapy). In addition, ECG findings are helpful in the diagnosis of hyperkalemia/hypokalemia, digoxin toxicity, and in the assessment of pacemaker function. Lastly, the ECG may demonstrate arrhythmias with important clinical implications. A common situation is the HF patient with atrial fibrillation, requiring the consideration of anticoagulation for the prevention of stroke and systemic thromboembolism.

The chest X-ray may demonstrate pulmonary congestion and an enlarged cardiac silhouette in patients with HF. In addition, the chest X-ray allows for further evaluation of other causes of dyspnea, such as lung disease, diaphragmatic paralysis, and pulmonary effusion.

MRI is a complex imaging modality that is currently used mainly for the diagnosis and risk stratification of infiltrative disorders (amyloidosis, hemochromatosis, and sarcoidosis), hypertrophic cardiomyopathy, myocarditis, and congenital heart disease. The MRI is useful in quantifying RV function (which is not always fully captured in the two-dimensional echo), presence of scar (late gadolinium enhancement), and LV chamber evaluation (non compaction, LVEF)

Cardiac catheterization is an essential part of evaluating HFrEF. Coronary artery disease is a common etiology of reduced LV systolic function. More importantly, revascularization (coronary artery bypass grafting, percutaneous coronary intervention) may significantly improve LV function and outcomes.[14] Therefore, coronary evaluation is mandated in most patients. In younger patients without significant coronary calcification, computed tomography (CT) angiography is a noninvasive alternative. Hemodynamic assessment via right heart catheterization is necessary in patients with borderline hemodynamics (precardiogenic shock, cardiogenic shock) and in candidates for ventricular assist device (VAD) or heart transplantation.

Cardiopulmonary exercise testing (CPET) offers a means of improved diagnosis (cardiogenic vs pulmonary vs other causes of dyspnea), as well as estimating prognosis. This test does not require the patient to reach a maximal HR because the anaerobic threshold is determined during the test itself. An important value to keep in mind is the VO_{2max} (peak oxygen consumption)—a value less than 14 mL/kg/min indicates a poor prognosis and a clear benefit from heart transplantation or left ventricular assist device (LVAD) rather than medical management.[15]

The 6-minute walk test is simpler and more readily available than the CPET. It provides useful prognostic information, although with limited accuracy and without the ability to differentiate between cardiac and noncardiac causes of exertional dyspnea and limitation.[16]

CLASSIFICATION OF HEART FAILURE

Patients with HF are typically categorized into two classification systems, in addition to the subgroups presented earlier.[4] The New York Heart Association (NYHA) functional classification allows semi-quantification of symptom severity. Class I patients have no symptoms, class II patients have symptoms during moderate to severe exertion, class III patients are symptomatic during mild to moderate exertion, and class IV patients are symptomatic at rest or with minimal exertion, including basic daily activities. The NYHA class serves as an important marker of prognosis and guides therapy accordingly.

A relatively recent classification scheme was introduced by the American College of Cardiology/American Heart Association (ACC/AHA), similar to the staging performed in oncology. Patients with stage A HF are only at risk for HF. These patients are asymptomatic; but if untreated, they might develop HF with time. Risk factors include hypertension, diabetes, and chemotherapy. Patients with stage B HF have already sustained a myocardial insult; however, they are still asymptomatic. Examples are patients post myocardial infarction, chemotherapy-induced cardiotoxicity with reduced LVEF. Stage C HF patients are the “typical” patients seen in clinical practice—symptomatic, requiring diuretics, angiotensin-converting enzyme inhibitors (ACEI), and beta-blockers. Stage D is an important distinction defining a subset of moribund patients who are repeatedly hospitalized and frequently inotrope dependent. These patients have a very limited prognosis, if not eligible for advanced HF therapy (LVAD, transplant). This recognition is also important to initiate proper palliative care.

HEART FAILURE TREATMENT

HF treatment requires several general measures, in addition to medical and device therapy. Sodium intake should be limited, because this is one of the major factors determining total body volume. However, recently the use of severe

sodium restriction has been criticized and even linked to excess mortality. Practically, patients should be informed of the following—do not add salt, do not add salt substitutes (which contain potassium and pose a risk of hyperkalemia when treated with ACEI and aldosterone antagonists), beware of sodium-rich foods (anything preserved in a can or box, pickles, deli, soy sauce, etc). Water restriction was also a common practice; however, the ability to excrete water is relatively independent from the sodium balance and total body volume. Therefore, this is mainly relevant in patients with problems of water balance—hyponatremia. In a recent study of patients hospitalized with acute decompensated HF, the use of an aggressive sodium and water restriction approach had no effect on outcome, except for increased perceived thirst in the water-restricted group.[17]

Alcohol and smoking should be avoided. Alcohol is directly toxic to the myocardium, especially when myocardial injury is already established. In addition to vasodilation, which lowers blood pressure along with the patient's vasodilating medications, alcohol may contribute to the occurrence of both atrial and ventricular arrhythmia. Obviously, alcohol cessation is especially important in alcoholic cardiomyopathy.

Smoking should also be discouraged for several reasons. First, this may improve the patient's lung function and dyspnea. Second, smoking is a major risk factor for coronary artery disease and may provoke subsequent myocardial infarctions. Lastly, owing to increased cancer risk and as a marker of poor compliance with medical advice, smoking is considered in most transplant centers a contraindication for heart transplantation.

Dietary modifications are required when the patient is obese, although the obesity paradox should be kept in mind. Excessive weight loss also might be harmful.

Physical activity should be encouraged, within the limitations of the patient's ability to perform exercise. This is where the role of a formal cardiac rehabilitation program is extremely important.

The patients should also be informed of hazardous medications—nonsteroidal anti-inflammatory drugs (NSAIDs). These are one of the most common causes for HF decompensation. NSAIDs disrupt renal function and interfere with the whole renin–angiotensin–aldosterone axis.

Medical therapy and device therapy are discussed in the following chapters.

Patient and Family Information for: HEART FAILURE WITH REDUCED EJECTION FRACTION

WHAT IS HEART FAILURE?

The heart is the organ responsible for pumping blood throughout the body, delivering oxygen and essential nutrients. This muscular pump is divided into the right and left sides. The right side of the heart receives blood without oxygen from the rest of the body and delivers the blood to the lungs. After the blood flows through the lungs and receives oxygen, it arrives at the left side of the heart. The left side of the heart is much more muscular, because it has to eject the blood (which now has oxygen) to the rest of the body—from head to toe, except for the lungs. The force of flow is powerful enough to generate a blood pressure, which is routinely measured.

HF is defined as a problem with the heart's ability to eject blood and/or fill with blood. Various diseases cause the heart to weaken as a muscular pump, thereby resulting in HF. The ability of the heart to contract and eject blood is measured by the term EF.

WHAT IS EJECTION FRACTION?

EF represents the percentage of blood flowing out of the heart during each contraction. The EF is never 100%, because the heart cannot contract, totally empty out all of its contents, and then refill. Actually, the heart is usually half filled even at the end of its contraction. Therefore, the normal EF is 55% to 60%. An EF below 50% is considered abnormal. When the EF is reduced below 30%

to 35%, the heart's pumping action is considered severely reduced. HF can also occur with a "normal" EF—the heart can eject blood properly, but has trouble filling. A common cause of this situation is hypertension. After years of the heart trying to pump out blood against a high blood pressure, the heart muscle thickens (similar to the enlargement of muscles after lifting weights). The thickened heart muscle requires a much higher pressure to fill (think of trying to fill a balloon vs filling a tire). These high pressures cause the blood to go back to the lungs and fill with fluid, ending up with shortness of breath. The causes and treatment of HF differ according to EF—HFrEF and HFpEF. However, many of the symptoms and signs of HF are the same.

CAUSES OF HEART FAILURE

HF is the result of several diseases affecting the heart as a pump. Usually problems with the heart muscle cause HF. However, the heart as a pump also has valves and an encasement (pericardium). Therefore, diseases of the heart valves (aortic stenosis, aortic regurgitation, mitral stenosis, and mitral regurgitation) and pericardium (constrictive pericarditis) also result in HF.

Common diseases affecting the heart muscle include the following:

Coronary artery disease—Blockages in the heart's blood supply, previous "heart attacks."

Hypertension or high blood pressure—The EF is usually preserved in this situation.

Alcohol—The heart muscle can recover once alcohol intake is stopped.

Drugs—Cocaine, amphetamines; may result in irreversible damage.

Chemotherapy—There are several chemotherapies that are toxic to the heart muscle. Common examples include doxorubicin (Adriamycin) given for lymphoma and, sometimes, for breast cancer, and trastuzumab (Herceptin) given for breast cancer.

Familial/genetic heart disease—This may be a disease limited to the heart muscle, causing weakness and impaired contraction—dilated cardiomyopathy. Sometimes this is part of a general muscular disease (as in Duchenne muscular dystrophy).

Infection—Viruses can cause myocarditis, resulting in heart damage.

Congenital heart disease—These are complex diseases. HF is a problem even

after palliative or corrective surgery.

Peripartum—This rare form of HF can present following pregnancy.

SYMPTOMS AND SIGNS OF HFrEF

Shortness of breath—dyspnea—is a common symptom of HF and may appear in several forms. Shortness of breath occurs because of the increased pressure in the heart muscle, causing a backward flow of blood toward the lungs. The lungs then fill with fluid, resulting in breathing difficulty. Shortness of breath is worsened during exercise—the heart cannot keep up with the increased need for blood flow, and more blood remains in the lungs.

Dyspnea may also occur when lying down—during the day, gravity helps pull blood away from the heart (standing and walking). When lying down, this effect is neutralized. This is known as orthopnea. Patients with severe HF will complain of sleeping upright in a chair during the night.

Bendopnea is a similar symptom—shortness of breath while bending over. Many patients with advanced HF will have trouble tying their shoe laces or picking up objects. This is also due to the blood flow to the heart being affected by gravity.

Shortness of breath during the night—PND. In this situation, the patient awakens at night with shortness of breath, sometimes even wheezing.

"Cardiac asthma"—sometimes the fluid in the lungs can cause wheezing, mimicking the sounds heard during an asthma attack. Many times, HF episodes (especially before diagnosis) can be mistaken for bronchitis, chronic obstructive pulmonary disease exacerbation, or an asthma attack.

Peripheral edema/swelling—fluid can accumulate in the rest of the body, not only in the lungs. This commonly occurs in the legs, due to gravity.

Abdominal pain—accumulation of fluid in the liver and gut area causes abdominal pain, abdominal swelling, and loss of appetite.

Weight gain—this can be due to fluid accumulation.

Weight loss can occur in patients with very advanced HF—because of increased energy requirements by the failing heart and changes in body metabolism.

DIAGNOSTIC TESTS

There is no single test for the diagnosis of HF. Several tests are required:

Echocardiogram—ultrasound of the heart. The single most important test in HF is the echocardiogram. First, the echocardiogram provides us with the EF—the major distinction between HFrEF and HFpEF. Again, this is important because the medical treatment for HFrEF is different from the treatment for HFpEF. Second, the echocardiogram allows for evaluation beyond the percentage of heart muscle contraction—including valves, the heart's encasement (pericardium), and other important measures of heart function (right-sided function, flow in the right and left sides, estimation of filling pressures, and muscle thickness).

BNP—This is a blood test. In response to increased pressures inside the heart, the heart secretes a hormone named BNP. This hormone is measurable and can help diagnose HF. In addition to diagnosis, BNP can also provide a rough measure of the extent of HF—in patients with congestion and fluid retention, the BNP levels are high. Once the HF is treated and congestion is relieved (compensated HF), BNP levels can return to lower values. Therefore, in addition to HF diagnosis and assessment of severity, BNP may help guide therapy.

The ECG is a basic cardiac test demonstrating the electrical activation of the heart. The ECG is helpful in HF, because it can hint at possible causes and also direct medical decisions. For example, the ECG can demonstrate previous heart attacks. The ECG may also demonstrate a conduction problem known as LBBB. When this occurs in the setting of HFrEF, a biventricular pacemaker, which can synchronize the heart's contraction between the right and left sides, should be considered. In patients who already have a pacemaker, the ECG can help determine pacemaker function. Lastly, the ECG may demonstrate heart rhythm disturbances, which are not always felt by the patient.

The chest X-ray is also a basic test—in HF it can demonstrate fluid in the lungs and an enlarged heart. More importantly, it can help the physician look for other causes of shortness of breath, such as pneumonia or lung disease.

MRI—In this test, use of a powerful magnet and the detection of energy waves released by provoked hydrogen atoms generate a high-resolution picture of the heart tissue. Advances in computer technology and quick processing of images allow evaluation of serial images and heart function. The advantage over echo/ultrasound technology is that MRI is not angle dependent. MRI can also characterize tissues and detect abnormalities not "seen" by echo. However, MRI is expensive, not always widely available, and requires time. In addition, the examination takes place within a tube, which might pose a problem in patients

with claustrophobia. Lastly, metal objects are problematic because of the strong magnetic field. Therefore, only patients with MRI-safe pacemakers and without metal implants (orthopedic) are candidates for MRI.

Cardiac catheterization—this is usually an essential part of evaluating HFrEF. Coronary artery disease and heart attacks are a common cause of reduced heart function. More importantly, revascularization and opening of the blockages may improve heart function and outcomes. Therefore, coronary catheterization is mandated in most patients with reduced heart function. In younger patients, CT angiography is a noninvasive alternative. Direct measurement of pressures using a catheter inserted into the neck or groin veins is necessary in patients with advanced HF to determine medical therapy and plan for VAD or heart transplantation.

CPET is a test where the patient performs exercise (either on a bike or a treadmill) with a specialized mask measuring oxygen and carbon dioxide coming in and out of the lungs. This test does not require the patient to reach a maximal HR. The CPET offers a means of improved diagnosis whether the shortness of breath originates from HF, lung disease, muscle weakness, or a combination of problems. It is an objective test. One of the measurements is the peak oxygen consumption—a value less than 14 mL/kg/min indicates a clear benefit from heart transplantation or LVAD rather than medical management.

The 6-minute walk test is simpler and more readily available then the CPET. The patient is asked to walk for 6 minutes and the distance is measured. This test also provides useful information concerning the timing of heart transplantation or LVAD. However, it has limited accuracy and does not have the ability to differentiate between HF and other causes of shortness of breath.

CLASSIFICATION OF HEART FAILURE

Patients with HF are typically categorized into two classification systems.

The NYHA functional classification: NYHA class I patients have no symptoms, NYHA class II patients have symptoms during moderate to severe exercise, NYHA class III patients are symptomatic during mild to moderate activities, and class IV patients are symptomatic at rest or with minimal activities, including basic daily activities (bathing, toilet, etc).

A similar but different classification scheme was introduced by the ACC and AHA.

Patients with stage A HF are only at risk for HF. These patients are asymptomatic, but if untreated, they might develop HF with time. Risk factors include hypertension, diabetes, and chemotherapy. Patients with stage B HF have already sustained an injury to their heart muscle; however, they are still asymptomatic. Examples are patients after a heart attack, or patients after chemotherapy with a reduced EF. Stage C HF patients are the “typical” patients—symptomatic, requiring standard medical treatment with diuretics, ACE inhibitors, and beta-blockers. Stage D is an important distinction defining a subset of patients who are repeatedly hospitalized or cannot be discharged from the hospital. These patients are very sick—if they are not eligible for advanced HF therapy (LVAD, transplant), palliative care should be initiated. In addition to the importance of determining stage D, patients who feel well and are in stage A or B also deserve special attention—despite feeling well, they should receive medications to *prevent* future HF.

HEART FAILURE TREATMENT

HF treatment requires several general measures, in addition to medical and device therapy.

Salt—Sodium intake should be limited, because this is one of the major factors determining the amount of total body fluids. The basic rules: Do not add salt. Do not add salt substitutes (which contain potassium—this is usually a problem with the medications given in HF). Beware of sodium-rich foods (anything preserved in a can or box, pickles, deli, soy sauce, etc).

Water restriction was also a common practice; however, the ability to get rid of water is relatively independent from the ability to get rid of sodium. Therefore, this is mainly relevant in patients with problems in water balance—hyponatremia. In a recent study of patients hospitalized with acute HF, the use of an aggressive sodium and water restriction approach had no effect, except for increased perceived thirst in the water-restricted group.

Alcohol and smoking should be avoided. Alcohol is directly toxic to the heart, especially when injury to the heart muscle is already established. In addition, alcohol may lower blood pressure, which may be low anyway because of HF medications. Lastly, alcohol may contribute to the occurrence of electrical heart disturbances—arrhythmia. Obviously, alcohol cessation is especially important in HF resulting from alcoholism.

Smoking should also be discouraged for several reasons. First, this may improve the patient's lung function and decrease the sensation of shortness of breath. Second, smoking is a major risk factor for coronary artery disease and may provoke subsequent heart attacks. Lastly, owing to increased cancer risk and as a marker of poor compliance with medical advice, smoking is considered in most transplant centers a contraindication for heart transplantation.

Dietary modifications are required when the patient is obese. However, excessive weight loss also might be harmful.

Physical activity should be encouraged, within the limitations of the patient's ability to perform exercise. This is where the role of a formal cardiac rehabilitation program is extremely important.

Patients should also be informed of hazardous medications—NSAIDs. These medications (Advil, ibuprofen, naproxen) disrupt renal function and interfere with hormonal activation in HF. NSAIDs are a common cause of HF deterioration.

Medical therapy and device therapy are discussed elsewhere.

Heart Failure with Preserved Ejection Fraction

INTRODUCTION

Heart failure with preserved ejection fraction (HFpEF) is a clinical syndrome characterized by the impaired ability of the heart to meet the metabolic needs of the body, resulting in breathlessness, fatigue, and/or fluid retention. HFpEF is defined by the left ventricular ejection fraction (LVEF) ≥ 50%. Patients with LVEF <40% are defined as having heart failure with reduced ejection fraction (HFrEF). The subgroup of patients in the borderline range (LVEF 40% to 49%) is termed borderline, intermediate, or as having heart failure with mid-range LVEF with characteristics and treatment patterns that need further research.[1]

Historically, diastolic heart failure has been the term used synonymously with HFpEF; but, currently, with new insights into the pathophysiology of the disease, diastolic dysfunction is thought to be one of the several factors contributing to the development of HFpEF and it is not necessarily the only component of the syndrome.

EPIDEMIOLOGY

Heart failure is a major source of morbidity and mortality in the United States with the estimated prevalence of 5.7 million cases, and nearly half of these cases are patients with HFpEF.[2] It has been projected that the prevalence of heart failure will increase by 46% by 2030.[3] The prevalence increases dramatically with age, and it is more common in women than in men at any age. The mortality rates are grossly similar in patients with HFrEF and HFpEF, with recent data showing some improvement in survival for patients with HFrEF.[4] This has been attributed to the use of guideline-directed medical therapies. However, no such evidence-based treatment strategies exist for HFpEF. Therefore, the development of medical and device therapies for HFpEF is a major unmet medical need.

PATHOPHYSIOLOGY

The pathophysiology of HFpEF is complex and is the subject of active ongoing research. It is postulated that HFpEF is a heterogeneous syndrome to which various mechanisms contribute. These mechanisms can contribute to various degrees in each individual patient and can be divided into the following categories:

1. Cardiac abnormalities
    a. Diastolic dysfunction
    b. Systolic dysfunction
    c. Atrial fibrillation and atrial dysfunction
    d. Pulmonary hypertension and right ventricular dysfunction
    e. Chronotropic incompetence
2. Vascular abnormalities and impaired ventricular–vascular coupling
3. Extra cardiac abnormalities
4. Cardiovascular aging

CARDIAC ABNORMALITIES

Diastolic Dysfunction

In a normal person, diastole is the summation of an active process of relaxation related to calcium reuptake and myofilament dissociation and passive stretching resulting from mechanical properties of the sarcomere and extracellular matrix at

the molecular level and the chamber and pericardium at the organ level. During the isovolumic relaxation phase of the cardiac cycle, the left ventricle relaxes and creates a sucking force that helps the ventricle fill up during diastole when the mitral valve opens. Many studies indicate that in HFpEF the rate of ventricular relaxation during isovolumic relaxation is decreased. Also, diastolic dysfunction is associated with reduced left ventricular compliance.[5] As a result, the left ventricle can only accommodate volumes similar to the normal heart at higher filling pressures. Also, due to impaired relaxation properties and chamber stiffening, patients with HFpEF poorly tolerate increased heart rates as seen with exercise and atrial fibrillation.

Systolic Dysfunction

The systolic function of the heart is commonly measured by LVEF, but LVEF does not reflect all aspects of the left ventricular systolic performance. The left ventricular systolic function is complex and can be fully evaluated using advanced echocardiographic techniques such as speckle tracking echocardiography. Several studies have demonstrated markedly impaired longitudinal systolic function in patients with HFpEF despite preserved LVEF. Further studies will help subdivide the HFpEF syndrome based on the different aspects of the left ventricular systolic performance beyond the LVEF assessment.

Atrial Dysfunction

The left atrium contributes to about 20% of cardiac output in a normal individual, and this number has been shown to be up to 45% in patients with diastolic dysfunction because the left ventricular filling depends on the ability of the left atrium to push blood at higher pressures.[6] Left atrial dysfunction is common in patients with HFpEF as measured by advanced echocardiographic techniques and may contribute to transition from asymptomatic diastolic dysfunction to symptomatic heart failure.

Atrial fibrillation is common in patients with HFpEF. It is poorly tolerated in these patients and can precipitate acute decompensated heart failure.

Pulmonary Hypertension and Right Ventricular Dysfunction

Pulmonary hypertension is common in patients with HFpEF and is associated with worse prognosis. Elevated left atrial pressure leads to elevated pulmonary pressures and then chronic elevation in the left atrial pressure causes pulmonary

arteriolar and venous remodeling, resulting in increased pulmonary vascular resistance. Right ventricular dysfunction can result from pulmonary hypertension and/or can be a part of the disease process independent of the elevated pulmonary pressures.

Chronotropic Incompetence

Studies have shown a blunted heart rate response to exercise and prolonged post-exercise heart rate recovery in patients with HFpEF.[7, 8] These findings may contribute to the symptoms and they have also been linked to worse prognosis.[9]

VASCULAR ABNORMALITIES

Vascular remodeling is a part of aging, but it is greatly amplified by cardiovascular risk factors such as diabetes mellitus and hypertension. Vascular stiffening results in impaired ability to accommodate an increased systemic load during stress and exercise. Vascular remodeling is a part of the same systemic process that affects the diastolic properties of the left ventricle. As a result, the ability of the cardiovascular system to function efficiently under various loading conditions and maintain low filling pressures is compromised because of impaired ventricular–vascular coupling.

EXTRA CARDIAC FACTORS

A range of extra cardiac contributing factors have been implicated in the pathogenesis of HFpEF. These include anemia, pulmonary disease, renal disease, and obesity. Obesity and metabolic syndrome are especially important because of the high prevalence in the general population; also, weight loss may improve diastolic properties of the left ventricle.

CARDIOVASCULAR AGING

HFpEF is predominantly a disease of the elderly that emphasizes the importance of age-related cardiovascular changes in the disease pathogenesis. Aging leads to a wide range of changes within the cardiovascular system, including alteration in the left ventricular diastolic function and vascular stiffening. Aging does not invariably result in heart failure, but age-related changes are greatly amplified by cardiovascular risk factors and disease states (such as atherosclerosis) and contribute to the development of the HFpEF phenotype.

CLINICAL FEATURES

The clinical presentation of HFpEF can be variable: patients can present with mild symptoms of exercise intolerance and tiredness or be admitted with acute pulmonary edema if an immediate precipitating factor (such as atrial fibrillation or uncontrolled hypertension) is present. The range of symptoms is similar to HFrEF and includes dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, peripheral edema, and weight gain. As with HFrEF, it is important to characterize and quantify the functional status in a standardized way such as the New York Heart Association functional classification **(Table 12.1)**.

TABLE 12.1 New York Heart Association Functional Classification for Cardiac Diseases

I	Patients have cardiac disease without limitation of physical activity. Ordinary physical activity does not cause symptoms such as fatigue, palpitation, dyspnea, or chest pain
II	Patients have cardiac disease resulting in slight limitation of physical activity. Ordinary physical activity results in fatigue, palpitation, dyspnea, or chest pain
III	Patients have cardiac disease resulting in marked limitation of physical activity. Less than ordinary activity causes fatigue, palpitation, dyspnea, or chest pain
IV	Patients have cardiac disease resulting in symptoms at rest, and physical activity causes further discomfort

Physical examination can demonstrate signs of fluid overload such as elevated jugular venous pressure, lung rales, hepatomegaly and hepatojugular reflux, ascites, and peripheral edema. The lateral displacement of the apical impulse and the third heart sound usually point toward HFrEF.

Besides the symptoms and signs of heart failure, the history and physical examination should also be directed toward identifying the risk factors that can lead to the development of HFpEF such as hypertension, coronary artery disease, obesity, and diabetes mellitus. In cases of acute decompensated heart failure, the precipitating factors should be explored; these include medication noncompliance, poorly controlled hypertension, arrhythmia, and thyroid disease.

DIAGNOSIS

Diagnosis of HFpEF is not always straightforward. The following components

should be considered in patients suspected to have HFpEF:[1, 10]

1. Symptoms consistent with heart failure diagnosis
2. Presence of physical signs of heart failure, mostly evidence of fluid overload
3. Preserved LVEF (≥50%)
4. Elevated natriuretic peptide levels
5. Evidence of structural or functional alterations underlying heart failure as assessed by echocardiography

Natriuretic peptide levels are elevated in patients with HFpEF, but they are on average lower than the levels seen in patients with HFrEF. The structural alterations commonly observed in patients with HFpEF include left atrial enlargement and left ventricular hypertrophy; the functional alterations include decreased annular tissue velocities, elevated *E/e′* ratio, and pulmonary hypertension. Advanced echocardiographic assessment may demonstrate impaired longitudinal left ventricular systolic function. If the diagnosis remains uncertain after initial testing, invasive hemodynamic evaluation may be helpful. Elevated left ventricular filling pressures at rest support the diagnosis of HFpEF; however, many individuals demonstrate hemodynamic compromise only with stress. In these patients, hemodynamic measurements during exercise can be performed using either echocardiography (diastolic stress test) or uncommonly invasive hemodynamic testing.

A 12-lead electrocardiogram (ECG) should be performed initially on all patients presenting with heart failure. Initial laboratory evaluation of patients presenting with heart failure should include complete blood count, comprehensive metabolic panel, hemoglobin A1c, fasting lipid profile, urinalysis, ferritin and transferrin saturation, and thyroid-stimulating hormone. Serial monitoring, when indicated, should include serum electrolytes and renal function. Echocardiogram is the cornerstone of patient evaluation, as described earlier.

Further testing should be tailored to the clinical scenario and may identify specific causes, risk factors, or precipitating factors for HFpEF phenotype. These include coronary artery disease, systemic diseases (such as sarcoidosis), infiltrative disorders (such as amyloidosis), and so on. Also, further testing may be necessary to exclude other conditions presenting with a similar phenotype such as hypertrophic cardiomyopathy and constrictive pericarditis.

MANAGEMENT

There are no consistently proven treatment strategies that would reduce mortality in patients with HFpEF. The basics of management revolve around symptomatic treatment of volume overload with diuretics, control of hypertension, and treatment of risk factors such as atrial fibrillation, coronary artery disease, and diabetes mellitus.

DIURETICS

One of the main goals of HFpEF therapy is to achieve euvolemia by judicious use of diuretics. Diuretic treatment provides a symptomatic benefit similar to that in patients with HFrEF.

DRUGS AFFECTING RENIN-ANGIOTENSIN SYSTEM

Among the various drug therapies tested in HFpEF, several trials have targeted the renin–angiotensin system, but they have largely failed to show any significant mortality benefit. The trials specifically studied an angiotensin-converting enzyme inhibitor perindopril and angiotensin receptor antagonists candesartan and irbesartan. The summary of various trials is shown in **Table 12.2**.[11–13]

TABLE 12.2 Summary of Randomized Controlled Trials with Various Pharmacologic Agents in Patients with HFpEF

	PEP-CHF	CHARM-PRESERVED	I-PRESERVE	TOPCAT	RELAX
Patients, number	850	3023	4128	3445	216
Drug	Perindopril	Candesartan	Irbesartan	Spironolactone	Sildenafil
Mean follow up (years)	2.1	3	4.1	3.3	24 weeks
Primary end point	All-cause death/HF hospitalization	CV death/HF hospitalization	All-cause death/CV hospitalization	CV death/aborted cardiac arrest/HF hospitalization	Change in peak O_2 consumption, median
Hazard	0.92 (0.70–	0.89 (0.77–	0.95 (0.86–	0.89 (0.77–1.04)	−0.2 (IQR,−1.7–

ratio	1.21)	1.03)	1.05)		1.11)
P value	0.54	0.12	0.35	0.14	0.9

CV, cardiovascular; HF, heart failure; HFpEF, heart failure with preserved ejection fraction.

It is now clear that HFpEF is a heterogeneous disease with variable contribution by different pathophysiologic components; and the trials that studied renin–angiotensin system antagonists applied broad criteria for patient selection and did not target any specific pathophysiologic component. Currently, the use of these agents is necessary for hypertension control and diabetes management, but there is no convincing evidence to support their role as disease-modifying agents for HFpEF. Use of a neprilysin inhibitor in combination with an angiotensin receptor blocker is being studied now in the HFpEF phenotype.

ALDOSTERONE ANTAGONISTS

The mineralocorticoid receptor antagonist spironolactone has been studied in a large randomized controlled trial in HFpEF (TOPCAT). The study showed no significant reduction in the composite primary end point of cardiovascular death, hospitalization for heart failure, or aborted cardiac death as compared with placebo. From the components of the primary outcome, spironolactone did show benefit in reducing hospitalizations (P = 0.04). As the pathophysiologic components of HFpEF phenotype are further refined, it is possible that certain subgroups of patients with HFpEF may benefit from an aldosterone antagonist.

PHOSPHODIESTERASE 5 INHIBITORS

Early animal study data showed improvement in ventricular structure and function with the use of sildenafil in pressure overload hypertrophy. However, when sildenafil was tested in a clinical trial of 216 patients with HFpEF, no significant benefits regarding exercise capacity, clinical status, or quality of life were noted with the follow-up period of 24 weeks.[14]

β-BLOCKERS

There are limited data on the use of β-blockers in patients with HFpEF. The potential theoretical advantage of using β-blockers in HFpEF comes from the possibility of prolonging the diastolic period because of the negative

chronotropic effect of β-blockers. However, there is significant prevalence of chronotropic incompetence in patients with HFpEF that offsets the potential benefit of β-blockers. Limited data comes from registries like the Organized Program to Initiate Life-saving Treatment in Hospitalized Patients with Heart Failure (OPTIMIZE-HF).[15] The study evaluated 7154 hospitalized patients and showed that β-blockers had no effect on 1-year mortality and hospitalization rates in patients with HFpEF but significantly improved both end points in the HFrEF group.

CONTROL OF HYPERTENSION AND OTHER CONTRIBUTING FACTORS

Hypertension is an important factor in the development of HFpEF and precedes the development of HFpEF in the majority of the cases. Early blood pressure treatment is the most important intervention that could possibly prevent the progression of hypertensive heart disease to symptomatic HFpEF. The choice of drugs should follow the common practices for hypertension control unless compelling indications are present for specific drug use (eg, rate control of atrial fibrillation with a β-blocker). Other contributing factors that should be addressed in the treatment strategy include anti-ischemic therapies in patients with coronary artery disease, proper diabetes control, and so on.

ROLE OF EXERCISE

Exercise training in HFpEF has shown benefit in improving exercise tolerance and managing obesity. The HF-ACTION trial focusing on patients with HFrEF showed that exercise had a modest reduction for both all-cause mortality and rehospitalization. In one meta-analysis, exercise training was associated with an improvement in cardiorespiratory fitness and quality of life.[16]

CONCLUSIONS

In the past decade there have been several advances in the management of HFrEF, but no breakthrough treatment discoveries have been made for HFpEF. The efforts to understand the pathophysiology of HFpEF have broadened our

understanding of this phenotype from a disorder of diastolic function to a complex interplay of multiple abnormalities. Despite these advances, there is still a need to standardize the diagnostic criteria and better characterize the disease processes based on specific pathophysiologic features rather than LVEF alone. Future therapies targeting these pathophysiologic mechanisms may provide better clinical outcomes.

Patient and Family Information for: HEART FAILURE WITH PRESERVED EJECTION FRACTION

DESCRIPTION AND CAUSES

Heart failure with preserved ejection fraction, also known as HFpEF, is a disease of the heart caused by increased stiffness of the heart and blood vessels and inability of the heart to relax properly. As a result, the heart function does not meet the demands of the body even though the pumping function of the heart (measured as “ejection fraction”) is preserved. Impaired heart function can cause fluid accumulation in the lungs and other organs of the body. Patients commonly feel shortness of breath and fatigue with exertion as initial symptoms. As the disease progresses, shortness of breath can develop at rest, commonly with inability to sleep lying flat. Patients can also notice swelling of the ankles and stomach discomfort due to fluid accumulation in the abdomen.

The exact cause of the disease is not quite clear, but several health problems are known to contribute to the development of HFpEF. Hypertension (high blood pressure) is considered the main one. High blood pressure over time causes abnormal thickening of the heart muscle and increased stiffness of blood vessels: these are the major contributors to HFpEF. Some patients have coexisting obesity and diabetes. Coronary artery disease (blockage of the arteries supplying blood to the heart) is seen in some patients and it can also precipitate HFpEF. Abnormal heart beats, most typically atrial fibrillation, commonly coexists with HFpEF and can contribute to inefficient pumping of the heart.

HFpEF is known as the disease of the elderly. The heart muscle and blood vessels become stiff as people age; therefore, aging increases the chances of developing HFpEF. Also, women are twice more likely to develop HFpEF as

compared to men. The reason for this is not fully understood.

ASSESSMENT AND TESTING

The physician establishes the diagnosis of HFpEF by taking history (asking questions about the patient's symptoms), performing physical examination, and ordering appropriate tests. Besides confirming the diagnosis, the physician needs to determine the underlying structural heart disease that causes heart failure and its contributing factors so that it can be effectively treated. Blood tests are commonly done, and ECG and chest X-ray are also typically performed. Ultrasound examination of the heart (also known as echocardiogram) helps visualize cardiac chambers, and it is the most commonly used tool to evaluate the structure and function of the heart. Other tests are performed as deemed necessary by the physician. Cardiac catheterization is an invasive test that includes placing catheters into the heart chambers and major vessels to diagnose vessel blockage or get important pressure readings from various heart chambers. It is also used for interventions if vessel blockage seems to be causing the patient's symptoms.

TREATMENT

Treatment of HFpEF is challenging because there are no proven therapies that can change the natural cause of the disease. Therefore, therapies are focused on symptom relief and modification of risk factors for this condition. Diuretics (also known as water pills) are of great benefit because they remove excess fluid from the lungs and other organs of the body. They help decrease shortness of breath and leg swelling. Blood pressure medications are also important because hypertension has been identified as a major risk factor for developing HFpEF. The blood pressure control is individualized by the physician based on patient's age and coexisting medical conditions. The patient needs to follow closely with the physician because blood pressure control can be challenging and may involve multiple adjustments of medication types and dosages. Lifestyle modifications should be a routine part of patient management in HFpEF. Exercise training has shown to improve the exercise capacity and quality of life in patients with HFpEF. The physician may recommend a cardiac rehabilitation

program with dynamic exercise training.

Salt restriction is recommended in patients who have symptoms of heart failure or have high blood pressure because excess salt can cause fluid buildup in the body.

The patient’s weight should be monitored routinely because weight gain may be the early sign of excess fluid in the body. Patients should avoid smoking because it increases the chances of heart attack and can worsen heart failure. Alcohol is one of the important contributors to high blood pressure and its use should be restricted in any patient with heart disease.

Mechanical Complications of Myocardial Infarction

Mechanical complications of acute myocardial infarction (AMI) result in some of the deadliest cardiovascular outcomes. It is difficult to assess the true incidence of these complications because both clinical and autopsy series differ considerably. Nevertheless, they are thought to be responsible for about 15% of all AMI deaths.[1] It is important to realize that these catastrophic events can occur within minutes to hours of the inciting event, or even days to weeks later. Mechanical complications of AMIs can be divided into two major categories: acute phase complications and chronic phase complications. **Table 13.1** outlines these complications.

TABLE 13.1 Acute Phase Versus Chronic Phase Complications in Acute Myocardial Infarction

ACUTE PHASE	CHRONIC PHASE
Left ventricular free wall rupture	True ventricular aneurysm
Ventricular septal rupture	Ventricular pseudoaneurysm
Right ventricular infarction	Left ventricular thrombus
Acute mitral regurgitation	

LEFT VENTRICULAR FREE WALL RUPTURE

Left ventricular free wall rupture (LVFWR) is almost an entirely fatal complication of myocardial infarction (MI). Despite great progress in the reduction of both mortality and morbidity from AMI, death related to LVFWR has been high.

Among patients who die after an AMI, many large studies have found a 14% to 26% incidence of cardiac rupture.[2] According to the National Registry of Myocardial Infarction, which reviewed data from 350,755 patients with AMI, the incidence of cardiac rupture was <1%.[3] Approximately 50% of the time, myocardial rupture occurs within the first 5 days of MI and within 2 weeks in over 90% of cases.[4, 5] Regardless, acute or subacute myocardial rupture is a serious and predominantly fatal complication of AMI.[6]

Studies have also suggested a higher mortality from free wall rupture with thrombolytics because cardiac rupture was responsible for 7.3% of all deaths and 12.1% with thrombolytic agents. Thrombolytic therapy does not necessarily increase the risk of rupture but it may accelerate occurrence, often within the first 24 hours of drug administration.[7] In contrast, the incidence of cardiac rupture may be lower in patients treated with percutaneous coronary intervention. This was suggested in an observational study of 1375 patients who received a thrombolytic agent or underwent primary angioplasty, the incidence of rupture was 3.3% and 1.8% respectively.[8] It is well known that myocardial rupture after MI is less common in patients with successful reperfusion.[9]

One study found that myocardial rupture was 9.2 times more likely to occur in patients who had no prior history of angina or MI, ST-segment elevation or Q-wave development on the initial electrocardiogram (ECG), and peak MB-creatine kinase above 150 IU/L.[4] Absence of collateral blood flow and greater size of infarct territory correlate with a higher risk of myocardial rupture. Other risk factors for rupture include anterior location of the infarction, age >70, and female sex.[8, 10]

PATHOPHYSIOLOGY

Myocardial rupture more frequently involves the left ventricle than the right ventricle, and rarely involves the atria.[3] The infarct commonly affects the

anterior and lateral walls of the left ventricle near the junction of the infarct and normal myocardium. Ventricular free wall rupture is defined as an acute, traumatic perforation of the ventricles, which may include pericardial rupture.[6] With unsuccessful or no reperfusion, coagulation necrosis develops within the first 3 to 5 days.[5] As the necrosis progresses, neutrophils infiltrate the myocardial space and release lytic enzymes that disintegrate the necrotic myocardium leading to perforation. The rupture thus is a result of transmural infarction and the actual perforation can range in size from millimeters to centimeters depending on infarct size.[5] Early phase rupture is defined as within 72 hours post MI and late rupture is greater than 4 days.

The hallmark of rapid deterioration is primarily due to the extravasation of blood into the pericardial space with resultant instantaneous, acute pericardial tamponade. Because these events occur so quickly, the condition of patients usually deteriorates before any therapeutic intervention. Less commonly, subacute rupture can provide a longer therapeutic window because the rupture may be temporarily contained by pericardial adhesions or by thrombosis at the rupture site. It is in these patients that immediate, life-saving, cardiovascular surgery is possible **(Figure 13.1)**.[11]

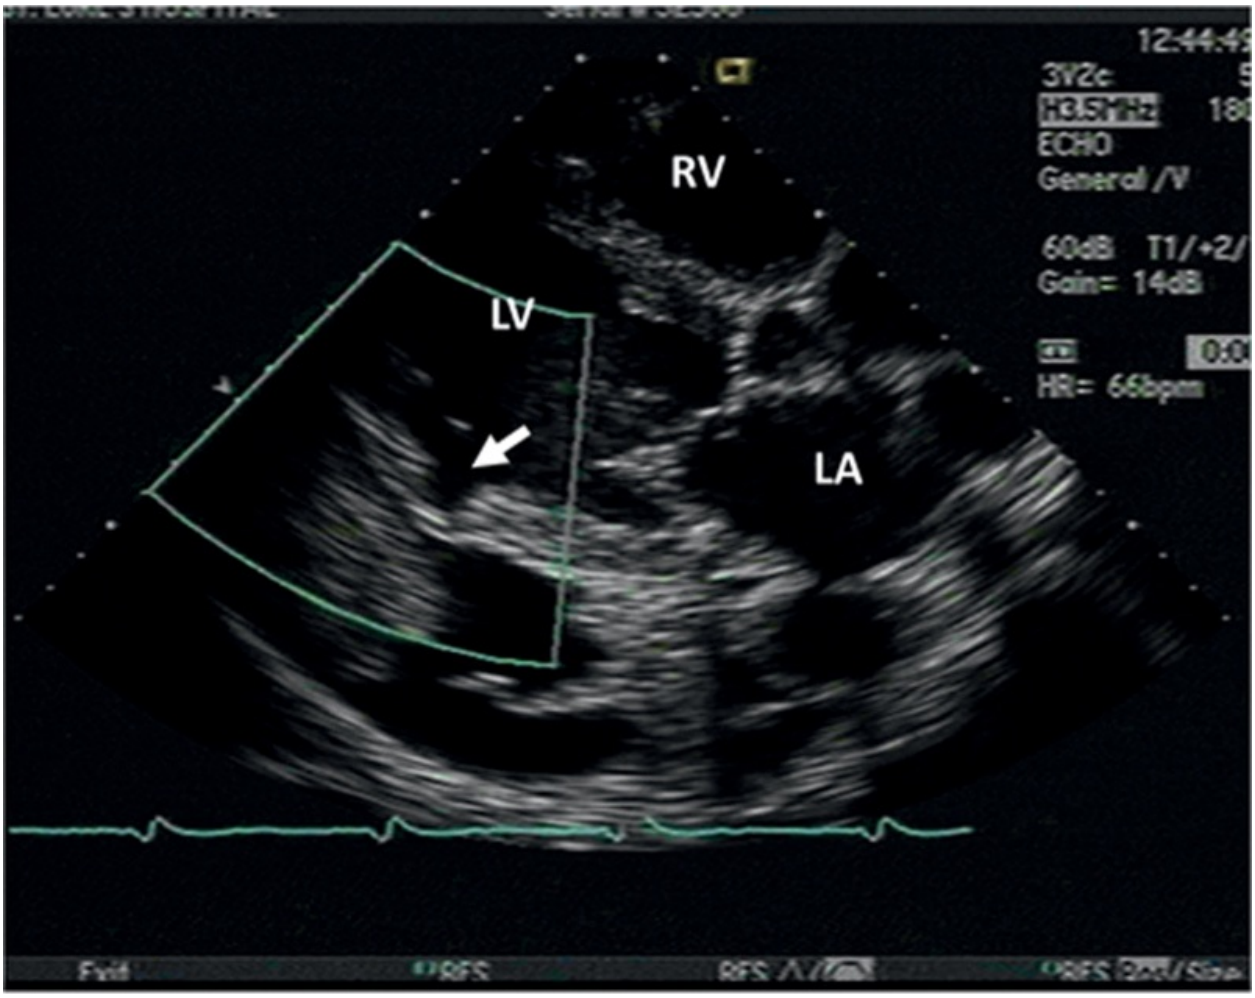

FIGURE 13.1 Parasternal long-axis view of a transthoracic echocardiogram demonstrating a posterior free wall rupture (*arrow*). LA, left atrium; LV, left ventricle; RV, right ventricle.

CLINICAL PRESENTATION

The clinical course of myocardial rupture is variable and challenging to diagnose, because patients may rapidly decompensate. Their clinical course parallels that of any patient suffering from pericardial tamponade. Thus, the presentation of rupture can vary from sudden death in an undetected or silent MI to incomplete/subacute rupture in those with known MI.[12] **Figure 13.2** demonstrates a case of LVFWR causing pericardial tamponade with thrombus formation in the pericardial space.

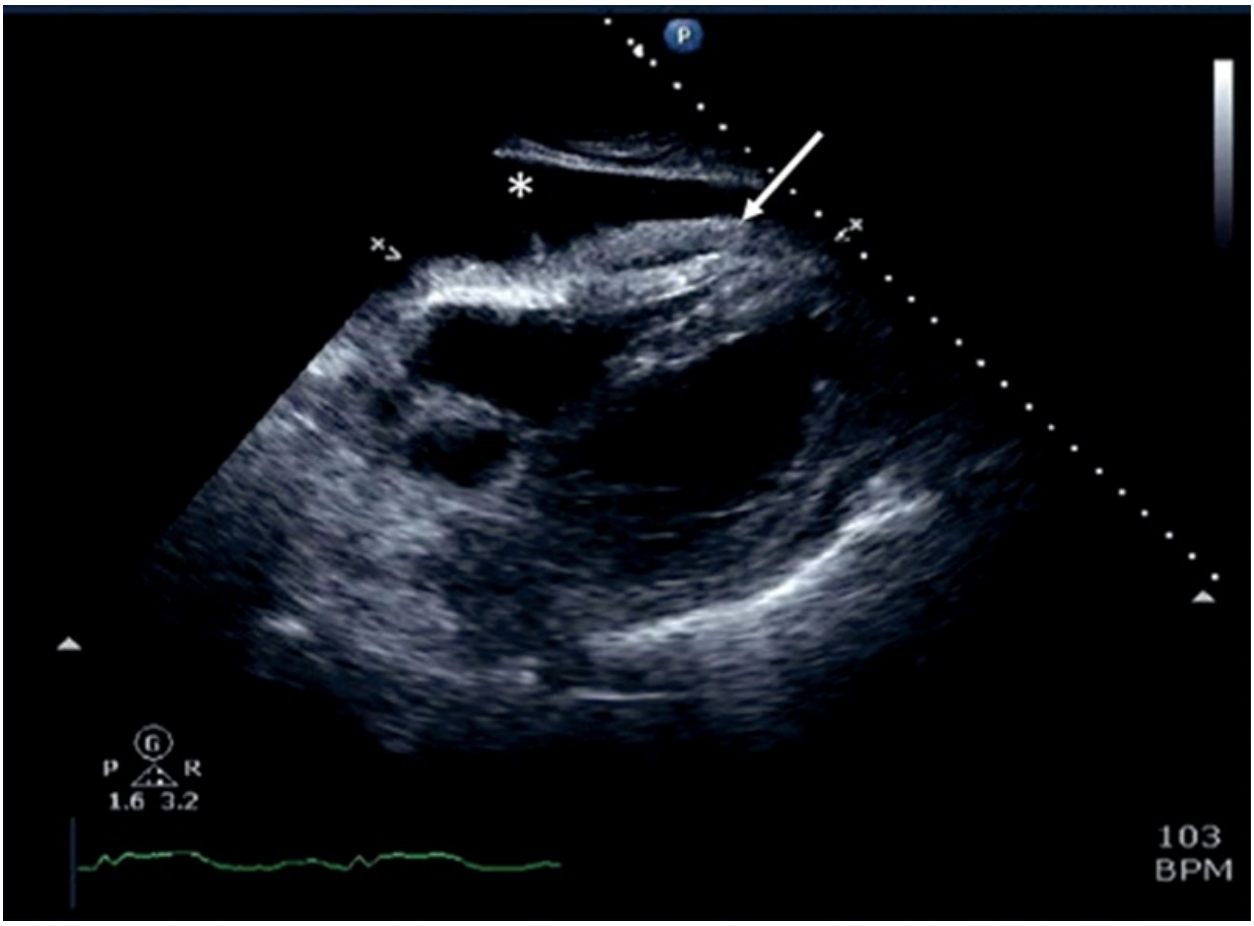

FIGURE 13.2 Subcostal view showing pericardial effusion (*asterisk*) with a thrombus in the pericardial space (*arrow*). This resulted from a ventricular free wall rupture after an acute myocardial infarction and the patient developed cardiac tamponade physiology.

Complete rupture of the left ventricular (LV) free wall usually leads to hemopericardium and death from cardiac tamponade. Patients may complain of transient chest pain or dyspnea. Acute tamponade can cause tachypnea, tachycardia, muffled heart sounds, elevated jugular venous pressure, and pulsus paradoxus. The presence of rupture is first suggested by the development of sudden profound right heart failure and shock, often progressing rapidly to pulseless electrical activity and death. Emergent transthoracic echocardiography (TTE) will confirm the diagnosis and emergent pericardiocentesis can transiently relieve the tamponade.[12]

Incomplete/subacute rupture of the LV free wall can occur when organized thrombus and the pericardium seal the ventricular perforation. Patients may present with persistent or recurrent chest pain (particularly pericardial pain), nausea, restlessness, agitation, abrupt hypotension, and/or electrocardiographic

features of localized or regional pericarditis.[4, 5] The diagnosis of incomplete/subacute rupture is again confirmed by TTE.[12]

There are three types of ventricular free wall rupture **(Figure 13.3)**. Type I is a slitlike or fissure full-thickness rupture, usually occurring within the first 24 hours with abrupt onset of symptoms. Type II is more subacute and occurs as a result of erosion of the myocardium at the infarct site. Type III has a later onset, occurring because of the expansion of the infarct zone with wall thinning and rupture through an aneurysmal segment.

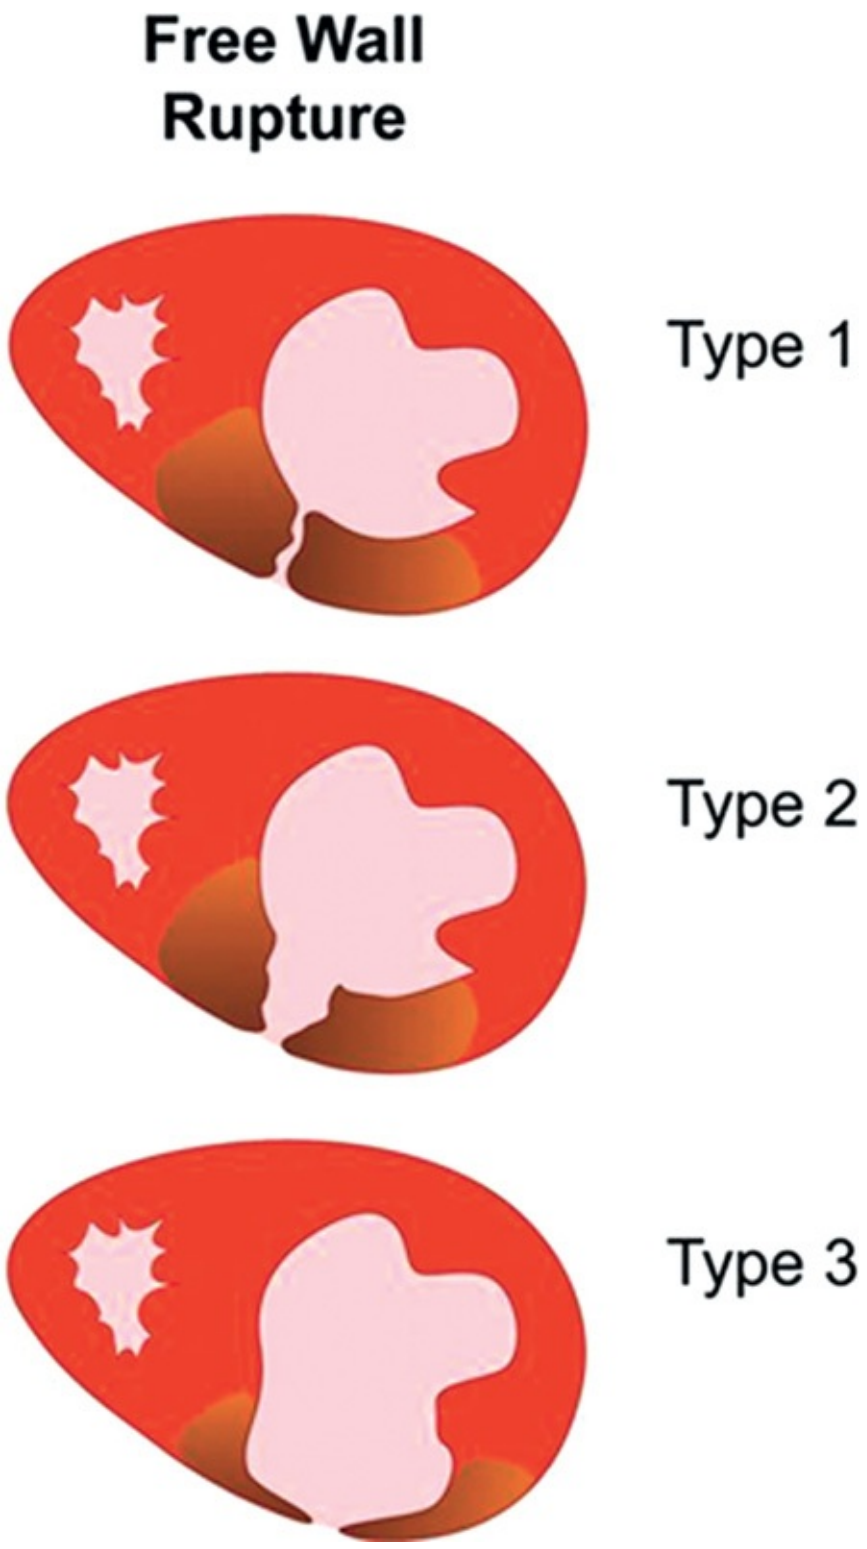

FIGURE 13.3 Classification of myocardial free wall rupture. (Adapted from Reynolds HR, Hochman JD. *Eur Heart J*. 2010;31:1433-1435, modified from Becker AE, van Mantgem JP. Cardiac tamponade. A study of 50 hearts. *Eur J Cardiol*. 1975;3:349-358.)

TREATMENT

As mentioned, the mortality for acute and subacute free wall rupture is high because of rapid clinical deterioration. Survival depends primarily on the prompt recognition of myocardial rupture and provision of immediate therapy. Patients displaying suggestive symptoms, signs, and ECG changes require emergent bedside echocardiogram and echocardiographically guided pericardiocentesis if fluid is visualized. Immediate surgical intervention is indicated if the pericardiocentesis identifies the fluid as blood. Medical therapy aimed at hemodynamic stabilization should also be instituted. In addition to pericardiocentesis, this includes fluids, inotropic support, vasopressors, and even intra-aortic balloon pump counterpulsation and percutaneous cardiopulmonary bypass when available and indicated.[4]

With rapid recognition and initiation of both medical and surgical therapy, the potential for survival, particularly with subacute rupture, can improve dramatically. In 1 study, 25 of 33 patients (76%) with subacute ventricular rupture survived the surgical procedure and 16 (48%) were long-term survivors.[13]

VENTRICULAR SEPTAL RUPTURE

Another deadly complication of AMI involves rupture of the interventricular septum. Rapid diagnosis, aggressive medical therapy, and prompt surgical intervention are essential to increase the chances of survival.

In the era before reperfusion therapy, rupture of the interventricular septum is thought to have occurred in 1% to 2% of patients with AMI and accounts for approximately 5% of deaths in this setting.[14] It typically occurs in the first week after infarction, with a mean time from symptom onset of 3 to 5 days.[15] The classic risk factors for septal rupture in the pre-reperfusion era include hypertension, advanced age, female sex, and the absence of a history of MI or angina.[16] Prognosis for ventricular septal rupture (VSR) in the prereperfusion era was very poor, with an in-hospital mortality of about 45% in those treated surgically and about 90% in those treated medically.[15] With the advent of thrombolysis and percutaneous intervention, incidence and outcomes have changed.

In the reperfusion era, studies show a much lower incidence and an

accelerated time to diagnosis of interventricular septal rupture than had been previously reported. Early reperfusion therapy may prevent the extensive myocardial necrosis that is associated with ventricular rupture.[15] Patients generally have a mean time of 1 day from infarction to development of a VSR. Many have postulated that this acceleration of rupture may be due to thrombolysis causing hemorrhage during the "lytic state," so that if a VSR occurs, its time course may be accelerated.[15] In the reperfusion era, advanced age, anterior infarct location, female sex, and no previous history of smoking were found to be the most potent predictors of a VSR.[15]

PATHOPHYSIOLOGY

The pathophysiology of interventricular septal rupture is similar to that of free wall rupture. Without reperfusion, coagulation necrosis develops within the first 3 to 5 days. The septum becomes necrotic and is infiltrated by neutrophils, which release lytic enzymes, thereby disintegrating the necrotic myocardium.[16] A transmural septal infarction underlies the rupture of the interventricular septum, with the tear ranging in size from millimeters to centimeters.[14]

The ventricular septum is a very vascular structure. The rarity of septal rupture and the variable infarct location relate to the fact that the interventricular septum has a dual blood supply. The anterior two-thirds is supplied by the left anterior descending (LAD) coronary artery and its branches. The posterior one-third is supplied by branches of the posterior descending artery, which come from the right coronary or the left circumflex artery, depending on the dominance of the circulation.[17] Studies have been conflicting in terms of which artery is predominantly responsible for septal rupture, but anterior MIs are considered to be more frequent, followed by inferior infarctions. Similar to free wall rupture, interventricular septal rupture occurs most frequently with a first MI when there is less likely to be collateral blood flow. In this setting, with an abrupt cessation of flow in the infarct-related artery, no collateral flow exists to support the infarcted zone, thereby making the septum prone to rupture **(Figure 13.4)**.

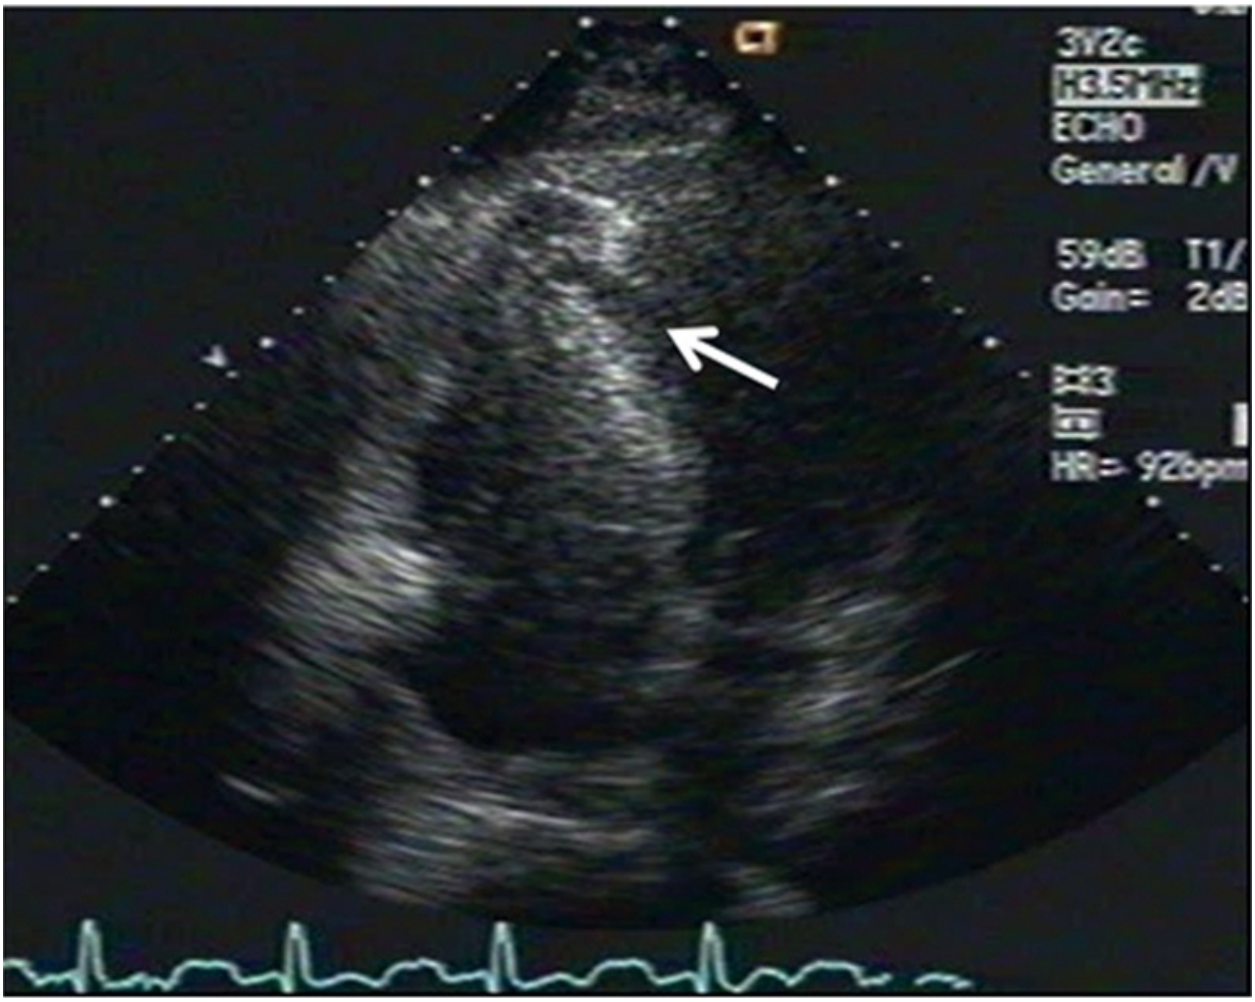

FIGURE 13.4 Apical four-chamber view of a transthoracic echocardiogram demonstrating a ventricular septal rupture in the distal portion of the interventricular septum (*arrow*).

CLINICAL PRESENTATION

Symptoms of rupture include shortness of breath, chest pain, signs of low cardiac output, and shock.[16] In 1934, Sager proposed a set of clinical criteria for suspecting a ruptured septum. The sudden onset of a systolic murmur, often accompanied by a thrill, in a patient with rapid hemodynamic decompensation is highly suggestive of a ruptured interventricular septum.[18] The rupture produces a harsh, loud, holosystolic murmur along the left sternal border, radiating toward the base, apex, and right parasternal area with a palpable thrill present in half of the patients. Compared to acute mitral regurgitation (MR), initially there is often right ventricular (RV) failure and absence of severe pulmonary edema before LV failure ensues. As the disease progresses, complete biventricular failure invariably occurs.[16]

In the setting of cardiogenic shock, the thrill and murmur may be difficult to appreciate because turbulent flow across the defect is reduced. Pulmonary hypertension may cause the pulmonic component of the second heart sound to be accentuated. RV and LV S3 gallops are often heard. Tricuspid regurgitation may be present and biventricular failure generally occurs within hours to days.[16]

TREATMENT

In the correct clinical setting, immediate echocardiogram is crucial to confirm the diagnosis. After the diagnosis is made, medical therapy may consist of mechanical support with an intra-aortic balloon pump, afterload reduction, diuretics, and inotropic agents.[16] Prompt surgical intervention is essential because most patients have a rapid deterioration and die. It was previously believed that shortly after an AMI, the myocardium was too fragile for safe repair of the rupture. A waiting period of 3 to 6 weeks, to allow the margins of the infarcted muscle to develop a firm scar to facilitate surgical repair, was standard before surgical intervention.[19] Medical therapy carries close to 100% mortality. While surgical therapy is associated with poor results—only about 13% survival, it is still considered the primary therapy.[20] Surgical therapy consists of placing a myocardial patch across the ruptured septum with concomitant coronary artery bypass as needed. A recent review in the European Heart Journal shows reported 30-day mortality at various time points after AMI, and outlines an approach for the management of VSR shown in **Figures 13.5** and **13.6**.[21] **Figure 13.7** demonstrates a case of apical VSR in a patient with an acute LAD territory MI.

RIGHT VENTRICULAR INFARCTION

Right ventricular infarction (RVI) was described over 60 years ago, but for decades it was not considered to be important because it showed no hemodynamic consequence in animal models.[22] Over time, it has become important to diagnose because it defines a specific clinical entity that is associated with considerable morbidity and mortality.[23] RVI complicates up to half of inferior wall LV infarctions.[22] Prompt recognition of this mechanical complication of AMI is crucial because its initial management differs from that of other types of infarction.

PATHOPHYSIOLOGY

The physiology of the right side of the heart varies considerably from that of the left. It is a low-pressure system that has one-sixth of the muscle mass of the left ventricle. Despite this, both ventricles have the same cardiac output.[22] This is due to the fact that the pulmonary vascular resistance is one-tenth that of the peripheral systemic resistance.[24] These factors are important in the hemodynamic consequences of RVI.

Coronary blood flow to the right ventricle is unique in that it occurs in both systole and diastole.[22] The right coronary artery (RCA) supplies the right ventricle through the acute marginal branches in the majority of patients, as well as the inferior wall and posterior interventricular septum through the posterior descending artery in right-dominant systems. Typically, RVI occurs when there is occlusion of the RCA proximal to the acute marginal branches. It can also occur with an occlusion of the left circumflex in those who have a left-dominant system. Although quite rare, occlusion of the LAD artery may result in infarction of the anterior right ventricle.[22]

The incidence of RVI in association with LV infarction ranges from 14% to 84% across different studies. Incidence of isolated RVI accounts for less than 3% of all cases of infarction.[22] When isolated to the right ventricle, the occlusion is usually in the acute marginal vessels or of a nondominant RCA.[24] Many RCA

occlusions do not result in RV necrosis.[23] Less than half of inferior MIs involve the right ventricle. This may be due to lower RV myocardial oxygen demand as a result of its smaller muscle mass, or from its improved oxygen delivery from the biphasic nature of the coronary blood flow during both systole and diastole. A rich left-to-right collateral system is also thought to play a part.[22]

Acute underperfusion of the RV free wall and adjacent interventricular septum leads to a stunned and noncompliant right ventricle. Loss of RV contractility results in a serious deficit in LV preload with a resultant drop in cardiac output, thereby causing systemic hypotension.[25] Augmented atrial contractility is necessary to overcome the increased myocardial stiffness associated with RVI.[26] Factors that impair filling of the noncompliant right ventricle and cause decreased preload are likely to have profound adverse effects on hemodynamics in patients with large RVIs. These factors include volume depletion due to the use of diuretics and nitrates or any diminution in atrial function caused by concomitant atrial infarction or the loss of atrioventricular (AV) synchrony.[22]

To complicate matters, acute RV dilatation causes a leftward shift of the interventricular septum, increasing LV end-diastolic pressure with a resultant decrease in LV compliance and cardiac output. LV compliance is further aggravated by increased intrapericardial pressure as a result of RV dilatation **(Figure 13.8)**. As a consequence, the LV filling and systolic function may be below normal.[23] If significant LV dysfunction complicates RVI, the results can be disastrous.

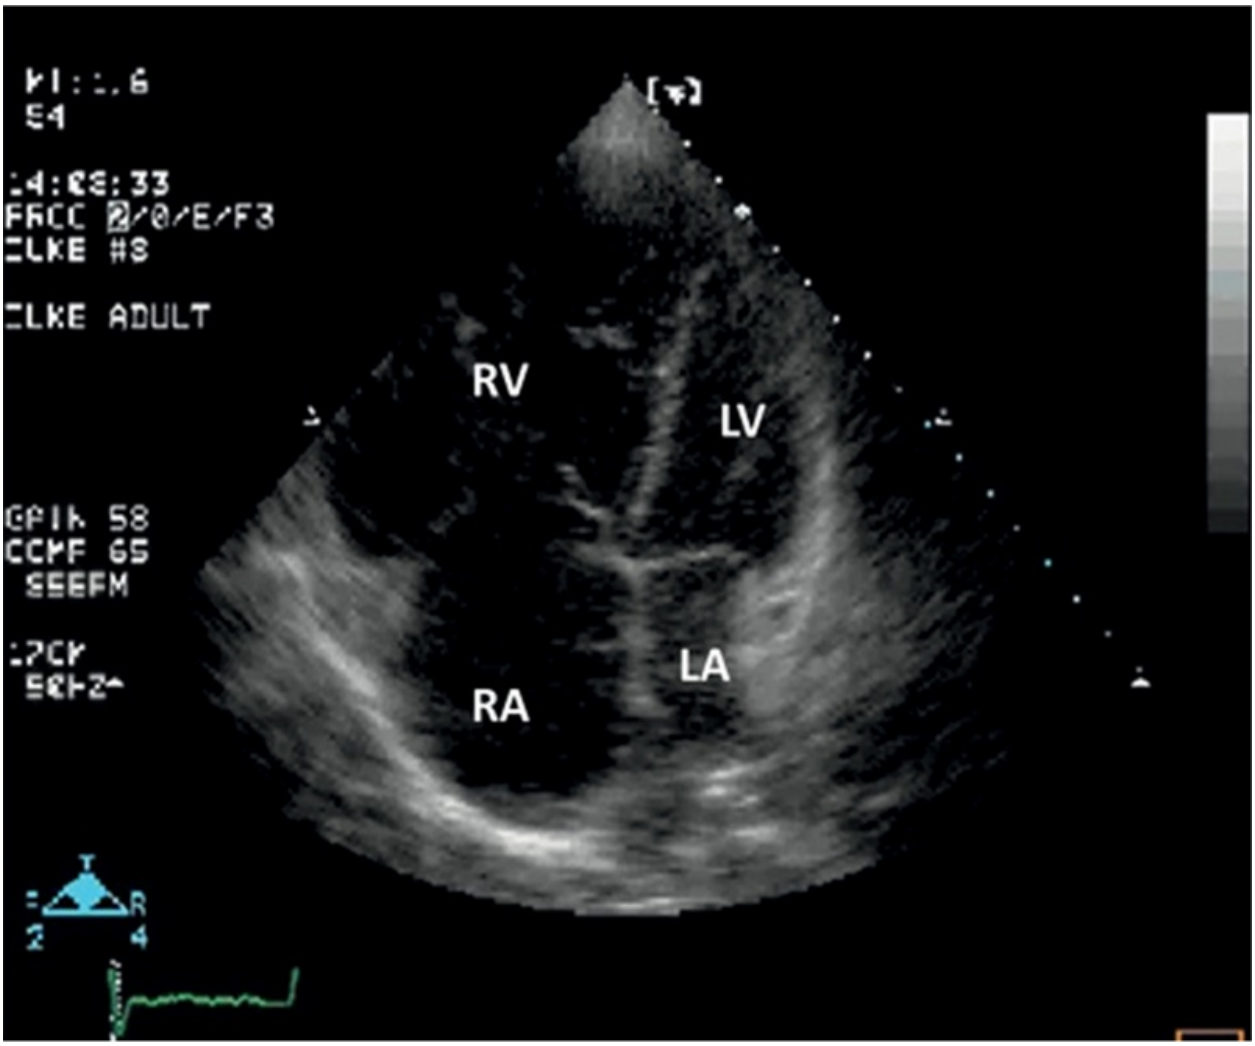

FIGURE 13.8 Apical four-chamber view of a transthoracic echocardiogram demonstrating a dilated and severely hypokinetic right ventricle with compression of the left ventricle. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

CLINICAL PRESENTATION

Given that management of RVI is quite different from LV infarction, recognizing its clinical presentation is paramount. A patient presenting with an inferior MI and the triad of hypotension, clear lung fields, and elevated jugular venous pressure, is virtually pathognomonic for RVI.[22] This triad is very specific, but has a sensitivity of less than 25%.[27] Auscultation may reveal a right-sided S3 and S4.[28] Tricuspid regurgitation may also be noted if the right ventricle is sufficiently dilated.

Pulsus paradoxus (decreased systolic blood pressure with inspiration) and Kussmal sign (elevated jugular venous distension with inspiration) have also

been reported in RVI.[28] Careful examination of neck veins in the setting of an inferior MI should alert the physician to the drastic consequences that use of nitrates, diuretics, and morphine can have. These agents should be avoided because they reduce preload and can promote or exacerbate hypotension.

The ECG is crucial for the diagnosis of RVI. The most frequent finding is any degree of ST elevation in leads II, III, and aVF with or without Q waves. Occlusion sufficiently proximal in the RCA to cause RV free wall injury also frequently compromises the blood supply to the sinoatrial node, atrium, and AV node, producing effects such as sinus bradycardia, atrial infarction, atrial fibrillation, and AV block.[25] Involvement of the RV free wall may be suspected with the presence of ST depression in precordial leads V2 and V3 when compared to V1. Confirmation of RV ischemia can be quickly obtained when right-sided leads V4R through V6R show ST-segment elevations greater than 1 mm **(Figure 13.9)**.[25] A 1-mm ST elevation in V4R is 70% sensitive and 100% specific for RVI.[22] ST-segment elevation in V4R has been shown to be a strong independent predictor of major complications and in-hospital mortality.[23] When the ECG shows signs of RVI, echocardiography can aid in the diagnosis.

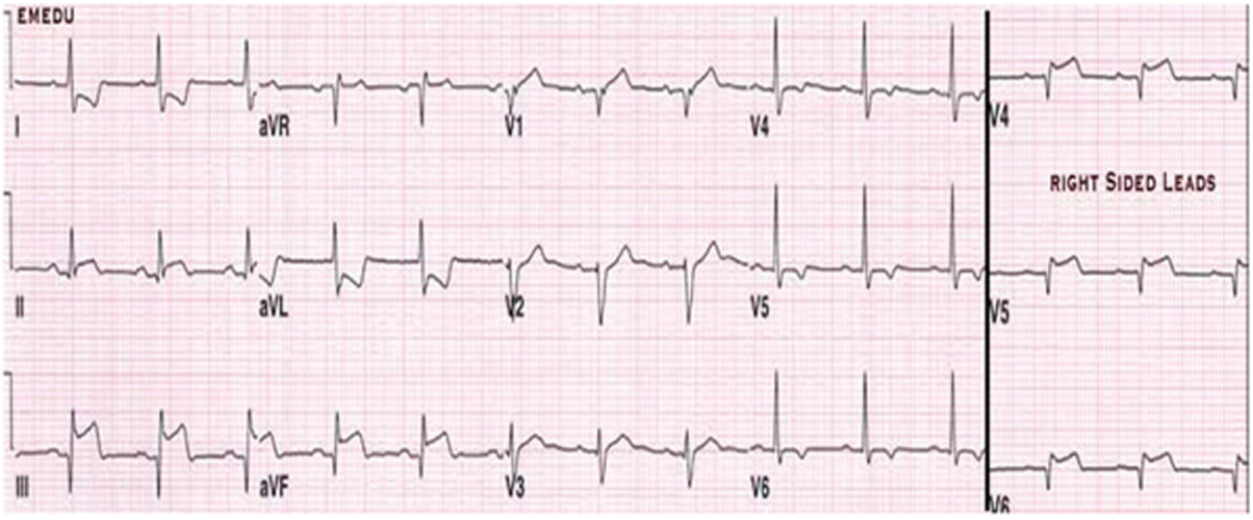

FIGURE 13.9 Electrocardiogram showing an inferior wall myocardial infarction with right-sided leads showing significant ST elevation in V4R through V6R.

TREATMENT

The treatment strategy of RVI includes early maintenance of RV preload, reduction of RV afterload, inotropic support of the dysfunctional right ventricle

and early reperfusion.[22] When the right ventricle is ischemic, use of drugs such as nitrates and diuretics will reduce preload and may reduce cardiac output and cause severe hypotension. Volume loading alone with normal saline will often increase filling of the right ventricle and in turn increase filling of the underfilled left ventricle and increase cardiac output.[23]

Excessive fluid administration can further elevate right-sided filling pressures without improvement in cardiac output. In some cases, volume loading will cause further RV dilatation, which in turn further compromises LV output through pericardial restraining effects.[22] Inotropic support with dobutamine should be initiated if the cardiac output fails to improve with up to 1 L of fluid administration.[23]

Often, inferior MI can result in bradyarrhythmias and AV dyssynchrony. When stroke volume is impaired, cardiac output depends on heart rate; therefore, bradycardia can be deleterious. The development of a high-degree AV block has been reported in as many as 48% of patients with RVI.[29] AV dyssynchrony causes loss of right atrial contribution to preload and can lead to further hemodynamic compromise. Several investigators have shown that AV sequential pacing in patients with complete heart block leads to significant increase in cardiac output and reversal of shock when ventricular pacing alone has no benefit.[30] Prompt cardioversion for atrial fibrillation should be considered to restore AV synchrony at the earliest signs of hemodynamic compromise.[22]

Reperfusion should be considered in the initial management of RVI. Recent studies have shown that those patients with predominant RV failure who underwent revascularization with either percutaneous angioplasty or coronary artery bypass grafting (CABG) had much better outcomes. Mortality was 42% for those revascularized versus 65% for those not revascularized. These numbers were similar for those with predominant LV failure (40% and 73%). The conclusion was made that RV failure complicating AMI carries a very high mortality risk similar to that for LV failure. Revascularization helps improve these numbers and should be considered immediately.[31]

Long-term prognostic data for those suffering from RVI is conflicting. It is generally thought that when patients survive to discharge, prognosis is favorable but large-scale studies are needed to confirm this theory.[22]

ACUTE MITRAL REGURGITATION

Acute MR is another major fatal mechanical complication of AMI. As with the other complications of AMI, the rapid recognition, diagnosis, and treatment can result in significant improvement in survival. The three main causes of MR in the setting of an AMI include ischemic papillary muscle dysfunction, papillary muscle or chordal rupture, and LV dilatation.[32]

MR of mild-to-moderate severity occurs in 14% to 45% of patients following an AMI. Most MR is transient in nature but sudden papillary muscle rupture can be a life-threatening event. Fibrinolysis for reperfusion may decrease the incidence of rupture; however, when administered, rupture may occur earlier in the post-MI period than in the absence of reperfusion. In the prefibrinolytic era, papillary muscle rupture was reported to occur between days 2 and 7 post AMI. However, it is now thought that a median time to papillary muscle rupture is 13 hours.[33] Papillary muscle rupture is found in 7% of patients in cardiogenic shock and contributes to 5% of the mortality after acute MI.[34]

Studies have shown that the risk factors for acute MR with papillary muscle rupture include advanced age, female gender, and absence of previous angina, inferoposterior AMI, single-vessel disease, and no history of diabetes. When considering acute MR without papillary muscle rupture, the risk factors also include female gender and advanced age; however, these patients are likely to have had a prior MI, recurrent ischemia, and multivessel coronary artery disease.[35]

PATHOPHYSIOLOGY

The mitral valve is located retrosternally at the fourth costal space and consists of an anterior and posterior leaflet. Any portion of the mitral apparatus can become anatomically disrupted and result in a portion of the mitral valve becoming flail and dysfunctional. The degree of resultant regurgitation is directly related to the extent of anatomic disruption. Most of the time in the setting of acute MI, the rupture of an entire papillary muscle or muscle head typically results in acute severe MR.[36] In most patients, the anterolateral papillary muscle receives dual blood supply from the LAD and circumflex coronary arteries and is less likely to be involved by the ischemic process than is the posteromedial papillary muscle, which is supplied solely by the posterior descending artery. Because of its single-vessel blood supply the posteromedial papillary muscle is 6 to 12 times more vulnerable to vascular compromise and rupture than the anterolateral papillary muscle. Often, the infarct expansion is

relatively small with poor collaterals, and up to 50% of patients have single-vessel disease, with many of them being a consequence of a first-time MI.[6, 37] Several studies support that acute MR is not only a common complication post AMI, but also that the degree of MR is predictive of patient survival. Large studies calculate the mortality of patients with moderately severe to severe MR during an acute MI to be 24% at 30 days and 52% at 1 year.[38] Mild MR in the setting of AMI is however not associated with clinically adverse events because it is likely reversible and secondary to the acute ischemic insult.

Of note, select patients with moderate-to-severe MR, but without papillary muscle rupture, are hemodynamically stable. In this setting, patients respond well to medical therapy and revascularization with or without eventual surgical intervention (mitral valve repair or replacement or CABG).[39]

TREATMENT

As with all of the acute phase complications of AMI, the proper treatment of acute, severe MR is emergent surgical correction of the mitral valve and CABG when indicated. Prompt diagnosis with echocardiogram and aggressive medical therapy before surgery markedly improve patient outcomes. **Figure 13.10** demonstrates an apical four-chamber view of a transthoracic echocardiogram showing MR as a result of an inferior wall MI. When considering hemodynamic compromise secondary to significant, acute MR, aggressive medical resuscitation involves improving forward flow by afterload reduction and thus improving the regurgitant fraction. Afterload reduction is accomplished with the use of nitrates such as sodium nitroprusside, diuretics, and intra-aortic balloon pump counterpulsation.

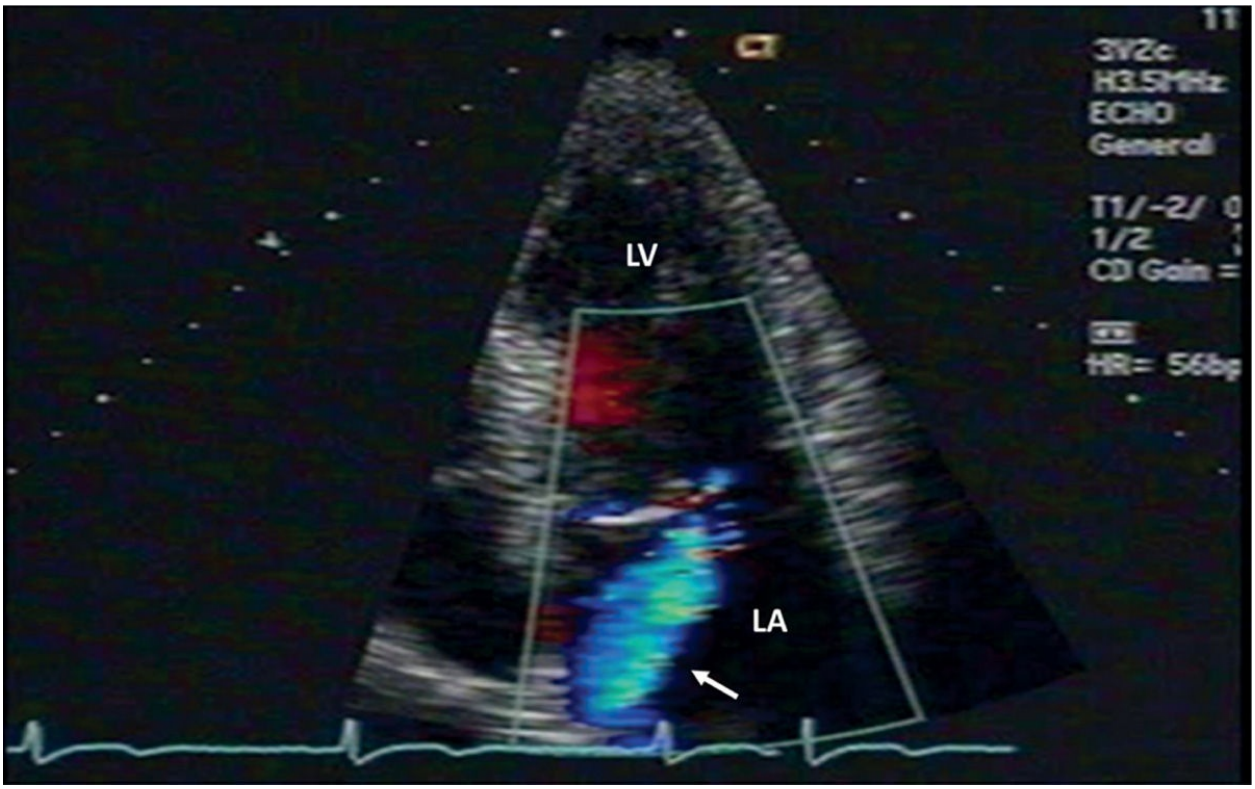

FIGURE 13.10 Apical four-chamber view of a transthoracic echocardiogram showing mitral regurgitation as a result of an inferior wall myocardial infarction (*arrow*). LA, left atrium; LV, left ventricle.

The operative mortality for these patients is an estimated 20% to 25% and heavily dependent on the timing of diagnosis and treatment. Despite such a high mortality, survival in patients restricted to medical therapy alone is significantly lower. Thus, emergent surgical intervention remains the treatment of choice for papillary muscle rupture.[40] Of note, mitral valve repair rather than replacement should be attempted in centers experienced in performing this procedure[38, 39]; and patients must meet the strict criteria for mitral valve repair, which includes the preserved integrity of the mitral apparatus (ie, intact papillary muscles and chordae). Interestingly, long-term results in 1 small study of 22 patients revealed a perioperative mortality of 27% and a 7-year survival for the survivors of surgery of 64% (the overall 7-year survival was 47%).[40] The only factor that improved both immediate and long-term survival was the concomitant performance of CABG. **Figure 13.11** shows a ruptured papillary muscle resulting in severe MR, requiring urgent surgical intervention.

TRUE VENTRICULAR ANEURYSM

In contrast to the acute complications of MI, the chronic complications of AMI are not immediately life-threatening. They have very different presentations and require different treatments. True left ventricular aneurysm (LVA) is a common chronic complication of AMI that is important to diagnose.

LVA is a common mechanical complication following an AMI, often occurring between 10% and 15% of patients. Before the era of current management, which includes strategies such as thrombolytic therapy, percutaneous coronary intervention, and the administration of afterload reducing agents, the incidence of LVA approached 40%.[41, 42] A recent analysis has shown that the incidence of LVA among 350 consecutive patients with ST-segment elevation MI, treated with thrombolytic therapy, was significantly lower in those with a patent infarct-related artery (7.2% vs 18.8%).[43] LVA of the apex and anterior wall are approximately four times more common than those of the inferior or inferoposterior walls.

Approximately 70% to 85% of LVAs are located in the anterior or apical walls, and in most cases are due to complete occlusion of the LAD coronary artery and the absence of collateralization. However, 10% to 15% of cases involve the inferior-basal walls because of RCA occlusion. A rare finding is a lateral LVA, which is the result of an occluded left circumflex coronary artery. Among patients with multivessel disease, LVA is uncommon if there is extensive collateralization or a nonoccluded LAD artery.

PATHOPHYSIOLOGY

LVA has been described as a well-delineated and distinct break, (“hinge point”) in the LV geometry and contour present in both systole and diastole. The walls consist of thin, scarred, or fibrotic myocardium, completely devoid of muscle, the result of a healed transmural AMI. The pathognomonic features include a wide mouth that enables communication with the aneurysmal cavity. Often, this is evident at 4 to 6 weeks following an AMI. The involved wall segment is either akinetic or dyskinetic during systole, and collapses inward when the ventricle is

fully vented during surgery **(Figures 13.12** and **13.13)**.

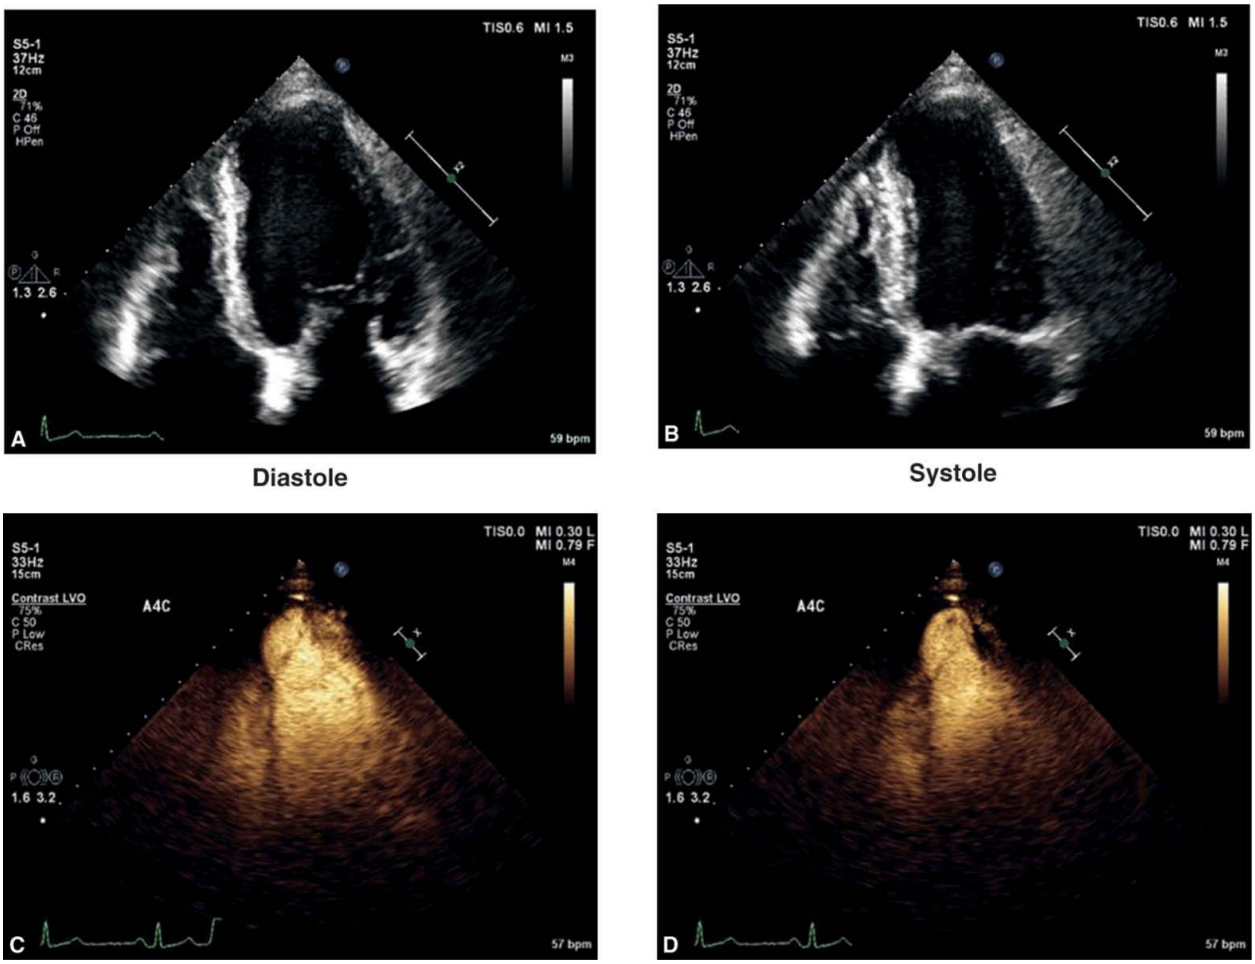

FIGURE 13.12 Apical four-chamber view in (A) dia stole and (B) systole and (C and D) with echo contrast, respectively, showing a large apical acute myocardial infarction with a large apical aneurysm with no clot.

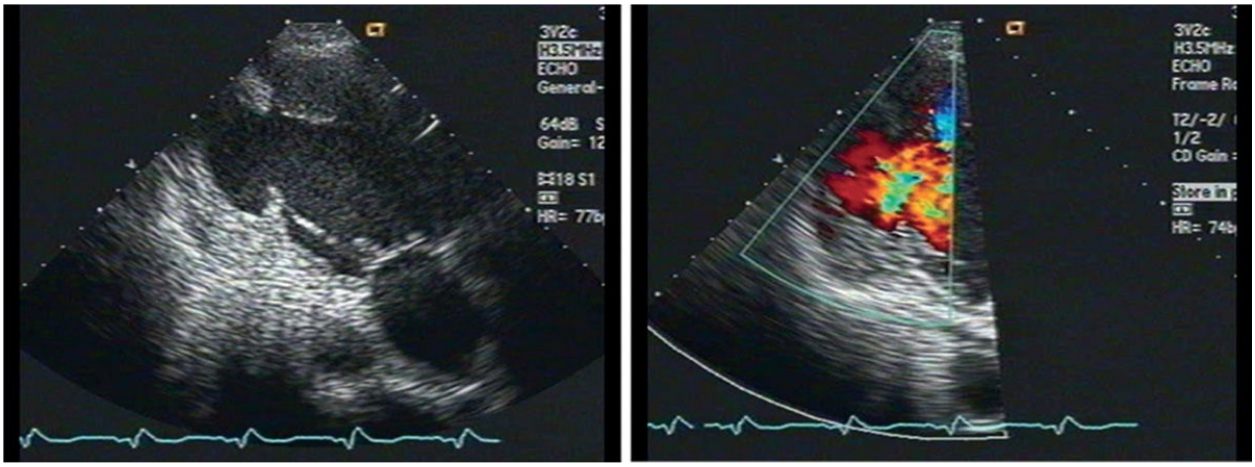

FIGURE 13.13 Apical three-chamber view **(left)** obtained from transthoracic echocardiogram revealing a large left ventricular aneurysm, enhanced with color flow Doppler **right)** establishing an area of

communication between the normal left ventricle and the aneurysmal portion.

Although the size of an aneurysm varies widely, most are within 1 to 8 cm in diameter. The wall of the aneurysm typically consists of a hybrid of necrotic myocardium and white fibrous scar tissue. This wall is extremely thin and delicate and may calcify over an extended period of time. Of note, it is imperative to distinguish between an LVA and a pseudoaneurysm, which is characterized by a narrow neck and a distinct "shelf-like" opening.

The endocardial surface is smooth and nontrabeculated. The aneurysm is filled with organized thrombus in more than 50% of cases, which has the tendency to calcify over time.[44] Dense adhesions between the aneurysm and the overlying pericardium are common phenomena. On a molecular level, initially, the ventricular wall is characterized by myocardial muscle necrosis and a concomitant intense inflammatory reaction, which eventually is replaced with scar tissue formation, and a mature aneurysm consists mostly of hyalinized fibrous tissue. The "border zone," that is, the layer between the aneurysm and the healthy myocardium, is characterized by patchy fibrosis and abnormal alignment of the muscle fibers.

CLINICAL PRESENTATION

A prior history of AMI is almost universally present in patients with an LVA that is not associated with other etiologies such as hypertrophic cardiomyopathy or Chagas disease. The physical examination may reveal one or more of the following findings; however, it may prove to be somewhat difficult to diagnose an LVA by physical examination because the findings are nonspecific.

- Cardiac enlargement with a diffuse apical impulse located to the left of the midclavicular line.
- An area of dyskinesis can occasionally be appreciated with palpation of the left lateral chest wall, in the area of the apex and anterior wall of the left ventricle.
- A third and/or fourth heart sound (S3 or S4) is often heard, which represents the onset of blood flow into a dilated and stiffened LV chamber.
- A MR-like systolic murmur may be appreciated because of the distortion of LV geometry that results in the absence of leaflet apposition, papillary muscle dysfunction, and/or annular dilatation.

The presence of an LVA should be suspected when a patient with a large, predominantly, anterior AMI develops one of the aforementioned physical examination findings. The ECG usually reveals evidence of a large AMI and there may be persistent ST-segment elevation; however, this finding is usually the result of a large area of scar and does not necessarily imply an aneurysm **(Figure 13.14)**.

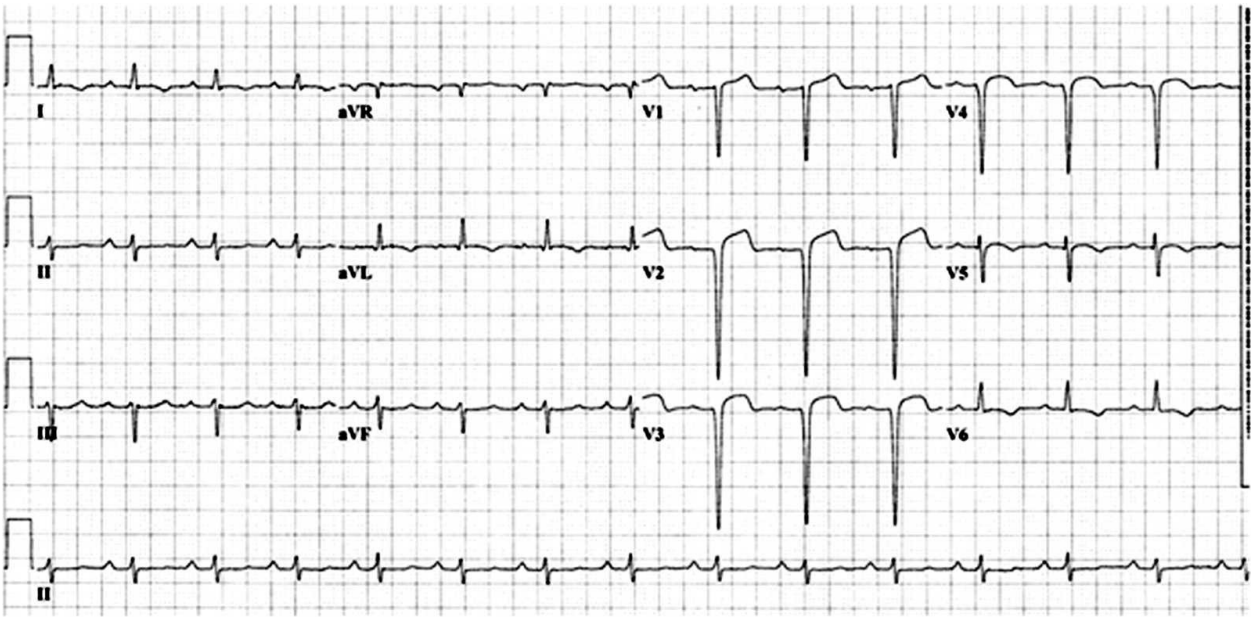

FIGURE 13.14 Electrocardiogram of a patient with a true left ventricular aneurysm displaying persistent ST elevation with Q waves in V1 through V4.

Although limited and rarely used today, chest radiography may aid in the diagnosis of an LVA; however, given the extreme limitations of chest radiography, the diagnosis is definitively made via two-dimensional echocardiography. A simple definition of an LVA on echocardiography imaging is the presence of a dyskinetic wall motion abnormality with the feature of diastolic deformity.[45, 46] TTE is most often used and has globally emerged as the diagnostic tool of choice. Even before the diagnosis is made, there are a number of serious complications that can result from an LVA, such as heart failure, ventricular arrhythmias, and thrombus formation.

During ventricular systole, the paradoxical bulging of the aneurysmal segment results in “stealing” part of the LV stroke volume, resulting in decreasing cardiac output and predisposing to LV volume overload. LV dilatation and increase in wall stiffness can increase oxygen demand. In the setting of underlying coronary

artery disease, the increase in oxygen demand may lead to myocardial ischemia with subsequent angina. The end result of long-standing volume overload and prolonged ischemia is a globally dilated, failing left ventricle. Heart failure symptoms are common.

The myocardial scarring present in LVA is a substrate for ventricular arrhythmias. Two mechanisms contribute to this possible deadly outcome. Firstly, myocardial ischemia and increased myocardial stretch can lead to enhanced cardiac automaticity. Secondly, the myocardium located at the border zone is made up of a mix of fibrotic tissue, inflammatory cells, and damaged muscle fibers, which is a suitable substrate for a reentrant tachycardia. Ventricular arrhythmias often result in sudden cardiac death.

As previously mentioned, a mural thrombus is identified in autopsy or surgery in >50% of patients with LVA. A possible fatal consequence of thrombus formation is possible systemic embolization, which can result in stroke, ischemic colitis, ischemic limbs, and a variety of other disastrous complications.

It is important to note that true LVAs may enlarge over time. However, unlike false aneurysms, a true LVA rarely ruptures because of the dense fibrosis that comprises the walls.[47, 48]

TREATMENT

Mild-to-moderate size asymptomatic aneurysms can be safely treated medically with an anticipated 5-year survival of up to 90%. Therapy includes reduction of afterload via angiotensin-converting enzyme inhibitors, nitrates, and anticoagulation (in the setting of significant LV dysfunction or evidence of thrombus formation). The optimal approach to the patient with a large, asymptomatic LVA remains a clinical dilemma. Concomitant repair of the aneurysm has been advocated when CABG or valve surgery is performed. In the absence of such indications for surgery, these patients should otherwise be treated with the same regimen as those with a small LVA; they should also be followed up closely for progressive LV dilation. Similar to other settings of chronic volume overload, a progressive increase in LV diameter and/or decrease in LV ejection fraction are a clear indication for surgery even before the presence of advanced heart failure or other symptoms.

As per the 2004 American College of Cardiology/American Heart Association (ACC/AHA) guidelines on ST-elevation MI, aneurysmectomy, accompanied by CABG, in patients with an LVA who have repetitive ventricular arrhythmias and/or heart failure unresponsive to medical and catheter-based therapy, is a

Class IIa recommendation and is therefore reasonable.[49] Surgical repair should be considered for symptomatic patients with either akinetic or dyskinetic segments, because they represent variants in the spectrum of the same disease. Surgical repair of an LVA is very effective, and results in a significant improvement in patient survival, symptoms, and functional class compared to medical treatment.[50–52] Furthermore, a marked decrease in surgical mortality has been achieved in the past 25 years. Endocardial mapping with subsequent endocardial resection and possible cryoablation are performed in patients with malignant ventricular arrhythmias.

LEFT VENTRICULAR PSEUDOANEURYSM

A left ventricular pseudoaneurysm (LVPA) or false aneurysm is a less common form of a ventricular aneurysm present in <1% of patients post MI. It is briefly discussed here.

PATHOPHYSIOLOGY

An LVPA forms when cardiac rupture is more or less contained by adherent pericardium or scar tissue. Unlike a true aneurysm, an LVPA is devoid of endocardium or myocardium and because these aneurysms are prone to rupture, a quick and accurate diagnosis is of extreme importance. Unlike a true LVA whereby the walls consist of dense fibrous tissue with excellent tensile strength, the wall of an LVPA is comprised of thrombus and varying portions of the epicardium and parietal pericardium. It is the result of an AMI (typically an inferior or posterolateral wall AMI) with myocardial rupture and hemorrhage into the pericardial space, becoming progressively compressive. Cardiac tamponade occurs, thereby preventing further hemorrhage into the pericardium. Over time, thrombus organizes with overall poor structural integrity, and thus is prone to inevitable rupture, which is a fatal event.[53]

CLINICAL PRESENTATION

It has been suggested that the most frequent symptoms associated with LVPA include chest pain and dyspnea. However, often symptoms can be somewhat vague and nonspecific. The other symptomatology includes that of tamponade, heart failure, syncope, arrhythmia, or systemic embolism. Cardiac murmurs are

present in about two-thirds of patients. The murmur is often indistinguishable from that of MR. Almost all patients have some degree of underlying ECG changes, which include ST-segment elevation and nonspecific T-wave changes. Evidence of a mass on chest X-ray is seen in more than one-half of patients; however, as previously mentioned, this is not specific or sensitive for the diagnosis of an LVPA.[54, 55]

The most reliable method for diagnosis of an LVPA is via echocardiography. A TTE is a reasonable first step, but a definitive diagnosis is made in only a fraction of patients. Echocardiography can usually distinguish a pseudoaneurysm from a true aneurysm by the appearance of the connection between the aneurysm and ventricular cavity. LVPAs have a narrow neck, typically less than 40% of the maximal aneurysm diameter, which causes an abrupt interruption in the ventricular wall contour (**Figures 13.15** and **13.16**). In contrast, true aneurysms are nearly as wide at the neck as they are at the apex. **Figures 13.17** compares true aneurysms versus false/pseudoaneurysms.

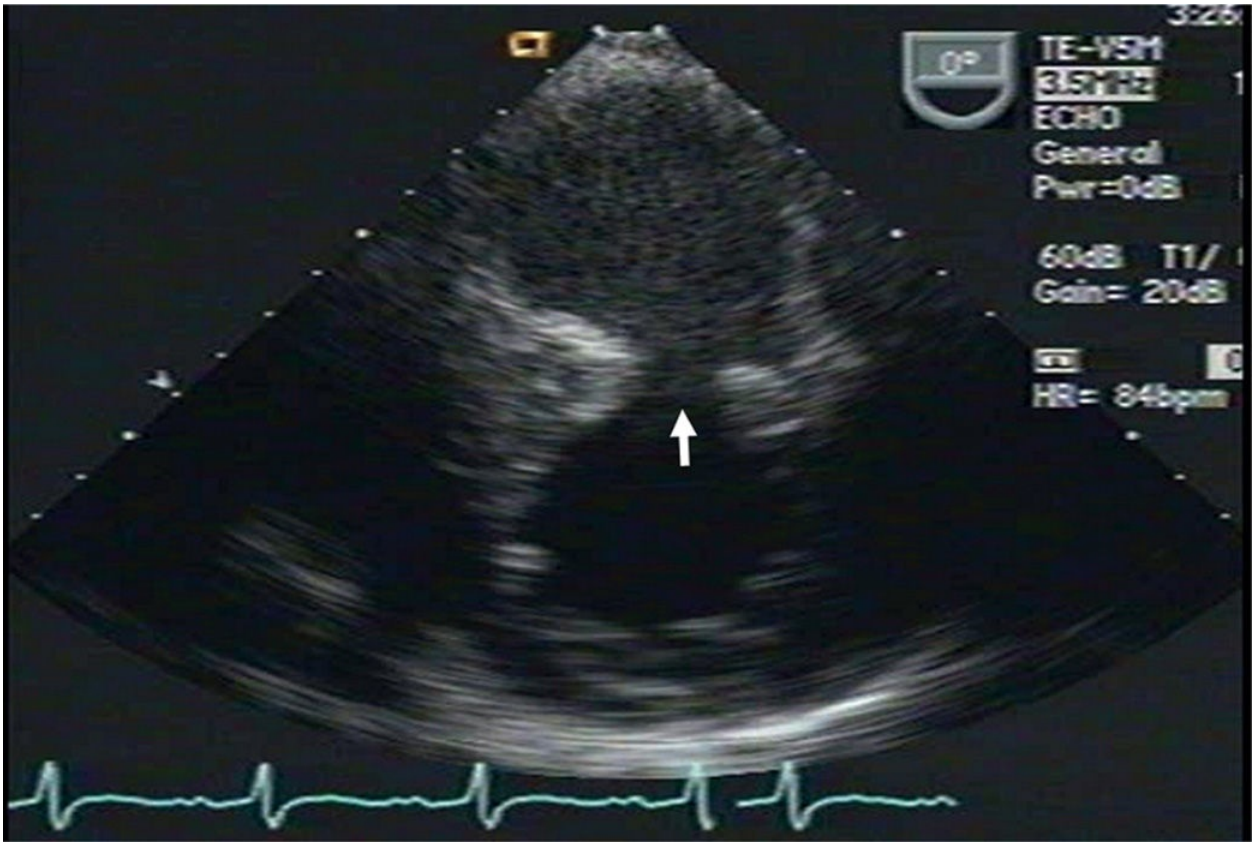

FIGURE 13.15 Short-axis view of the left ventricle (*lower cavity*) during transesophageal echocardiography. Large pseudoaneurysm (*higher cavity*). Notice the narrow "bottleneck" opening (*arrow*).

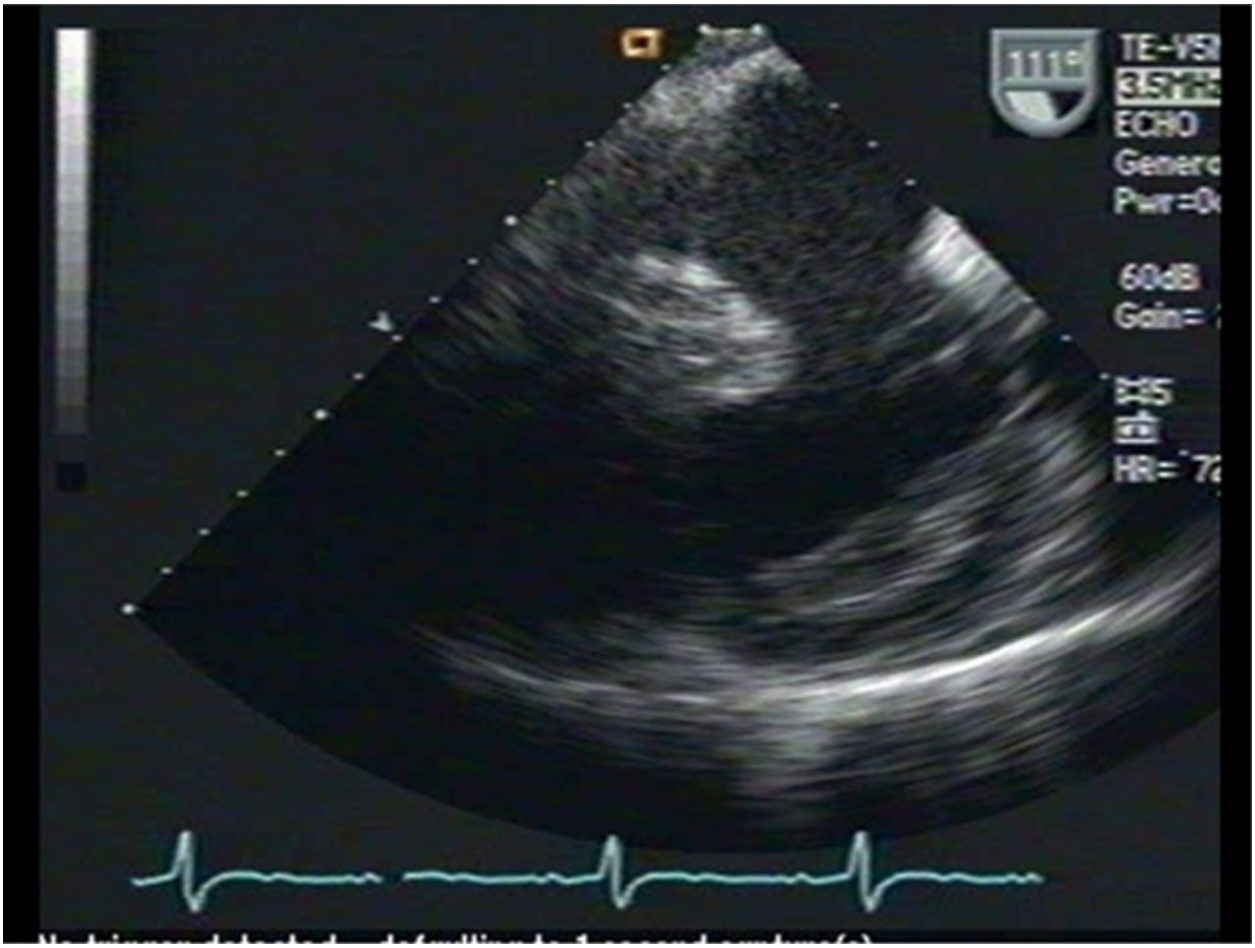

FIGURE 13.16 Short-axis view from transesophageal echocardiogram depicting a large pseudoaneurysm (*higher cavity*). Notice the narrow “shelf-like” opening into the aneurysmal cavity.

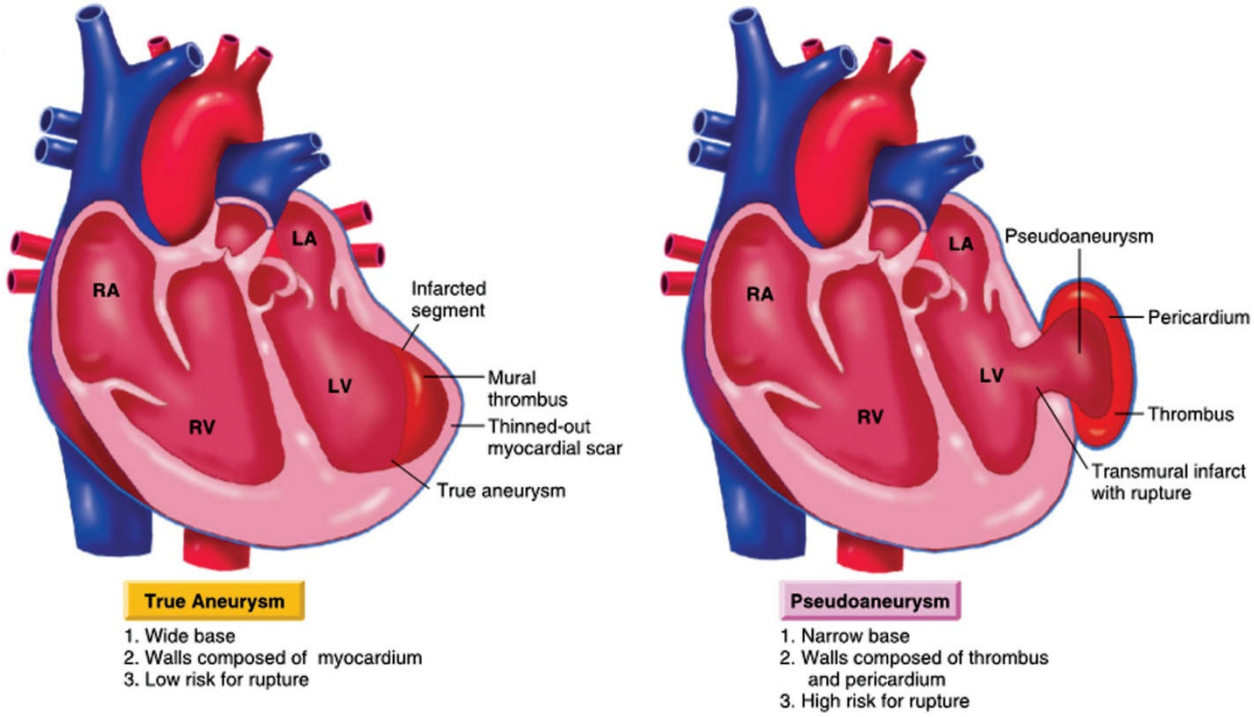

FIGURE 13.17 Differences between a pseudoaneurysm and a true aneurysm. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. Complications of acute myocardial infarction. In: Parley W, Chatterjee K, eds. *Cardiology*. Philadelphia, PA: JB Lippincott; 1987.)

TREATMENT

Untreated LVPAs have a 30% to 45% risk of rupture and, with medical therapy, a mortality of almost 50%. Thus, surgery is the preferred therapeutic option. With current techniques, the perioperative mortality is less than 10%, although the risk is greater among patients with severe MR requiring concomitant mitral valve replacement.

LEFT VENTRICULAR THROMBUS

A mural LV thrombus is a common sequela of an AMI and most commonly develops in the presence of a large infarction. Thrombi are prone to originate in regions of stasis; they are most commonly noted to occur in the apex but may also occur in lateral and inferior aneurysms. With extensive transmural infarction, mural thrombi may overlie the infarcted myocardium. Before current conventional medical therapy, the incidence ranged between 25% and 40%.[54]

The initiation of heparin and perhaps thrombolysis can reduce the development of an LV thrombus by 50%. The major risk of a thrombus is subsequent distal embolization, which is highest during the first 2 weeks following an AMI with eventual reduction of risk by 6 to 8 weeks. This is attributed to a relative endothelialization of the thrombus with reduction in its embolic potential. Echocardiography has high sensitivity (95%) and high specificity (85%) for identification of an LV thrombus and has emerged as the diagnostic modality of choice. Characteristically, a thrombus has a nonhomogeneous echo density with a margin distinct from the underlying wall, which is akinetic to dyskinetic (**Figures 13.18** and **13.19**).[56] A thrombus is more likely to occur following an AMI in the LAD artery distribution (up to 33%) versus the right coronary or circumflex (<1%) coronary arteries.

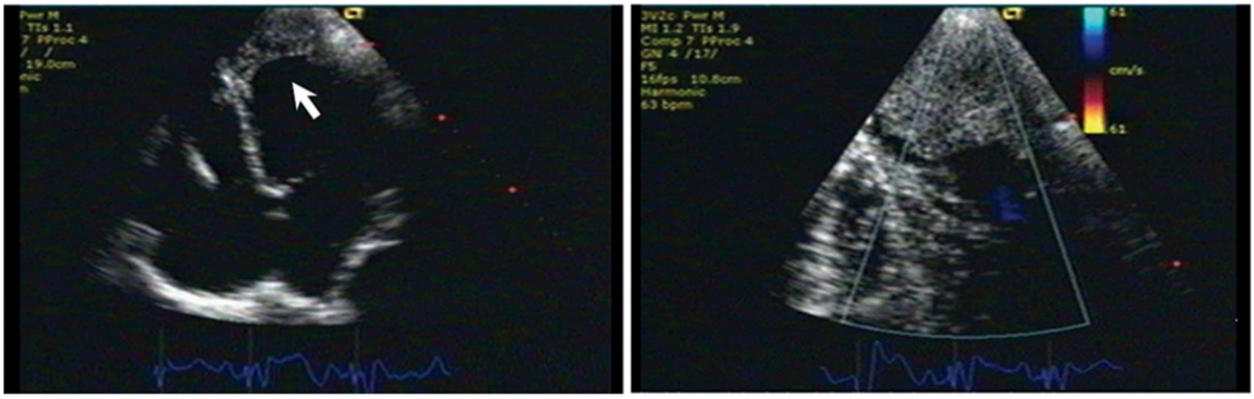

FIGURE 13.18 Apical four-chamber views of a transthoracic echocardiogram from a 74-year-old patient 3 months following AMI (*top*). Notice the large protruding apical thrombus (*arrow*). Color flow imaging (*bottom*) may be used to demonstrate abnormal flow patterns. AMI, acute myocardial infarction.

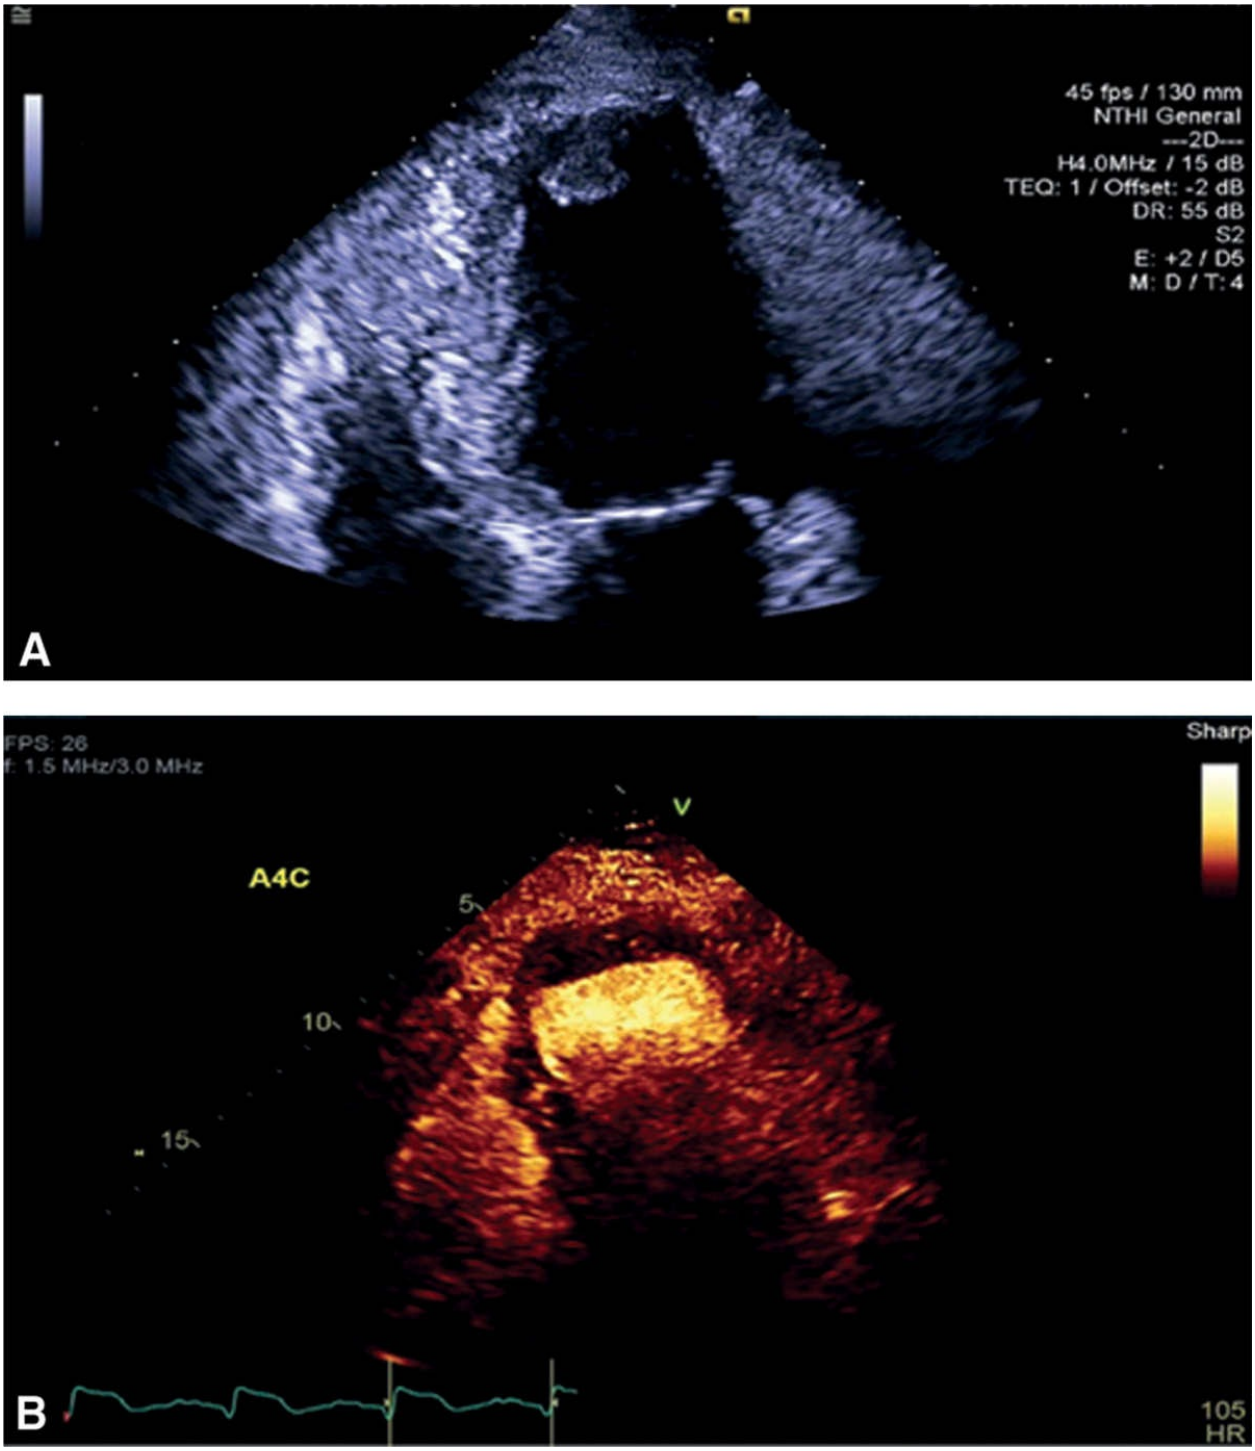

FIGURE 13.19 A, Apical four-chamber view of a transthoracic echocardiogram demonstrating a large left ventricular apical thrombus. B, Injection of an echo-contrast agent delineates the linear appearance of this large apical thrombus.

Current data on the correct treatment of LV thrombi is lacking. There are no large-scale trials that direct treatment; however, it is generally recommended that

patients who have an apical clot will receive full anticoagulation with traditional anticoagulant therapy, that is, warfarin. They should be initiated with heparin and converted to full-dose warfarin for at least 3 months with a goal international normalized ratio between 2 and 3.[1]

CONCLUSION

As outlined, mechanical complications of an AMI are important to recognize, to diagnose, and, especially, to treat. Recognizing the most important signs and symptoms should prompt an immediate echocardiogram and, in most cases, this may lead to surgical intervention. Most therapies carry with them a poor prognosis, but surgery is clearly a better option with improved survival over medical therapy alone. Physicians in cardiac care units (CCUs) must grasp all of these concepts to provide proper medical care.

Patient and Family Information for: MECHANICAL COMPLICATIONS OF MYOCARDIAL INFARCTION

For decades, heart disease has consistently been the leading killer in the world. When a family member or loved one has a heart attack, it can be a terrifying experience for everyone involved. Most of the time, everything goes smoothly, and that family member or loved one walks out of the hospital with a new outlook on life. However, there are occasions when a patient's condition can rapidly deteriorate and circumstances drastically change. These potential complications can happen at home, in transit to the hospital, in the emergency room, or even in the CCU. An understanding of the complications that go hand in hand with an acute heart attack is crucial for comprehending the nature of the disease.

The heart is the most important muscle in the human body. Like all muscles, it needs oxygen to live. However, unlike all muscles, it continuously beats around 100,000 times a day. A heart attack involves the blockage of blood flow to that muscle; this results in the cutting off its oxygen supply, for all intents and purposes, suffocating the muscle. Without oxygen, the heart muscle will die. The intense chest pain that a patient senses during an acute heart attack is due to this muscle death. Relieving that blockage will restore blood flow to the damaged muscle, replenish its oxygen supply, and hopefully allow it to live. The timely nature of this intervention is paramount to the heart's survival.

Prompt recognition and initiation of therapy for an acute heart attack is the most important factor in that patient's survival. The longer the heart muscle goes without oxygen, the faster it dies, and the worse the prognosis. The signs and symptoms of a heart attack include a left-sided or central chest pressure accompanied by any combination of shortness of breath, nausea, vomiting,

sweating, and left arm or neck pain. The moment these symptoms commence, immediate medical attention should be sought.

Doctors have various methods to relieve the obstruction, including medications and direct intervention in the blocked vessel. Medical therapy involves the administration of an IV medication called a thrombolytic. This medicine will rapidly break up the blood clot in the coronary artery that has been blocked, thereby thwarting the heart attack. Interventional therapy involves the placement a tube or “catheter” into one of several arteries in the arms or the legs that lead to the heart. These catheters are then advanced to insert directly into the coronary arteries and through the use of a moving X-ray, the thrombosis can be directly visualized and extracted. Subsequently, a little piece of hollow metal, called a “stent,” can be inserted in the artery and allow blood to freely flow to the dying heart muscle. The faster the therapy is delivered, the better. There are times when a substantial amount of irreversible damage has been done, causing the muscle to die and possibly tear, leading to life-threatening complications. There are other times when the muscle does not tear, but simply dies, and causes more chronic complications. In this chapter we discuss the disastrous complications of a heart attack.

When the heart muscle dies, it can eventually tear and cause sudden clinical deterioration and possibly death. If there is a delay in a patient’s presentation to the emergency room, therapy cannot be initiated and the heart muscle will die. This delay can be from hours to days. If there is no delay, and therapy is administered immediately, there is always a possibility that the therapy may not be completely successful, the artery will remain blocked, and the heart muscle will die anyway. This is an unfortunate reality because not all treatments are successful. On these rare occasions, the area of the heart muscle between the dead and viable tissue will completely sever. This will result in free communication between two areas of the heart, causing brisk bleeding and inevitable death. There are three such scenarios that must be promptly recognized because surgical therapy usually provides the only means for survival. These three scenarios include ventricular free wall rupture, interventricular septal rupture, and papillary muscle rupture.

It is not as important to know the intricate details of these complications as it is important to understand their deadly potential. Any sudden deterioration in clinical condition should prompt suspicion of myocardial rupture. Development of increased chest pain or shortness of breath accompanied by a new murmur on physical examination, an accelerated heart rate, and a drop in blood pressure

must be followed by an immediate echocardiogram, or ultrasound of the heart. This will provide visualization of the cardiac muscle and diagnosis of a myocardial tear. If the situation arises, IV medications can be administered to temporarily stabilize the patient, but emergent surgical intervention is paramount to provide any chance of survival.

Emergent surgery should be performed within hours of recognition of the rupture. IV medications will support the patient's blood pressure and heart rate until the operating room is ready for patient transfer. The surgical procedure will involve opening the chest wall, directly visualizing the heart, and repairing the torn tissue. Often, bypass of any blocked arteries will accompany repair of the damaged cardiac muscle. The procedure will take many hours to complete; and even if successful, the probability of eventual death is still very high. When the ruptured myocardium is repaired and the bypass complete, the patient still has a long and dangerous road ahead.

The postoperative period is every bit as important as the procedure itself. Making it out of the operating room does not mean that long-term survival is guaranteed. There are many factors such as age and comorbidities that complicate both the surgical procedure and the recovery period. The older a person is, the more unlikely it is for the person to survive such a difficult surgery and the more difficult it is to recover. Coexisting medical conditions such as asthma, emphysema, kidney disease, cancer, and diabetes, among others, all increase mortality. Friends and family must be realistic about the severity of the situation and expectations for survival. Most studies quote far less than 50% survival, with the actual numbers being less than 25%.

The left ventricle is the most important of the four heart chambers for survival. Most of what has been discussed involves damage to this all important chamber. The right ventricle is a less muscular part of the heart that can also be damaged during a heart attack. It is important to recognize RV injury, because its treatment is very different from that of garden variety LV injury. There are specific clinical signs and ECG findings that will lead to the diagnosis of an RVI. When present, a physician must be careful not to administer certain medications, such as nitroglycerin or diuretics, because they can lead to clinical deterioration. The astute medical professional can easily diagnose this situation and provide appropriate therapy. As with all heart attacks, restoring blood flow to the right ventricle will prevent poor clinical outcomes and improve survival. Surgical intervention is generally not necessary and if the patient survives to discharge, outlook is favorable.

Chronic complications of a heart attack are probably more common than the acute ones. Depending on the timing of the revascularization, a certain amount of heart muscle invariably dies. As described earlier, the longer the muscle goes without oxygen, the more of it dies. The most common phrase used is: “time is muscle.” Patients who suffer large heart attacks and do not receive adequate therapy lose large amounts of muscle forever. The heart weakens, blood does not get pumped forward as it should, and over the following weeks an aneurysm can form. An aneurysm is described as a weakening of the muscle to the point that it forms a pocket within or outside the walls of the heart. To either side of the aneurysm is living tissue, and within the aneurysm is dead tissue. Aneurysms are divided into two categories that require different therapies: true aneurysms and pseudoaneurysms.

The more common and less dangerous of the two types of aneurysms are the true aneurysms. The entire aneurysm forms a pocket that is made of dead cardiac tissue. An indentation is created in the myocardium with a wide neck that contains the aneurysm. True aneurysms are entirely made of dead myocardial tissue. Because the muscle does not contract, there is invariably stasis of blood flow within the pocket, making it prone to forming blood clots. Often, a piece of the blood clot can break off and cause many complications including stroke. True aneurysms should be treated with the same aggressive medical therapy that all heart attack patients receive. This includes but is not limited to beta-blockers, angiotensin-converting enzyme inhibitors, and aspirin. If a blood clot is present, patients should be administered blood thinners to prevent against stroke. Rarely, surgical intervention is necessary to excise the aneurysm when there is evidence of deadly arrhythmias that are resistant to medical therapy.

Pseudoaneurysms are extremely rare and are very dangerous. A pseudoaneurysm represents a contained rupture of the cardiac tissue. As has been described previously, tearing of the heart muscle results in brisk bleeding and, often, death. Occasionally, this bleeding can be contained by the thin layer of tissue surrounding the heart called the pericardium. The pericardium is a rigid layer of tissue that encases the heart and at times will seal off a myocardial rupture, thereby preventing certain death. A pseudoaneurysm forms when the pericardium bubbles outward and contains a rupture during a heart attack.

Instead of the wide neck seen in true aneurysms, a pseudoaneurysm has a narrow neck that communicates with the left ventricle. There is no dead myocardium in the pseudoaneurysm because it is entirely made of pericardium. Invariably, the pocket of the pseudoaneurysm contains a blood clot, because

there is complete stasis of blood flow. A pseudoaneurysm is prone to rupture because it consists of only the thin pericardium that has sealed off the prior rupture. When demonstrated by echocardiogram or computed tomography scan, surgical consultation is appropriate. Surgical excision of the pseudoaneurysm is the only treatment that can be offered to prevent rupture and certain death.

Both acute and chronic complications of a heart attack have become less common as medical therapy has advanced. The development of thrombolytics and interventional procedures have improved survival and drastically reduced the number of disastrous complications that can occur. In the unfortunate cases when they do occur, advancements in surgical technology and techniques have further improved the chances of survival. Even with all these advancements in therapy, however, prompt recognition and timely diagnosis can be the difference between life and death. Survival to hospital discharge is not certain when these complications occur and family members must realize that there is a long road ahead.

When a patient does survive a complication of an AMI, he or she must realize that great care must be taken to improve the likelihood of long-term survival. Outpatient follow-up with a cardiologist, surgeon, and medical doctor should be in place before discharge. The patient will invariably be on a new regimen of medications that can be extremely complicated. Survivors will often need a significant amount of rehabilitation before they can return to their pre–heart attack state. Social support and family encouragement both increase the likelihood of recovery. Patients should not leave the hospital without a strict understanding of what medications they are to take and who they are to follow up with. A structured regimen of medication compliance, physician follow-up, and cardiac rehabilitation can turn a life-threatening situation into a rewarding experience for patients, families, and all medical professionals involved.

Cardiogenic Shock Complicating Acute Myocardial Infarction

INTRODUCTION

Over the past several decades, both the incidence of acute myocardial infarction (AMI) and the mortality rate for AMI patients have shown a steady decline because of multiple factors, including effective risk factor modification as well as improved medical, surgical, and percutaneous therapies for coronary artery disease.[1–3] The incidence of cardiogenic shock complicating AMI, however, remains unaffected, and the mortality resulting from this condition remains high and is a leading cause of death among patients hospitalized for AMI.[4, 5]

Myocardial infarction–related cardiogenic shock is a heterogeneous clinical entity in both etiology and presentation but is most commonly the result of acute left ventricular (LV) dysfunction caused by extensive cardiac muscle necrosis in the setting of an ST elevation myocardial infarction (STEMI). As the stroke volume acutely declines, the heart attempts to maintain cardiac output by increasing heart rate as a compensatory response. Once this compensatory mechanism becomes inadequate, tissue hypoperfusion ensues, leading to a systemic inflammatory response, multiorgan dysfunction, and eventually circulatory collapse. This may be further precipitated by a vasodilatory response of the peripheral circulatory system, resembling a systemic inflammatory state.

Early signs of impending cardiovascular collapse may be evident on arrival at the hospital, but the majority of patients will present in a well-compensated state and progress to shock only after clinical presentation.[6]

In part because of the heterogeneity of its etiologies and manifestations, there is no universally accepted definition of cardiogenic shock. The SHOCK (SHould we emergently revascularize Occluded Coronaries for cardiogenic shocK) trial required patients to meet both clinical criteria of cardiogenic shock (sustained hypotension and end-organ hypoperfusion) and either hemodynamic confirmation with a pulmonary artery catheter or radiographic confirmation of pulmonary edema in the setting of anterior wall infarction (**Table 14.1**: SHOCK inclusion criteria for which patients should be revascularized early).[7] It is important to note that these are stringent criteria set for the purposes of a randomized control trial and that in clinical practice the myocardial dysfunction associated with ischemia exists along a spectrum: patients may meet only some of these criteria at the time of their initial evaluation.[8] In the setting of physical and biochemical findings of peripheral organ hypoperfusion despite adequate intravascular volume status, the clinician should suspect cardiogenic shock by the bedside. Recognition of early signs of falling cardiac output may facilitate earlier and more aggressive treatment of patients with a more grave prognosis (**Table 14.2**: Killip Classification, which outlines the early signs of decompensating cardiac function).[9]

TABLE 14.1 Shock Inclusion Criteria

INCLUSION CRITERIA	PARAMETERS
Ischemic criteria	ST-segment elevation, Q-wave infarction, new left bundle-branch block, or posterior infarction with anterior ST-segment depression
Clinical Criteria	Hypotension: SBP <90 mm Hg for at least 30 min or the need for supportive measures to maintain blood pressure End-organ hypoperfusion: cool extremities or urine output < 30 mL/h despite a heart rate of ≥ 60 beats/min
Hemodynamic criteria	Cardiac index ≤ 2.2 L/min/m^2, pulmonary capillary wedge pressure ≥ 15 mm Hg (not necessary if radiographic criteria are met)
Radiographic criteria	Pulmonary congestion on chest radiograph in setting of anterior wall myocardial infarction

SBP, systolic blood pressure.

TABLE 14.2 Killip Classification

KILLIP CLASS	DESCRIPTION
I	No evidence of heart failure
II	Mild heart failure: rales over one-third or less of posterior lung fields, systolic blood pressure of 90 mm Hg or higher
III	Pulmonary edema involving more than one-third of lung fields, systolic blood pressure of 90 mm Hg or higher
IV	Cardiogenic shock: extensive rales, systolic blood pressure less than 90 mm Hg

INCIDENCE

Cardiogenic shock remains an infrequent but life-threatening complication of AMI. Evidence of shock is either present on arrival or develops after admission in 4% to 10% of patients hospitalized for ST elevation AMI.[5, 10] There is significant regional variation in temporal trends in incidence over time; it remains unclear to what extent this is driven by a changing burden of disease versus being reflective of changing definitions and evolving patterns of coding and classification.[11]

ETIOLOGY AND PATHOPHYSIOLOGY

Cardiac myocytes are among the most aerobically active cells in the body and are dependent on a blood supply commensurate with their relatively high oxygen demand.[12] When this relationship is disrupted through either acute plaque rupture (type 1 myocardial infarction) or through a mismatch in supply and demand (type 2), myocyte contractility is compromised, and the heart attempts to compensate through other mechanisms. When these mechanisms are inadequate, cardiac output begins to fall, and a downward spiral toward cardiogenic shock begins (**Figure 14.1**).[13]

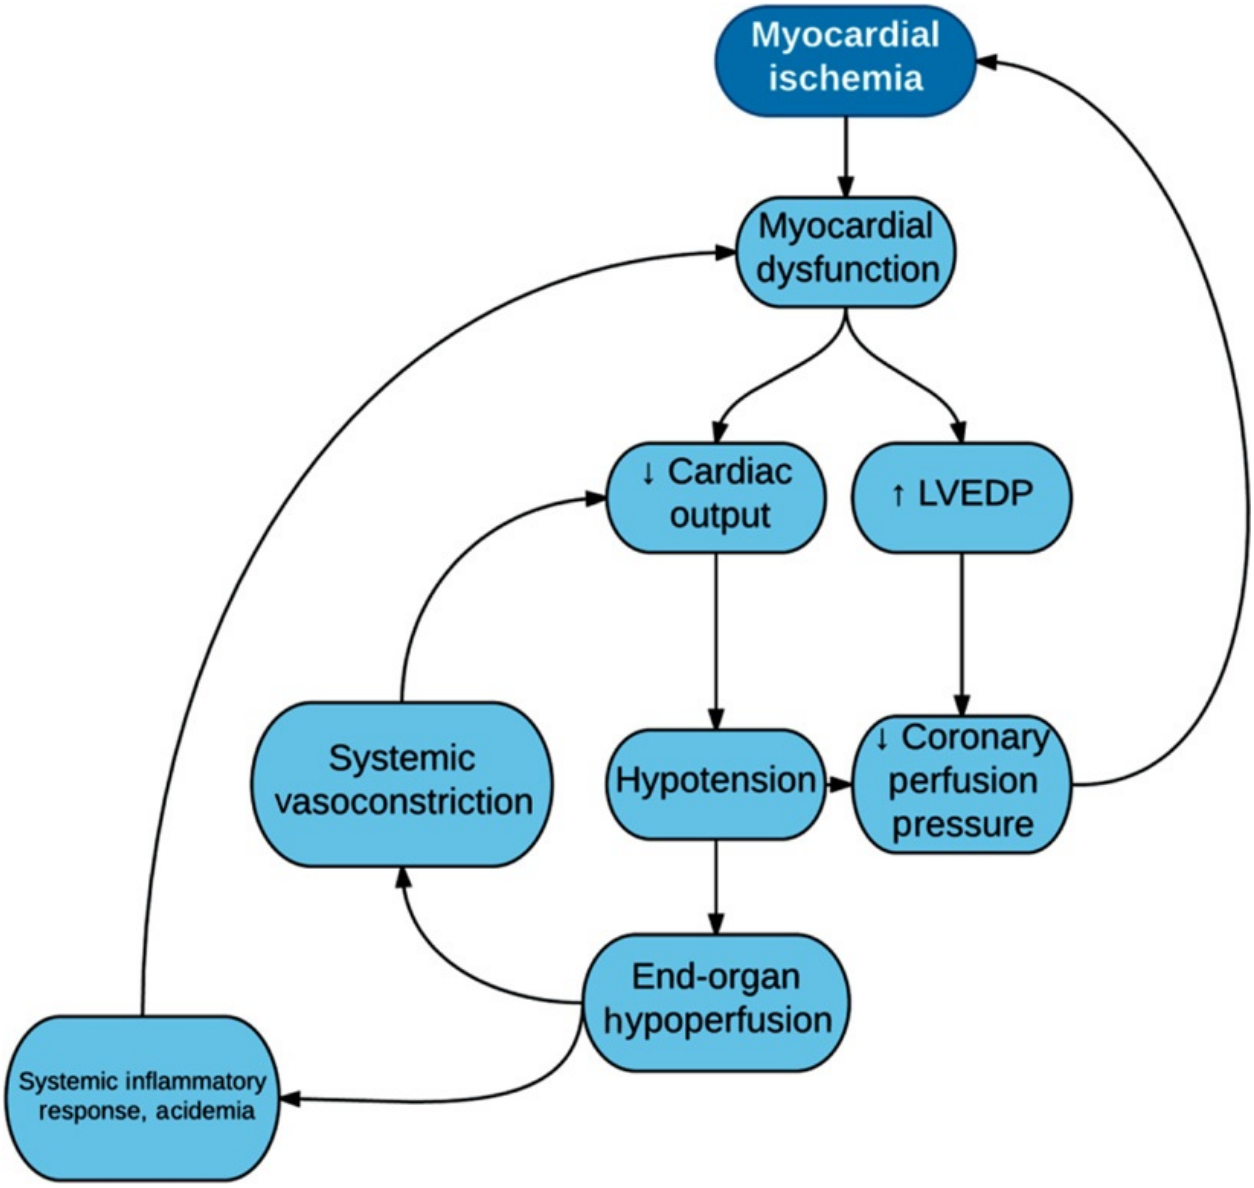

FIGURE 14.1 The hemodynamic and biochemical decompensation cascade of cardiogenic shock. LVEDP, left ventricular end diastolic pressure.

Coronary perfusion occurs primarily during diastole and is dependent on the gradient between the proximal aortic pressure and the left ventricular end diastolic pressure (LVEDP). As cardiac output begins to fall, LVEDP begins to rise and diastolic pressures begin to decrease, further reducing the coronary perfusion gradient in the culprit vessel as well as the coronary circulation as a whole. This can result in remote ischemia in the noninfarct regions and further compromises cardiac output, creating a vicious spiral that culminates in frank circulatory collapse.

Beyond the immediate hemodynamic effects, a similarly injurious biochemical cascade begins. The fall in cardiac output leads to a reflexive activation of the sympathetic nervous system and an ensuant catecholamine surge; renal hypoperfusion also activates the renin–angiotensin–aldosterone axis. The resulting increase in heart rate and vasoconstriction lead to an increase in myocardial oxygen demand through increased wall stress, heart rate, and contractility.

In parallel to this, tissue destruction related to both local myocardial ischemia and systemic end-organ damage leads to acidemia and the release of inflammatory cytokines, including IL-6; these trigger an increase in nitric oxide synthase production in vascular smooth muscle cells. This vasodilator response may be a dominant feature in a proportion of patients with cardiogenic shock. Both nitric oxide and acidemia itself may act as negative inotropes and exacerbate an acute decline in cardiac function.[14, 15]

In addition to the direct myocardial dysfunction and sequelae described above, AMI may also result from several mechanical complications, including mitral regurgitation (caused by acute LV dilatation or papillary muscle ischemia/rupture), ventricular septal rupture, or ventricular free wall rupture. Although relatively uncommon, early comprehensive bedside echocardiography is critical to rule out these complications because they portend a worse prognosis and mandate consideration for surgical intervention.

It is important to maintain a wide differential in patients with hemodynamic instability to ensure that syndromes with similar presentations such as underresuscitated sepsis or hemorrhagic shock are not missed. Noncoronary cardiovascular emergencies such as acute thoracic aortic dissection, pulmonary embolism, myocarditis/pericarditis, tension pneumothorax, and tamponade should also be considered and ruled out with further testing if necessary.

MANAGEMENT

DIAGNOSIS

The cornerstone of management of cardiogenic shock is prompt recognition and accurate diagnosis of the dominant mechanism affecting circulatory instability. A quick but comprehensive history should be taken with a focus on determination of risk factors, comorbidities, medication use, and allergies (particularly to antiplatelet agents or to contrast medium). A focused physical exam should also

be performed to screen for mechanical or valvular etiologies of shock (eg, a murmur suggestive of ventricular septal rupture or of acute mitral regurgitation) as well as to look for evidence of early cardiogenic shock (including but not limited to impaired mentation, cool extremities, pulmonary congestion, or an elevated jugular venous pressure).

STABILIZATION AND RESUSCITATION

In concurrence with planning for emergent revascularization, a physiologic baseline for the patient should be established and early resuscitative measures initiated. Initial measurements of relevant biomarkers such as cardiac enzymes (troponin T and CK-MB) and lactate should be made. Adequate intravascular volume status should be confirmed clinically if not invasively.

We perform routine invasive hemodynamic monitoring in this patient population. Placement of a pulmonary artery catheter receives a class I recommendation from the American College of Cardiology for patients with respiratory distress or clinical evidence of impaired perfusion in whom the adequacy or excess of intracardiac filling pressures cannot be determined from clinical assessment.[16, 17] A right heart catheter enables continuous monitoring of vital hemodynamic parameters such as cardiac index, cardiac power, and mixed venous oxygen saturations, all of which are strong prognostic outcome variables. It also enables quantification of systemic vascular resistance (SVR), which helps gauge the response of the periphery to the acute myocardial insult. Similarly, invasive arterial blood pressure monitoring is useful to assess the real-time response to vasoactive therapies or when indirect blood pressure monitoring is unreliable.

If hypotension persists despite adequate filling pressures, pharmacologic or mechanical support should be initiated. If a vasopressor is required, norepinephrine should likely be used over dopamine. A recent randomized trial failed to show a significant difference between norepinephrine and dopamine across all subtypes of shock; however, a predefined subgroup analysis of patients with cardiogenic shock showed a significant increase in mortality with dopamine therapy.[18] Vasopressin may also be considered in cases with persistently low SVR.

MECHANICAL CIRCULATORY SUPPORT

Although vasopressor therapy may play a critical role in temporizing a patient

with impending circulatory collapse, this must be weighed against the associated risks, including tachyarrhythmia, peripheral vasoconstriction leading to distal malperfusion, and an increase in myocardial oxygen demand triggering worsening myocardial ischemia. More definitive support can be offered by a mechanical assist device. Although mechanical support is not a new therapy and placement of an intra-aortic balloon pump (IABP) was an integral component of the early revascularization strategy of the SHOCK trial, other durable options have become available in recent years.

Mechanical circulatory support (MCS) devices fall into three primary categories: pulsatile flow devices (IABP), axial continuous-flow devices such as the Impella (with flow from left ventricle to aorta), and centrifugal continuous-flow devices such as the TandemHeart (with flow from left atrium to femoral artery) and venoarterial extracorporeal membrane oxygenation (VA-ECMO). In addition to different positions and modalities of support, each of these devices differs in the extent to which it is able to support the circulation of a patient with worsening left-sided cardiogenic shock (as seen in **Table 14.3**).[19]

TABLE 14.3 Mechanical Circulatory Support Devices

	IABP	IMPELLA	TANDEMHEART	VA-ECMO
Output	0.3–1 L/min	1–5 L/min	2.5–5 L/min	3–7 L/min
Flow/mechanism	Aortic counterpulsation	LV to aorta continuous flow	LA to aorta continuous flow	Venous to arterial continuous flow (multiple configurations possible)
Preload	↓	↓↓	↓↓	↓
Afterload	↓	↓	↑	↑↑
Contraindications	Severe AI Severe PAD	Severe AI, critical AS, mechanical AVR Severe PAD Contraindication to anticoagulation LV thrombus	Severe AI Severe PAD Contraindication to anticoagulation VSD LA thrombus	Severe AI Severe PAD Contraindication to anticoagulation

AI, aortic insufficiency; AS, aortic stenosis; AVR, aortic valve replacement; IABP, intra-aortic balloon pump;; LA, left atrial; LV, left ventricular; PAD, peripheral arterial disease; VA-ECMO, venoarterial extracorporeal membrane oxygenation; VSD, ventricular septal defect..

The IABP is the most familiar, readily available, and easily insertable of the percutaneous MCS options. It is typically inserted transfemorally: arterial access

is obtained via the femoral artery, followed by advancement of a guidewire into the aorta; the balloon pump is subsequently advanced over the wire and placed in the descending aorta distal to the takeoff of the left subclavian artery. Once connected, the balloon pump is controlled either through electrocardiogram (ECG) gating or through pressure transduction to inflate during diastole and actively deflate during systole. This leads to a decrease in afterload because of the active deflation during LV ejection, augmenting cardiac output and reducing myocardial oxygen demand. In addition, the inflation during diastole raises the coronary perfusion pressure. IABP utilization is contraindicated in patients with severe aortic regurgitation, severe peripheral arterial disease, or significant coagulopathy. The most commonly used balloon size shifts approximately 40 mL of blood per inflation and increases cardiac output by up to 1 L/min.[20]

The Impella family of devices is offered in three primary sizes, two of which may be inserted percutaneously (the Impella 2.5 and CP) and one that must be inserted via surgical cutdown (the Impella 5.0). As with the IABP, these are typically inserted transfemorally. Arterial access is obtained via the femoral artery, followed by insertion of a guidewire. An introducer is advanced over the guidewire, and a diagnostic catheter is advanced into the left ventricle; a placement guidewire is then inserted into the apex of the ventricle, and the diagnostic catheter is removed. The Impella is then inserted over this guidewire and positioned so that it sits across the aortic valve with the inlet area 3 to 3.5 cm below the aortic annulus and the outlet in the ascending aorta. It is contraindicated in severe aortic stenosis or regurgitation; severe peripheral arterial disease; and in patients with mechanical aortic valves, LV thrombi, or contraindications to anticoagulation. The degree of support offered varies with device size: The Impella 2.5 offers up to 2.5 L/min of support, the CP offers up to 3.5 L/min, and the Impella 5.0 offers up to 5 L/min.[19] When long-term temporary support is anticipated, the Impella 5.0 is often placed via the axillary approach using a graft.

The TandemHeart device is also typically inserted transfemorally. Venous access is obtained via the femoral vein; a transseptal puncture technique is then used to enter the left atrium, and a guidewire is advanced into the left atrium. An inflow catheter is then inserted over this to access the left atrium, where it drains oxygenated blood back to the centrifugal pump of the TandemHeart. This oxygenated blood is then reintroduced into the circulation in the femoral artery. Contraindications include uncontrolled bleeding diatheses or contraindications to anticoagulation, severe aortic regurgitation, and left atrial thrombi. It offers up to

4.5 L/min of support.

VA-ECMO offers both the capability of biventricular support as well as treatment of concomitant respiratory and circulatory collapse. It is most often inserted in a femoral vein to femoral artery fashion but can be performed in a wide variety of configurations. Regardless of the site of insertion, deoxygenated blood is drained via a venous inflow catheter into a centrifugal pump, oxygenated, and reintroduced into the arterial circulation. Contraindications include severe aortic insufficiency, severe peripheral arterial disease, and contraindications to anticoagulation. It offers the most extensive hemodynamic support of current MCS devices, with up to 7 L/min of flow. When placed peripherally, it is important to place an antegrade cannula to perfuse the distal limb and avoid ischemic complications.

Most recently, percutaneous right ventricular assist devices have emerged as an option for patients with refractory cardiogenic shock in the context of isolated right ventricular failure. Early data suggest promising outcomes, but the technical difficulty of device insertion and relatively good prognosis for isolated right ventricular infarction may limit widespread use.[21]

Although options for MCS have proliferated in recent years and their use is rapidly becoming more widespread, the evidentiary base to support their more frequent use has lagged behind.[22] Trials comparing the newer MCS options versus IABP in cardiogenic shock complicating AMI have largely been underpowered, and although some have shown superiority in improvement of hemodynamic parameters, there is to date little evidence supporting a mortality benefit.[23, 24] Given equivocal clinical benefits and significantly higher cost associated with percutaneous ventricular assist devices (VADs), IABP may remain the preferred first-line choice for cardiogenic shock, with escalation to more support only when necessary.[25]

REVASCULARIZATION

Early diagnostic angiography and subsequent percutaneous or surgical revascularization should be pursued in patients with cardiogenic shock complicating either STEMI or non–ST elevation acute coronary syndrome. This is a class I recommendation for both patient populations and is driven primarily by findings from the SHOCK trial.[7,26,27] The SHOCK trial randomized 302 patients with AMI complicated by cardiogenic shock to either medical therapy alone (with delayed revascularization if needed) or to emergent revascularization

via either coronary artery bypass grafting (CABG) or percutaneous coronary intervention (PCI) within 6 hours of randomization. Compared with medical therapy alone, urgent revascularization was associated with a nonsignificant reduction in 30-day all-cause mortality (46.7% vs 56.0%, $P = 0.11$); a lasting survival benefit was conferred with revascularization and was found to be significant at 6 months postrandomization (50.3% vs 63.1%, $P = 0.027$).

The ideal mode and extent of revascularization is an area of ongoing debate. For patients with only one- or two-vessel disease (including isolated left main disease), PCI of the infarct-related artery can be performed at the time of initial angiography.[28] The role for revascularization of nonculprit lesions is less clear; although restoration of blood flow to a wider area of the myocardium has strong theoretical benefits, this must be balanced against the additional procedural risk and contrast exposure inherent to a more extensive coronary intervention. Current guidelines recommend consideration of nonculprit vessel revascularization in the setting of broadly defined hemodynamic instability; although this is supported by observational studies and registry analysis, there is a paucity of randomized data.[29, 30] The ongoing CULPRIT-SHOCK trial will randomize patients with shock complicating AMI to either immediate multivessel PCI or to PCI of the culprit lesion only and should help to narrow this evidence gap.[31]

Emergent CABG offers definitive revascularization to patients with multivessel disease. In addition, prompt cardiopulmonary bypass may rescue a patient with impending circulatory collapse and halt the cycle of worsening end-organ perfusion described earlier. Within the SHOCK trial, CABG was recommended for patients with a left main stenosis of ≥ 50%, two or more total or subtotal occlusions, or stenoses of > 90% in two noninfarct major epicardial vessels. Based on these criteria, approximately 36% of patients in the emergent revascularization arm underwent CABG. Despite being a higher-risk population (higher incidence of diabetes, three-vessel disease, and left main disease), patients treated with CABG had similar rates of survival as those treated with PCI. In clinical practice, however, less than 5% of patients with cardiogenic shock currently receive early CABG.[11] Analysis of the National Cardiovascular Data Registry shows increasing rates of PCI in this setting, with only a small minority referred for CABG over a similar time frame.[32] Percutaneous intervention with its implicit commitment to dual antiplatelet therapy may preclude definitive surgical revascularization in these patients; it should thus be kept in mind that emergent CABG remains the treatment of choice and should be

considered for patients with complex left main disease, severe three-vessel disease not amenable to PCI, or with concurrent mechanical complications of AMI.

PERSISTENT SHOCK

Cardiogenic shock may not resolve despite aggressive revascularization and appropriate initial support. Persistent shock despite revascularization should prompt a reevaluation of the patient's situation with a focused physical examination, consideration of pulmonary artery catheter insertion if not already performed, and repeat echocardiography (**Figure 14.2** outlines the management of persistent shock).

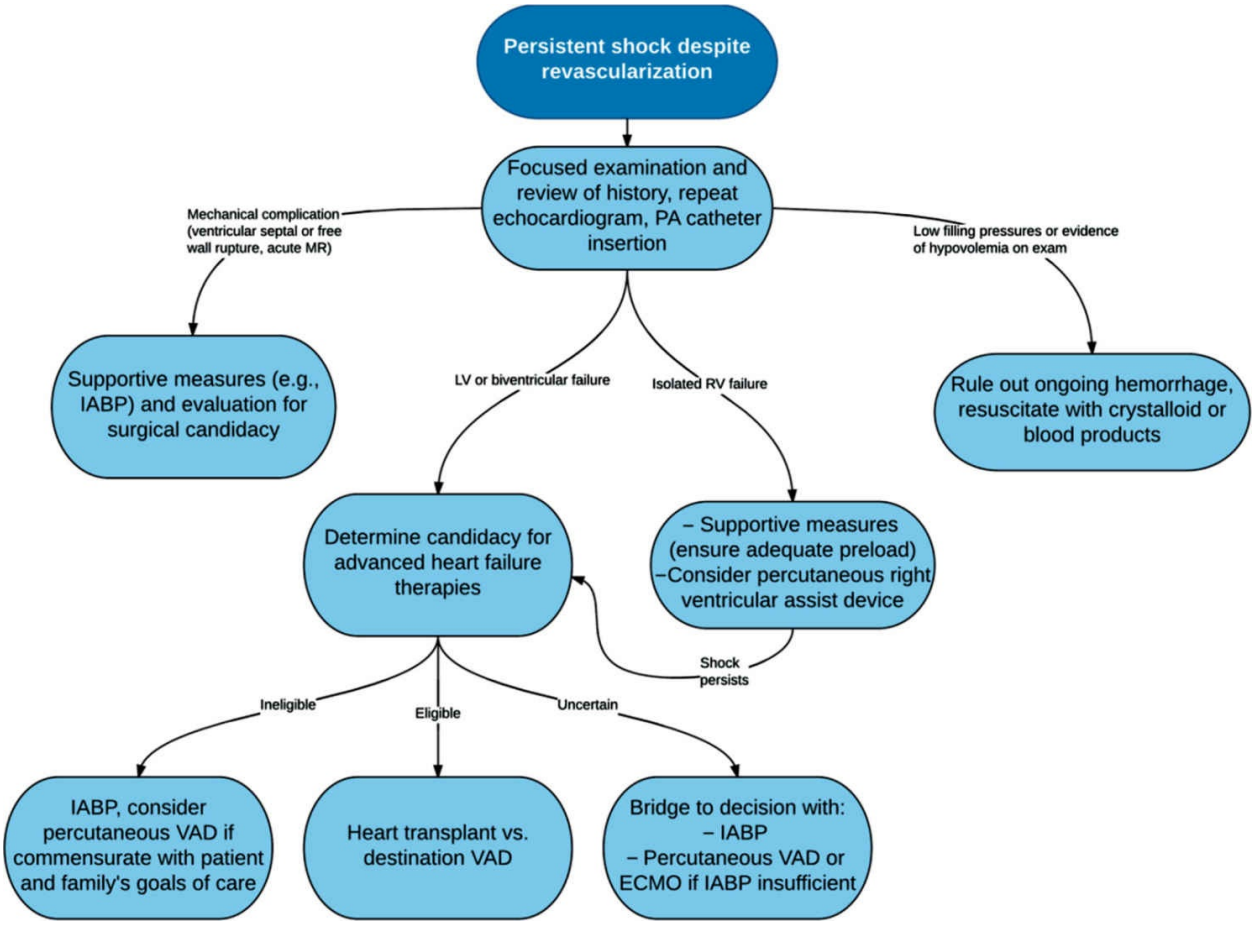

FIGURE 14.2 Management of persistent shock. ECMO, extracorporeal membrane oxygenation; IABP, intra-aortic balloon pump; LV, left ventricular; MR, mitral regurgitation; PA, pulmonary artery; RV, right ventricular; VAD, ventricular assist device.

If persistent shock resulting from LV failure is confirmed, the patient's eligibility for advanced heart failure therapies (ie, transplantation or destination left ventricular assist device) should be assessed; if they are an appropriate candidate, an expedited evaluation should be initiated. If the patient is ineligible, a percutaneous VAD may still be an option, but this should be discussed in the context of the goals of care of the patient and family. If candidacy is unclear initially, consideration should be given to deploying a bridge-to-decision MCS. In patients with a dismal prognosis, especially those with poor prior functional status, significant comorbidities, especially established renal failure, palliative options should be considered.

DISCHARGE PLANNING

Survivors of cardiogenic shock after AMI will require aggressive medical management for secondary prevention. High-intensity statin therapy, smoking cessation, weight loss, and management of other risk factors should be emphasized before their discharge. All patients should be referred to cardiac rehabilitation at discharge. LV ejection fraction should be assessed both before discharge and again 6 weeks after their acute event to determine eligibility for implantable cardiac defibrillator insertion.

SUMMARY

Despite advances in medical therapy and revascularization techniques for coronary artery disease, cardiogenic shock remains a major source of morbidity and mortality among patients hospitalized with AMI. The mainstay of treatment of cardiogenic shock is early recognition, followed by prompt treatment of the underlying cause (with surgical or percutaneous revascularization) while providing appropriate hemodynamic support.

Patient and Family Information for: CARDIOGENIC SHOCK COMPLICATING ACUTE MYOCARDIAL INFARCTION

DEFINITION

Every organ in the body requires a continuous supply of oxygen in order to function properly. Blood, pumped by the heart, is what carries oxygen to all the organs. If the pumping function of the heart becomes weak enough that it is unable to provide sufficient blood flow to the organs, the body begins to shut down, and this is known as *cardiogenic shock*. Many different conditions can cause cardiogenic shock, but the most common one is *myocardial infarction*, also known as a heart attack.

As with the rest of the organs in the body, the human heart also requires a constant supply of oxygen. The *coronary arteries* carry the oxygen-carrying blood to the heart tissue. If this blood flow is interrupted by a blockage in one or more of the coronary arteries, a heart attack results because oxygen cannot get to the portion of the heart that has the blockage. The heart tissue stops functioning properly when blood flow is disrupted, and it can die if it lacks blood flow for long enough. Large heart attacks can cause such significant damage to the heart that it is unable to pump strongly enough for the blood to reach all the organs in sufficient amounts. When this occurs, it is known as cardiogenic shock.

SIGNS AND SYMPTOMS OF CARDIOGENIC SHOCK

Patients with cardiogenic shock will often complain of shortness of breath. Other symptoms such as chest, neck/jaw, or arm pain are also common in patients with cardiogenic shock caused by a heart attack. As a result of the weak condition of the heart, patients with cardiogenic shock will often have low blood pressures and high heart rates. It is also common for patients to be confused, have cool skin, and make only minimal amounts of urine.

MANAGEMENT AND TREATMENT

Cardiogenic shock is a medical emergency, and patients with this condition need urgent care in a critical care unit. When physicians are concerned that cardiogenic shock is present, they will act quickly in an attempt to gather information to see the cause of the shock. Blood work will be obtained to determine the amount of red blood cells in the body, how well the kidneys are functioning, and an ECG, which is a tracing of the heart rhythm, will be done to see if a patient is having a heart attack. Patients will have intravenous (IV) lines placed in their blood vessels so that medicines that act quickly can be given. At times, it may even be necessary to place a large (IV) line, known as a central venous line, so that numerous medications can be given at the same time. Patients will also receive an echocardiogram, which is an ultrasound, to be able to see the pumping function of the heart and to be able to evaluate the heart structures.

Patients who have evidence of an ongoing heart attack need blood flow to the heart restored quickly in order to minimize the amount of heart damage. Some hospitals have the ability to perform cardiac angiography, which is a procedure that allows for identification of the blocked artery. If there is a blockage, using balloons and *stents*, which are devices that prop the blood vessel open, blood flow can be restored to the heart. Some patients have such severe blockages that they require emergency *coronary artery bypass surgery* to restore blood flow or fix defects in the heart caused by the heart attack. If the nearest hospital that performs catheterization is too far away or not available in a timely manner, some patients may be treated with medications designed to dissolve the blood clot in the coronary artery.

Patients who have blood flow restored through one of these methods (or in patients with cardiogenic shock resulting from a cause other than a myocardial infarction) may require a mechanical assist device that improves the heart’s

ability to pump blood to the remainder of the body. The oldest and most commonly used device is an *IABP*. The IABP sits in a large blood vessel near the heart and inflates and deflates in a way that maximizes blood flow to both the heart and the rest of the body. Other types of mechanical assist devices are the Impella, TandemHeart, and ECMO, which are catheter-based heart pumps. The Impella is placed inside the heart chamber and uses a motor to pump the blood from the heart to the arteries that will carry the blood to the rest of the body. TandemHeart is a continuous-flow assist device that sits outside the heart. The pump withdraws oxygenated blood from the left upper chamber of the heart (the left atrium) and propels it by a magnetically driven, six-bladed impeller through the outflow port, and returns it to the arteries. ECMO uses technology derived from heart and lung bypass that allows gas exchange outside the body as well as providing circulatory support. Patients with cardiogenic shock are also often treated with *mechanical ventilators* to assist with breathing, have *pulmonary artery catheters* placed to measure blood pressures, and are given medications that improve the function of the heart.

OUTCOMES/QUALITY OF LIFE

Cardiogenic shock is a serious problem that results in the death of one out of every two patients; however, survival in patients with heart attacks can be improved with the rapid restoration of blood flow to the heart. The amount of time, size, and area of the heart that is without blood flow are the most important factors in determining whether patients will survive heart attacks complicated by cardiogenic shock. Other factors that are critical in determining how well a patient will do is the heart function, age of the patient, kidney function, and other illnesses or comorbidities that the patient has to simultaneously battle.

Although patients with cardiogenic shock are at high risk of death, about half of all patients will survive. Patients who had a normally functioning heart before the event that led to the cardiac shock and who survive their hospitalization have good outcomes and can live for long periods of time. In fact, the vast majority of patients who survive cardiogenic shock and are discharged home will have minimal signs of heart failure one year after their hospitalization.

SUMMARY

Cardiogenic shock is a serious problem that can result in death. The most common cause of cardiogenic shock is a major heart attack. The treatment of patients with heart attacks begins with rapid restoration of blood flow to the heart by either opening up a blocked coronary artery or by bypassing the diseased arteries with surgery. After blood flow is restored, patients are treated supportively with MCS devices and medicines to improve the function of the heart. Despite the high risk of death, patients who were healthy before their illness and can survive the hospitalization have a good chance of resuming a normal life.

Hypertrophic Cardiomyopathy

INTRODUCTION

Hypertrophic cardiomyopathy (HCM) is characterized by hypertrophy of the left ventricular (LV) myocardium without ventricular dilatation. It occurs without a secondary cause such as hypertension or systemic disease, and is marked by variable morphologic, clinical, and hemodynamic abnormalities. HCM is one of the great masqueraders of cardiology. It may be mistaken for coronary artery disease as it presents with typical angina chest pain owing to myocardial ischemia in the absence of epicardial coronary stenosis resulting from supply and demand mismatch. It is additionally misleading when HCM presents with ST depressions, T-wave inversions, or pathologic Q waves. It may masquerade as mitral or aortic valve disease with a systolic murmur and heart failure symptoms. It can also be mistaken as pulmonary disease with symptoms of dyspnea on exertion. Tragically, patients with HCM can be asymptomatic until their initial presentation is sudden death, which can occur at rest or on the athletic playing field. With this wide diversity of possible presentations, HCM patients are not infrequently encountered in the cardiac care unit (CCU), and therefore an understanding of the disease is vital in its diagnosis and therapy. The pathophysiology includes the understanding and interplay of the following factors: LV outflow obstruction, concurrent mitral regurgitation, myocardial ischemia, atrial fibrillation (if present), sudden death, diastolic dysfunction, and

aspects of molecular biology and genetics. Diagnostic testing with transthoracic echocardiography (TTE), nuclear scintigraphy, exercise stress testing, cardiac catheterization, 24-hour electrocardiogram (ECG), and cardiac magnetic resonance imaging (cMRI) may be applied. Treatment may involve pharmacologic agents, the implanted defibrillator, surgical septal myectomy, transcoronary intervention in the form of alcohol septal ablation (ASA), or, in very rare cases, pacing.[1]

GENETICS

HCM is inherited as an autosomal dominant trait and occurs in 1:500, or about 0.2% of the general population. Emerging data from genetic population-based studies suggest an increased prevalence of HCM estimated to be 1:200 people or greater.[2] The risk of transmission is 50% from an affected parent, but the mutation may also occur sporadically. Missense (insertions or deletions occur less frequently) mutations of at least 11 genes that code for components of the myocardial sarcomere such as the thick myosin filament, intermediate filament, thin actin filament, Z-disc, or supporting proteins have been identified as a cause of HCM. The most common mutations (accounting for the majority of established mutations) found are in the ***β***-myosin heavy chain and myosin-binding protein C. Despite the presence of a known gene mutation, there is a wide variation in phenotype, and some genes demonstrate higher penetrance compared to others.[3] In a cohort of referred, unrelated patients with HCM who underwent gene testing for the eight most common mutations, 38% of the patients were found to have sarcomeric mutations. The remainder were noted to be genotype negative. Younger age at diagnosis, marked wall thickness, and a family history of HCM increased the frequency that a patient will be found to be gene positive.[4] Once a patient is identified to have HCM, all first-degree family members should be referred for clinical or genetic screening. Genetic screening should be performed in an experienced laboratory, and preceded by genetic counseling so that an informed decision can be made by the patient and their family regarding the possible results and subsequent management. In addition, multiple concurrent mutations may portend increased severity of disease.[1] In patients who have a positive genotype with negative phenotype (absence of hypertrophy), first-degree family members where a known mutation was not identified in the index case, or if genetic screening was discussed and declined,

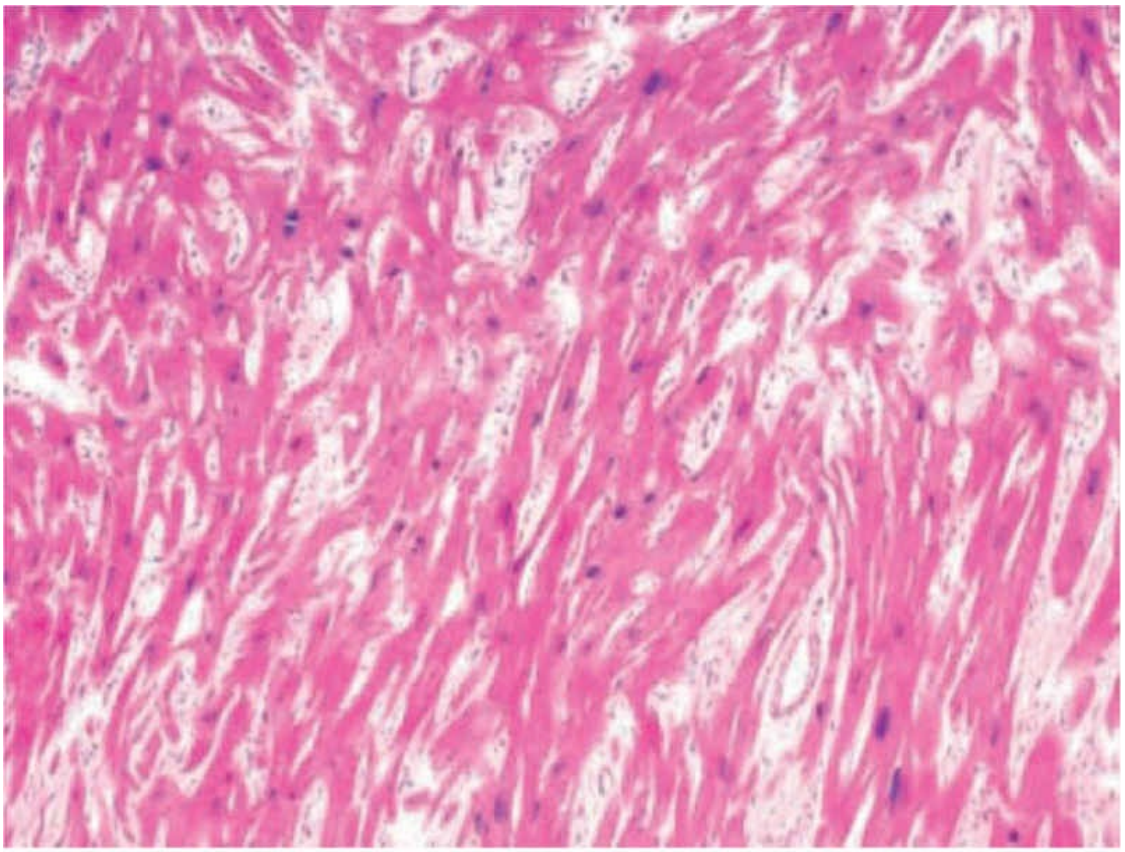
regular clinical screening via physical examination, ECG, and transthoracic echocardiogram should be utilized. This should be performed every 12 to 18 months for children and adolescents, and transitioned to every 5 years in adulthood.

Echocardiographic appearance also appears to predict a high likelihood of sarcomeric mutation in HCM; a reversed septal curvature causing a crescent-shaped LV cavity predicts gene-positive patients as compared with those with localized subaortic bulge and preserved septal curvature.[5] Although most genetically determined HCM occur on eight genes, many hundreds of HCM-causing mutations are dispersed over many gene loci. These genes may cause different phenotypes and may have different prognoses. Even among families with the same mutation on a particular locus, individuals vary with respect to phenotype and prognosis. This has markedly delayed genotype–phenotype correlation. The pathophysiologic linkage between mutations and hypertrophy appears to be mediated by mutation-induced functional abnormalities, most often because of increased contractile function. Recent theories about cause of hypertrophy have focused on inefficient utilization of ATP.

PATHOPHYSIOLOGY

On light microscopy, myocyte hypertrophy is noted, particularly in the subendocardium, as well as extensive myocardial fiber disarray—the combination of the two represent the pathognomonic abnormality. In normal individuals, myocytes are arranged in a linear and parallel configuration. However, patients with HCM demonstrate myocytes that are oblique or perpendicular to each other **(Figure 15.1)**. Furthermore, the nucleus of the cardiac myocyte is affected. Rather than having a central nucleus, enlarged nuclei are noted with pleomorphism and hyperchromasia. The myocyte myofibrillary architecture, which can be observed with phosphotungstic acid hematoxylin stain, is also disordered. Myocyte fiber disarray can be noted in other diseases, but myocyte hypertrophy and the percentage of the involved myocardium is less than 10%.[6] The interstitial connective tissue is also overly prolific with extensive fibrosis and is thought to account for the reduced LV chamber compliance and diastolic dysfunction seen **(Figure 15.2)**. Fiber disarray and myocardial fibrosis are thought to predispose to electrical reentry and sudden cardiac death (SCD). The coronary vasculature is not exempt from

adverse changes—smaller intramural arteries show intimal and medial smooth muscle hyperplasia and medial fibrosis, resulting in luminal narrowing **(Figure 15.3)**. The capillaries are similarly affected. These narrowings are thought to contribute to ischemia, which is well documented in HCM. Epicardial arteries can also be involved, less likely with stenosis than with myocardial bridging, which is noted in 15% to 30% of patients with HCM.



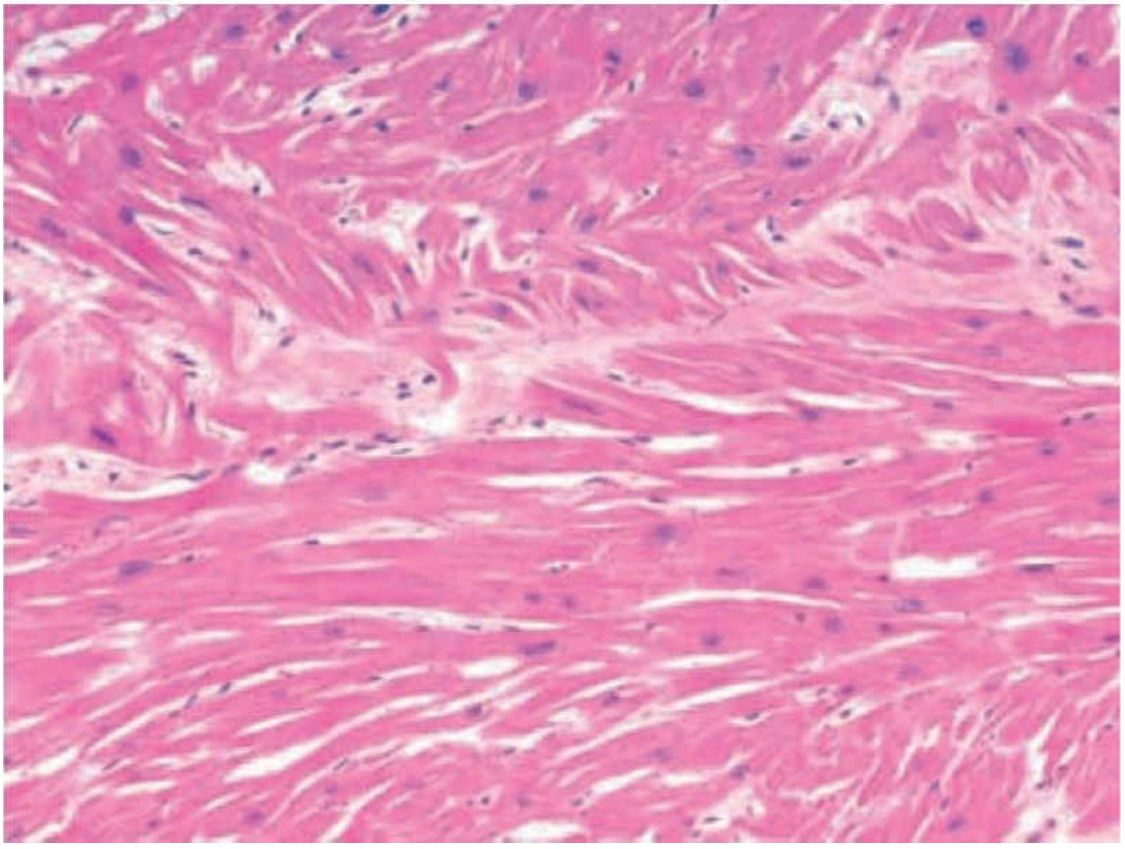


FIGURE 15.1 On light microscopy, myocyte hypertrophy is noted with extensive myocardial fiber disarray —the myocytes are oblique or perpendicular to each other, rather than being arranged in a linear and parallel configuration.

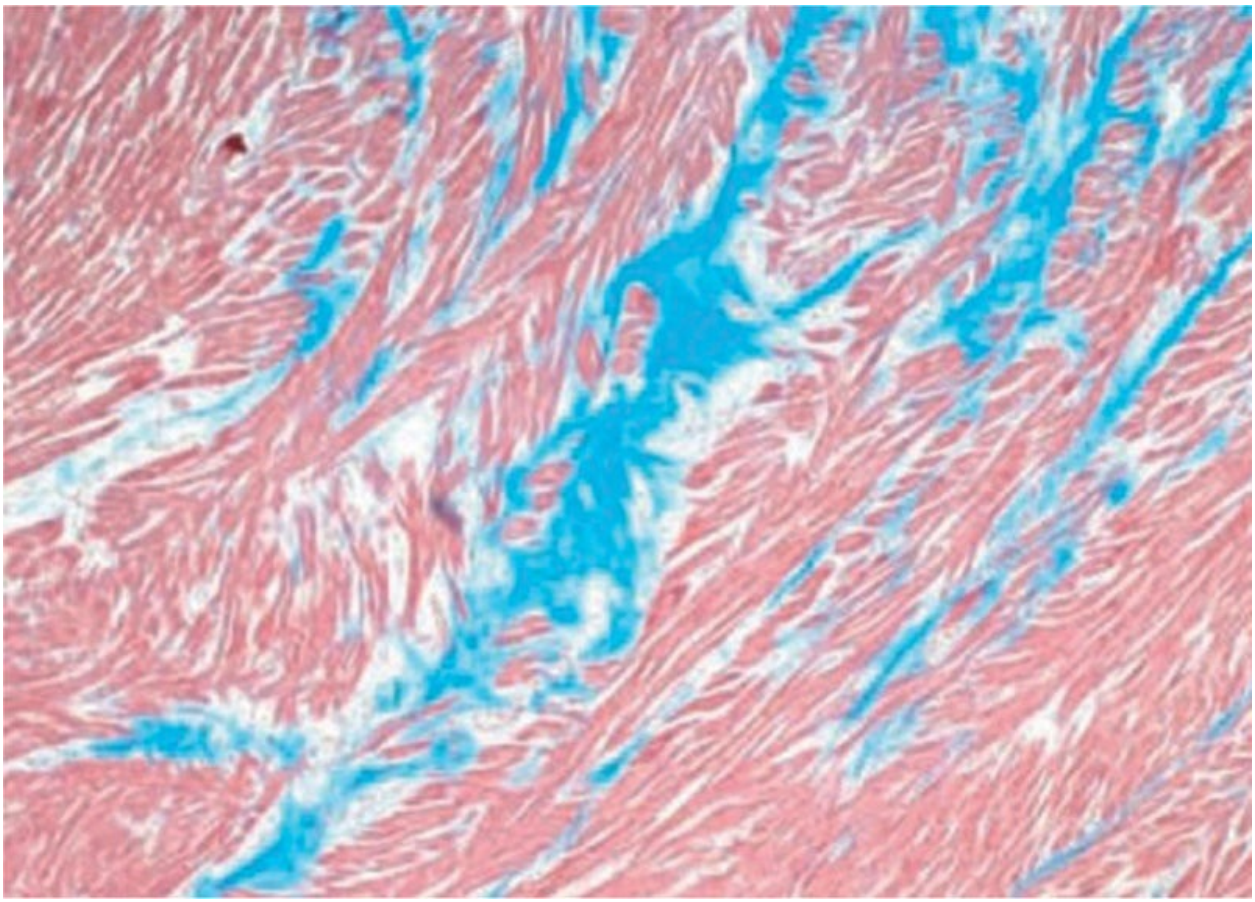

FIGURE 15.2 A modified Masson's trichrome stain of the myocardium is shown above and demonstrates extensive interstitial fibrosis with myocyte disarray.

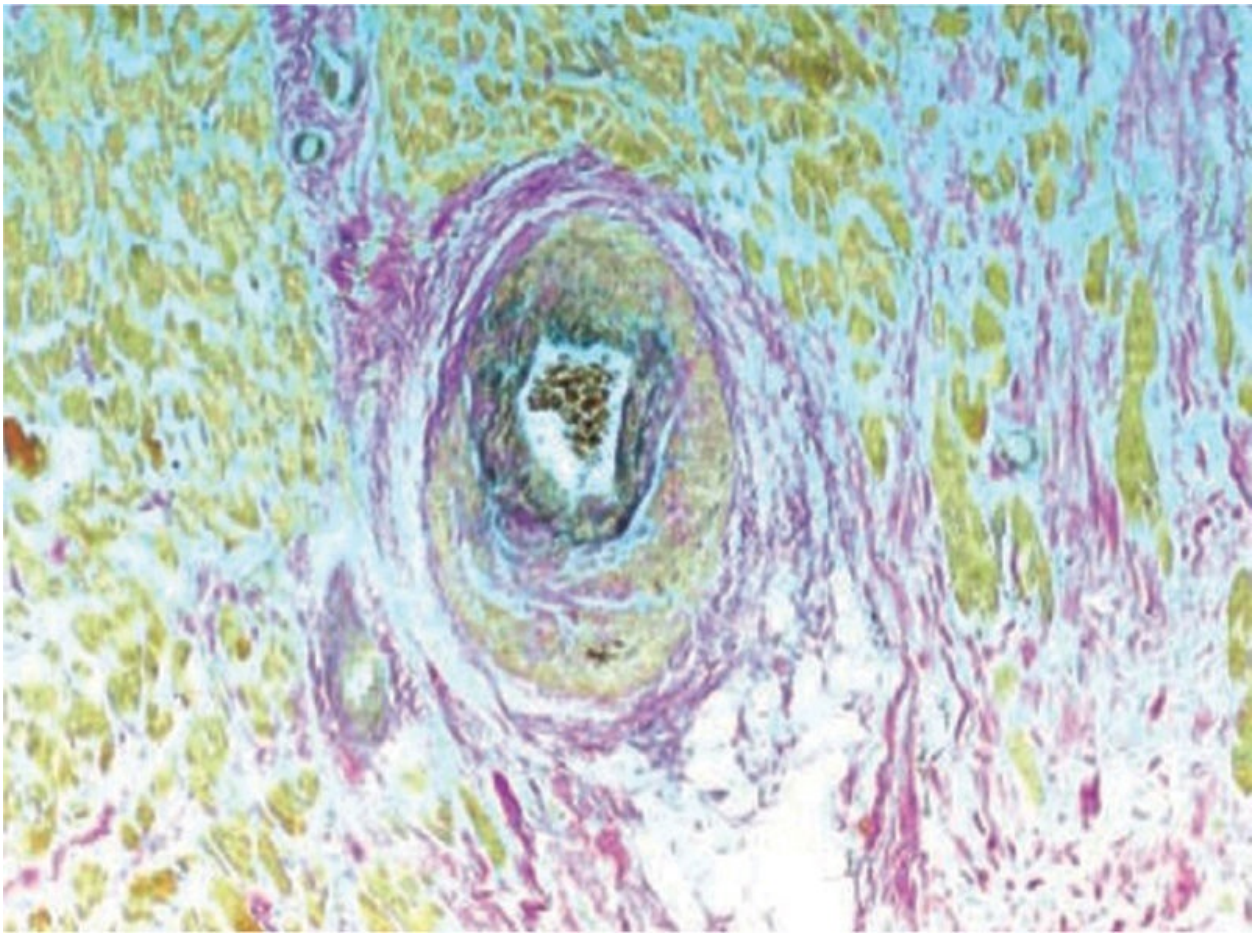

FIGURE 15.3 An intramural artery is shown above with intimal and medial smooth muscle hyperplasia and medial fibrosis, resulting in luminal narrowing. The capillaries are similarly affected. These narrowings are thought to contribute to ischemia.

DIAGNOSIS

The most common imaging modality used to establish a clinical diagnosis of HCM is TTE with an emerging role of cMRI. Additional testing in the initial evaluation of HCM should include an ECG, which is abnormal in up to 95% of patients.[7] A 24-hour ambulatory Holter monitor should be obtained to rule out episodes of nonsustained ventricular tachycardia, which generally adds prognostic information about risk of SCD. HCM is diagnosed when LV hypertrophy without dilatation occurs in the absence of a clinical condition that would cause the degree of hypertrophy noted.[1] Therefore, to make the diagnosis of HCM, it is important to evaluate for other cardiac or systemic conditions capable of producing the magnitude of hypertrophy evident (eg, aortic valve

stenosis, systemic hypertension, athlete's heart). Athlete's heart occurs in elite, highly trained competitive athletes, where wall thickness is increased but is usually less than 15 mm.[8] Compared to patients with HCM, these patients have normal or enlarged cardiac chambers, normal diastolic function, and have regression of their LV hypertrophy with temporary cessation of training. The location of abnormal hypertrophy in patients with HCM is most often the anterior septum, although the posterior septum and anterior wall can be involved as well. Typical of the heterogeneity of HCM is that hypertrophy can occur in any segment, even among relatives known to have the same genotype. Truly atypical HCM variants include thickening isolated to the lateral or posterior wall. Wall thickness should be evaluated for all patients with TTE, but may be limited by the obtained ultrasound window. MRI, which has become an important diagnostic tool in HCM, is useful in this situation. In a subset of patients, the site and extent of cardiac hypertrophy and abnormalities of the mitral valve result in obstruction to LV outflow. LV outflow tract (LVOT) obstruction is an important determinant of symptoms and is associated with adverse outcomes. This is caused by systolic anterior motion (SAM) of the mitral valve and contact of the valve with the hypertrophied septum (mitral–septal contact), which is demonstrated through echocardiography **(Figure 15.4)**.[9] The phenomenon of dynamic SAM is caused by a crucial anatomic overlap between the inflow and outflow portions of the left ventricle. **Figure 15.5** shows dynamic SAM as it progresses through the early moments of systole. The narrowing of the LVOT and the anteriorly positioned coaptation point of the mitral valve places the protruding leaflet into the edge of the flow stream, subjecting the undersurface of the leaflet to the pushing force of flow, as illustrated in **Figure 15.6**.

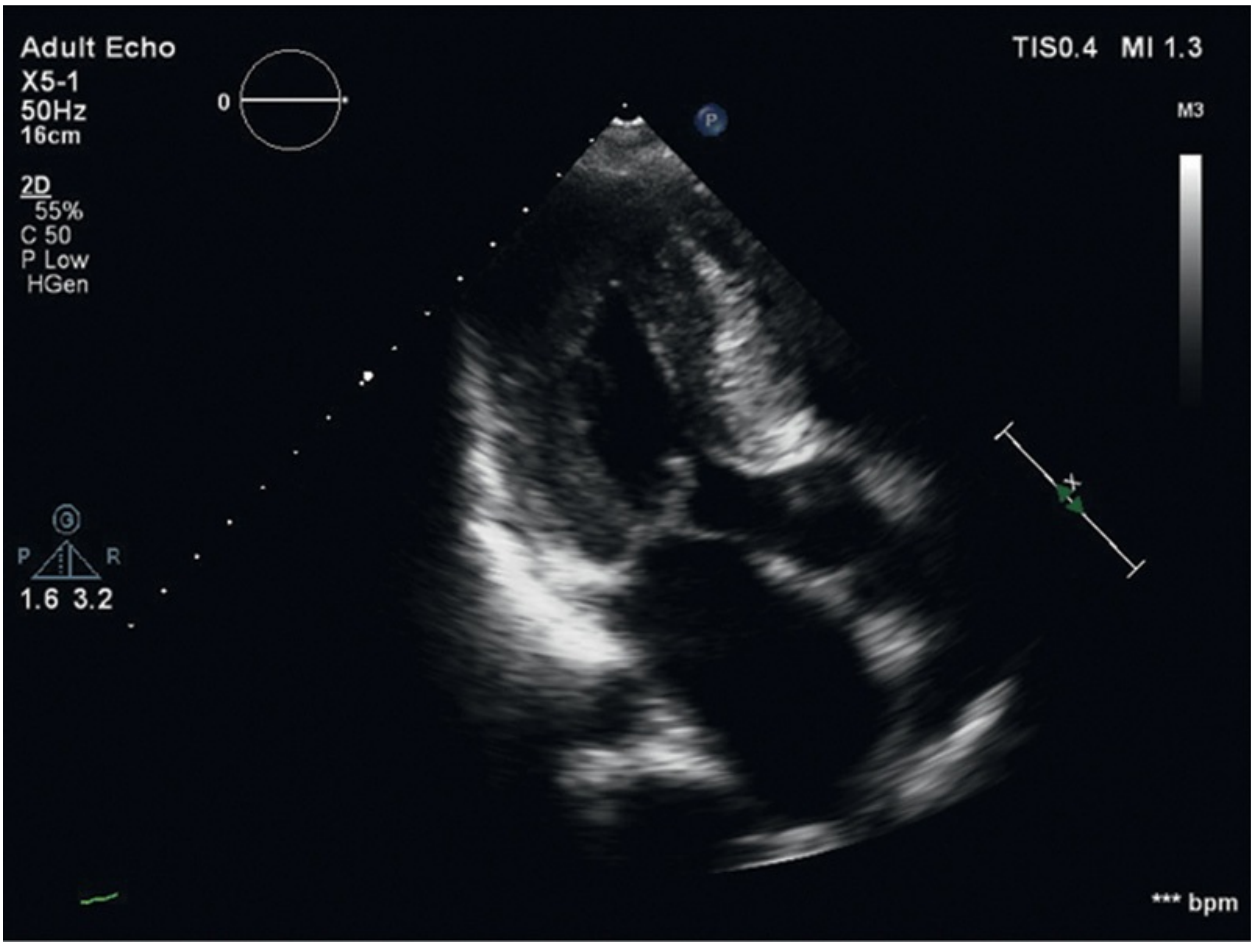

FIGURE 15.4 This apical three-chamber view on transthoracic echocardiography demonstrates systolic motion of the mitral valve with resulting mitral–septal contact. Note the hypertrophy of the left ventricular walls, particularly the anteroseptum.

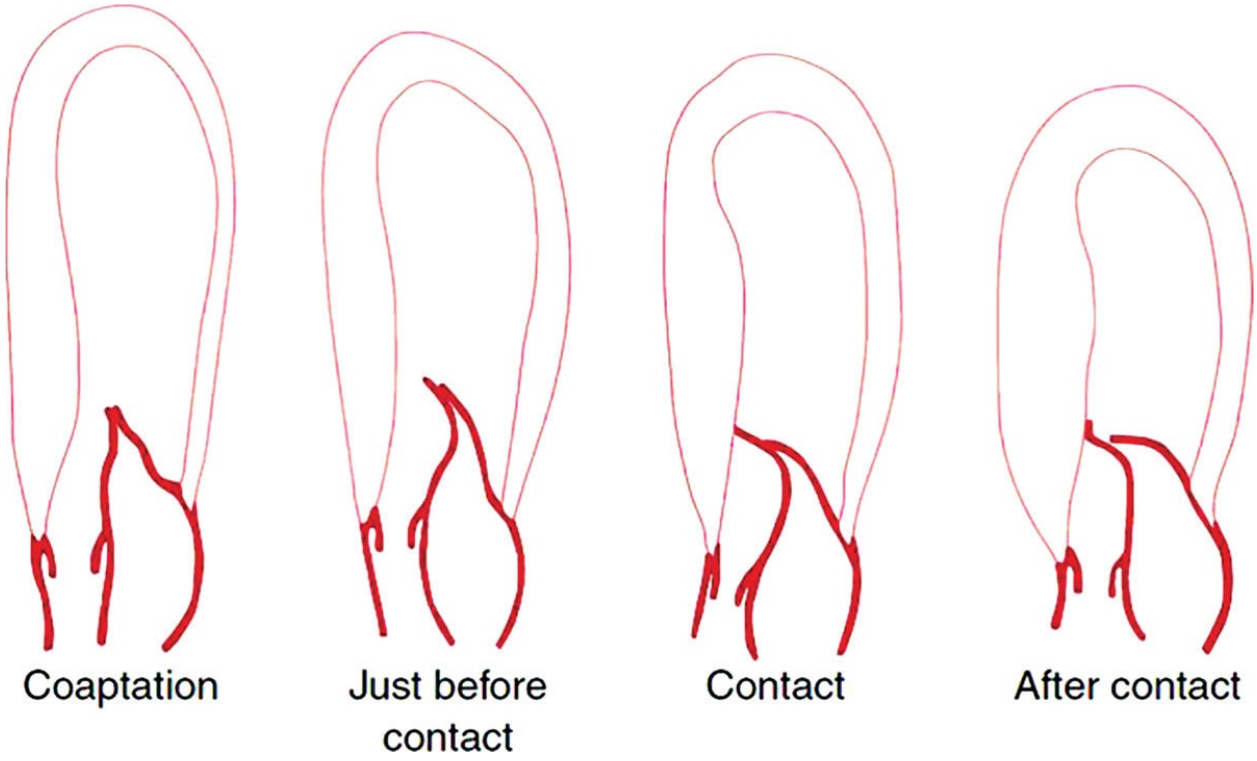

FIGURE 15.5 Systolic anterior motion of the mitral valve, schematically drawn from apical five-chamber view, as it proceeds in early systole. (Adapted from Sherrid MV, Chu CK, Delia E, et al. An echocardiographic study of the fluid mechanics of obstruction in hypertrophic cardiomyopathy. *J Am Coll Cardiol*. 1993;22:816-825.)

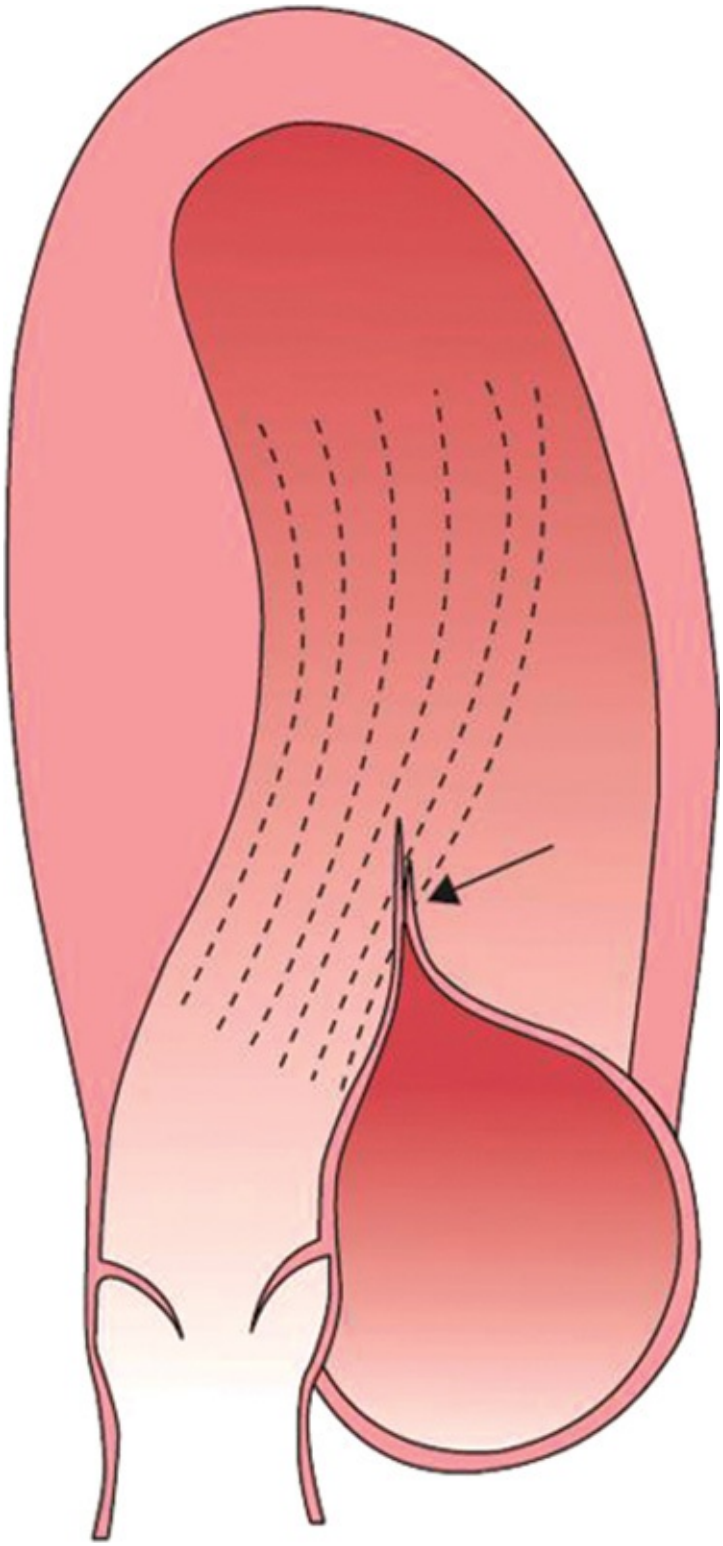

FIGURE 15.6 The pushing force of flow in the left ventricle is shown schematically above relative to the mitral valve in the apical five-chamber view. In obstructive hypertrophic cardiomyopathy, the mitral leaflet coaptation point is closer to the septum than normal. The protruding leaflets extend into the edge of the flow stream and are swept by the pushing force of flow toward the septum. Flow pushes the underside of the

leaflets (*arrow*). Note that the midseptal bulge redirects flow so that it comes from a relatively lateral and posterior direction; on the five-chamber view, flow comes from the "1 o'clock" direction. This contributes to the high angle of attack relative to the protruding leaflets. (Adapted from Sherrid MV, Gunsburg DZ, Moldenhauer S, et al. Systolic anterior motion begins at low left ventricular outflow tract velocity in obstructive hypertrophic cardiomyopathy. *J Am Coll Cardiol*. 2000;36:1344-1354.)

cMRI can provide additional clinically relevant information by quantifying LV mass, evaluating the right ventricle and mitral valve, identifying aberrant muscle bundles within the left ventricle (LV), and identifying myocardial fibrosis/scarring by late gadolinium enhancement (LGE). If myocardial mass has at least 15% with LGE, there is a 2-fold risk in SCD compared with those who are otherwise considered low risk. Finally, CMR can also play a role in distinguishing HCM from other cardiac pathology that may similarly demonstrate LV hypertrophy on echocardiography.[10]

LEFT VENTRICULAR OUTFLOW TRACT OBSTRUCTION

The degree of obstruction is quantified by measuring the pressure drop and the gradient across the LVOT. This is most commonly done noninvasively with continuous wave Doppler echocardiography. Pulsed wave Doppler correlation with the two-dimensional echocardiogram allows for determination of the site of obstruction, which must be ascertained in every patient, especially if intervention is contemplated. LV outflow obstruction causes a midsystolic drop in LV ejection velocities and flow when the gradient is >60 mm Hg. This echocardiographic pattern has been termed the "lobster claw" abnormality because of its characteristic appearance **(Figure 15.7)**. Significant obstruction is considered to be present with a resting gradient greater than 30 mm Hg. Changing preload and afterload may provoke a gradient by increasing the overlap between the inflow and outflow portions of the LV, reflecting the dynamic nature of the obstruction. After completing initial echocardiographic imaging with no evidence of a resting gradient, patients with concern for HCM such as septal hypertrophy or SAM should be additionally imaged while asked to perform the Valsalva maneuver or standing to elicit a possible gradient. Two-thirds of patients with HCM have resting or provokable LVOT obstruction, and one-third are nonobstructive. Exercise, and on occasion exercise in the postprandial state, can also be used to uncover latent obstruction. However, exercise testing is not indicated in patients with gradients over 4 m/s at rest, New

York Heart Association class III or IV symptoms, or prior history of ventricular arrhythmia.[11] These maneuvers are helpful in order to correlate patient symptoms with degree of obstruction and to provide a target for therapy. In addition, patients with gradients in excess of 50 mm Hg at rest or with provocation should be considered for invasive intervention if they remain symptomatic despite medical management.

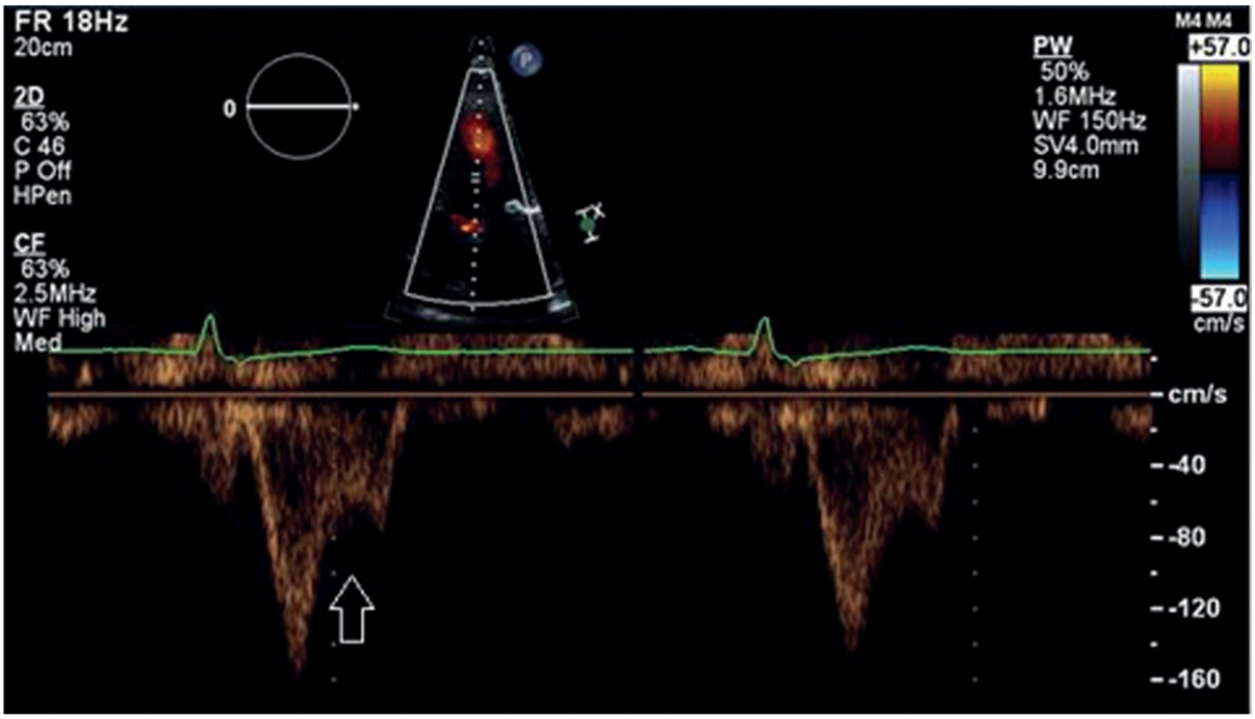

FIGURE 15.7 Midsystolic drop in LV ejection velocity in obstructive hypertrophic cardiomyopathy. On a pulsed wave Doppler recording just apical of the entrance to the LVOT in a patient with severe dynamic obstruction caused by systolic anterior motion and mitral–septal contact. The arrow points to the LV midsystolic drop in LV ejection flow velocity. This drop in velocity has been called the "lobster claw abnormality" because of its characteristic appearance. The drop in velocity results from the sudden imposition of afterload because of the mitral–septal contact and the gradient. LV, left ventricular; LVOT, left ventricular outflow tract.

TREATMENT

There are five aspects of care that should be covered in the treatment of every HCM patient, some of which may not necessarily be applicable in the setting of the CCU: (1) Risk of sudden death should be discussed, and individual stratification of risk should be done. The average risk of dying suddenly is 1%

per year for HCM patient populations, but the risk may be higher or lower depending on whether risk factors for sudden death are present. For patients deemed by their physicians to be at high risk, discussion of implantation of a defibrillator should be considered. (2) Treatment in hopes of alleviating symptoms should be initiated. (3) A discussion to avoid athletic competition and extremes of exertion should be conducted, as well as lifestyle modifications to avoid exacerbation of LVOT obstruction. (4) There should be an effort to detect and manage risk factors contributing to coronary artery disease such as hypercholesterolemia, diabetes mellitus, and cigarette smoking (HCM and coronary disease have an adverse synergistic effect on prognosis). (5) Clinical screening (physical exam, transthoracic echocardiogram and ECG) or genetic testing of first-degree family members should be performed to assess who is at risk or has inherited the gene mutation. Although many aspects of this evaluation can wait until a patient is stabilized after the CCU stay, it must be remembered that HCM is a lifelong condition and that these issues need discussion, management, and follow-up.

PHARMACOLOGIC TREATMENT OF SYMPTOMS

Figure 15.8 outlines an algorithm for the management of symptomatic HCM in patients grouped into obstructive and nonobstructive HCM categories.

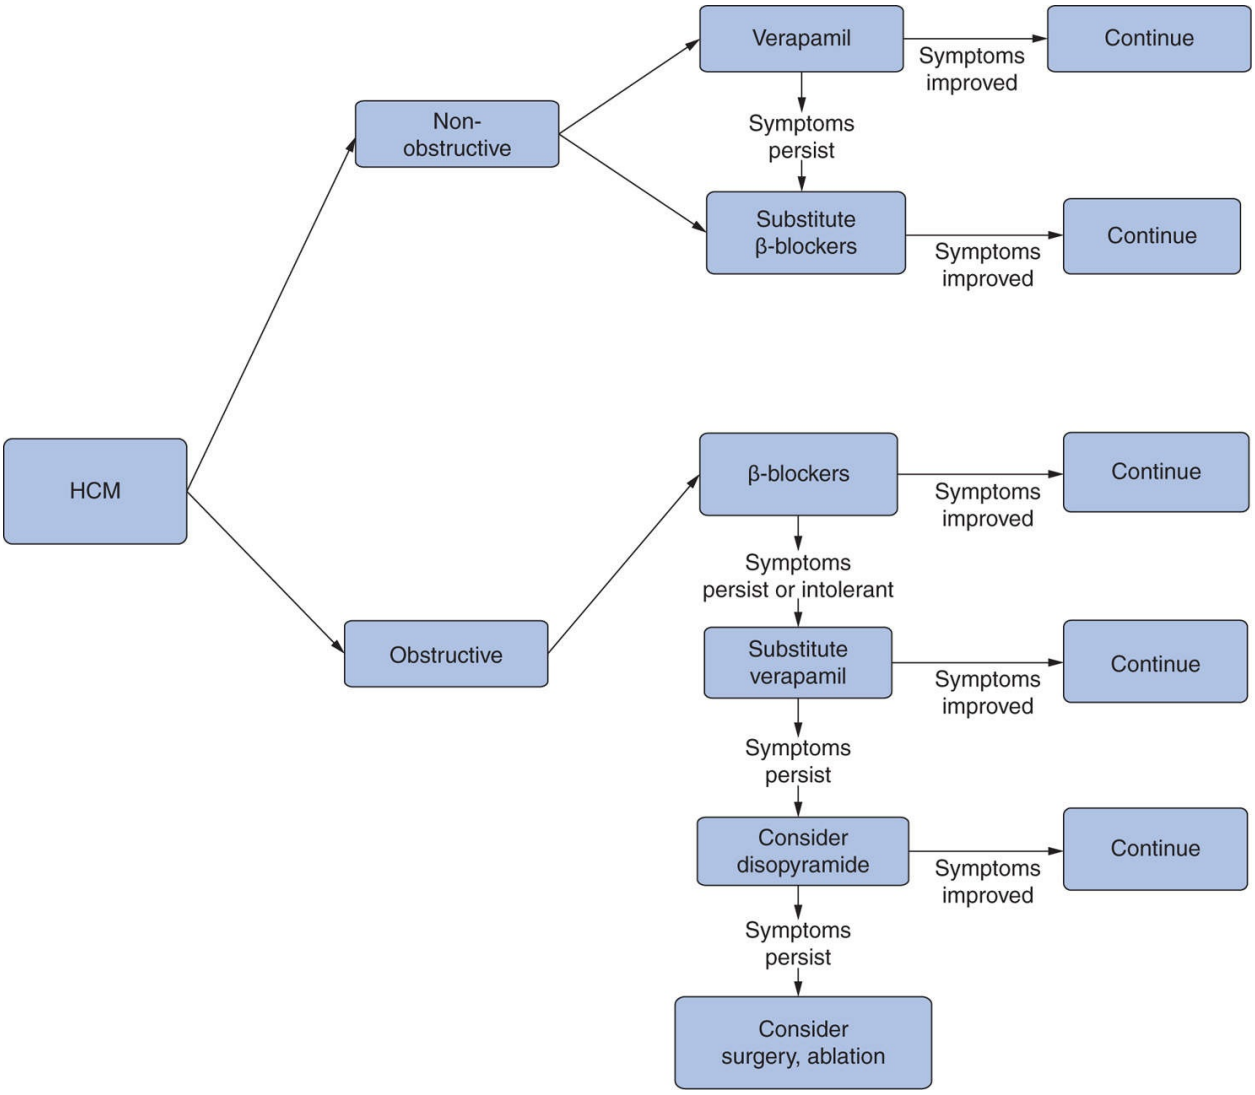

FIGURE 15.8 The management of patients with either obstructive or nonobstructive hypertrophic cardiomyopathy is detailed above. Pharmacologic therapy is driven by symptom response, and patients with obstruction who are refractory to medications are indicated for advanced intervention. HCM, hypertrophic cardiomyopathy.

NONOBSTRUCTIVE HCM

In nonobstructive HCM, symptoms are caused by diastolic dysfunction with impaired relaxation early in diastole and decreased chamber compliance in late diastole. This is coupled with small LV volumes and hypertrophy.

Few agents are available, and they are not particularly effective in improving severe symptoms owing to diastolic dysfunction. No pharmacologic agent has been consistently shown to improve LV relaxation and chamber compliance in HCM.[12] Therefore, treatment options for symptomatic nonobstructive HCM are

limited.[13] Two treatment goals are to improve LV diastolic function and to improve ischemia. Two classes of agents are currently used—***β***-blockade and calcium channel blockade. Neither class of agents has been shown to improve diastolic chamber compliance.[14] Verapamil's positive contribution in the pathophysiology of nonobstructive HCM appears to be relief of ischemia. Verapamil improves myocardial perfusion as assessed by stress radionuclide perfusion imaging and may thus improve symptoms.[15] Beta-blockade and, to a lesser degree, verapamil may cause chronotropic incompetence in HCM.[16] As diastolic dysfunction may limit the exercise-induced increase in stroke volume, patients with HCM often rely on increased heart rate to increase cardiac output. In such patients, pharmacologic limitation of increase in heart rate may impair exercise capacity. Whereas disopyramide has been shown to improve diastolic function in obstructed patients, by decreasing gradient and systolic load, it has not been shown to improve diastolic function in nonobstructed patients and should be avoided in this group, pending further investigation.[17, 18] For the patient with fluid retention, with edema or rales, diuretics may be helpful by relieving dyspnea and uncommon edema. Overdiuresis should be avoided because patients with HCM are often preload dependent for adequate cardiac output. If patients initially present with significant edema, another diagnosis should be sought as this is very unusual. Amyloid may be suspected in this clinical situation, especially if the ECG QRS voltage is low. The use of angiotensin receptor blocker losartan did not demonstrate improvement in exercise capacity or cardiac function. Clinical trials are ongoing because there is currently no good pharmacologic treatment for advanced symptoms in nonobstructive HCM.[19] Fortunately, patients with nonobstructive HCM appear to have a more benign clinical course compared with obstructed patients.[20]

OBSTRUCTIVE HCM

Pharmacologic therapy of symptoms in obstructive HCM (OHCM) is successful in two-thirds of patients. ***β***-blockers are initially used because of their negative inotropic effect. This improves dynamic LV outflow obstruction by decreasing ejection acceleration, which in turn lowers flow velocities early in systole and decreases early drag forces on the mitral valve. SAM and mitral–septal contact are delayed, thereby reducing the LVOT gradient. In addition, decreased myocardial tissue oxygen consumption alleviates possible myocardial ischemia, and negative chronotropy increases diastolic filling time.[13] ***β***-blockers also

decrease the sympathetically mediated rise in gradient and tachycardia. The doses should be titrated to cessation of symptoms, a heart rate ranging from 60 to 65 beats/min, or recommended maximum doses. However, ***β***-blockade is not expected to reduce resting gradient, and less than half of patients have sustained improvement in symptoms.[21] ***β***-blockers are effective in reducing exercise-induced LVOT obstruction.[22] For patients who are intolerant of ***β***-blockers or remain symptomatic verapamil therapy can be attempted in doses as high as 480 mg/day. Verapamil, a potent calcium channel blocker (CCB), also has negative inotropic properties but is also a vasodilator. It has been shown to decrease gradient and improve symptoms. Some studies have demonstrated an improvement in exercise tolerance as well. However, it is not used in patients with severe obstruction and severe symptoms because, on occasion, its vasodilating effects outweigh its negatively inotropic effects: the LVOT gradient may rise, and pulmonary edema and death have been reported. In addition, heart block and bradycardia may complicate its use. If there is no improvement with verapamil, disopyramide can be added to beta-blockade or verapamil.[23, 24] Disopyramide is a type I antiarrhythmic drug with potent negatively inotropic properties; in normal individuals, it can decrease echocardiographic fractional shortening by 28%. It is a sodium channel blocker and may have calcium channel blocking properties as well; however, it is not a vasodilator. Disopyramide is generally given to patients who are refractory to ***β***-blockade or verapamil and would otherwise require intervention with surgical septal myectomy or ASA. In a multicenter study, two-thirds of patients with OHCM treated with disopyramide combined with a ***β***-blocker could be managed medically with amelioration of symptoms and 50% reduction in LVOT gradient when followed for 3 years. The remaining one-third of patients could not be managed successfully with disopyramide and required invasive therapy secondary to inadequate symptom and gradient control or vagolytic side effects. There was a trend toward lower cardiac mortality and sudden death in the disopyramide group, without an increased risk of arrhythmia. The starting dose of disopyramide is 250 mg twice a day using the controlled-release preparation, and can be increased to 300 mg twice daily.[25] Disopyramide is generally given with a ***β***-blocker or verapamil to limit exercise-induced adrenergic response and to slow ventricular response, should atrial fibrillation occur. Mild vagolytic side effects, dry mouth, blurred vision, and constipation are common but generally subside. If they prove troubling, the dosage may be reduced, or controlled-release pyridostigmine may be added, 180 mg/day. A more serious vagolytic side

effect is urinary retention. Vagolytic side effects cause discontinuation of disopyramide in 7% of patients. Because of its impaired elimination in renal failure, disopyramide should be administered in reduced dosage or with serum monitoring. ECG surveillance of the QTc interval should be performed, and QTc prolonging medications should be carefully considered prior to initiation in patients who are on disopyramide.

DRUGS TO AVOID (OR DISCONTINUE) IN OBSTRUCTIVE HYPERTROPHIC CARDIOMYOPATHY

All vasodilators should be avoided in OHCM, a drug class that is commonly used in the CCU. Vasodilators will worsen LVOT obstruction. These include all nitrate preparations (sublingual, topical, and IV), dihydropyridine CCBs (amlodipine and nifedipine), angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and alpha-adrenergic blockers that are used for prostatism. Furthermore, drugs that increase contractility will worsen obstruction and should also be avoided in OHCM such as dopamine, dobutamine, milrinone, and digoxin.

SURGICAL SEPTAL MYECTOMY

Myectomy is the treatment of choice for patients who fail medical therapy.[24, 25] Candidates for myectomy have persistent disabling symptoms and gradients of >50 mm Hg at rest or after physiologic provocation. Myectomy has been successfully performed for 30 years, and in experienced centers it can be performed with low surgical mortality of 1%. It is uniformly successful in reducing both gradient and symptoms.

Interventions are not always successful, and the reason for heterogeneity in response is not clear. Understanding the central role of flow drag in the pathogenesis of SAM may prevent treatment failures. Inadequate myectomy resection focused on just the subvalvular septum, targeted to widen the outflow tract and to reduce Venturi forces, may result in persistent SAM and obstruction. A limited myectomy misses the impact of the midventricular septal bulge that redirects LV flow so that it comes from a relatively posterolateral direction. This sort of resection results in persistent SAM and either outflow obstruction or

mitral regurgitation because flow must still course around the remaining septal hypertrophy, and it still catches the mitral valve and pushes it into the septum, causing mitral regurgitation. To alleviate this sort of residual SAM, investigators from Germany have popularized the extended myectomy. More extensive resection redirects flow away from the mitral valve, precluding drag-induced SAM. A large decrease in the angle of attack of flow relative to the mitral valve has been shown after successful myectomy; flow is made more parallel to the mitral valve. The myectomy resection must be extended far enough down toward the apex to allow flow to track anteriorly along the surgically reduced septum away from the mitral valve. Surgical septal myectomy also addresses abnormalities in the attachments of the papillary muscles, which are common in HCM and which can often contribute to LVOT obstruction.[25] In addition, HCM patients typically have intrinsic mitral valve pathology such as mitral valve prolapse, increased leaflet length, and abnormal chordal attachments that contribute to obstruction. Surgical myectomy has the advantage of addressing mitral valve abnormalities with a repair.[26, 27] Targeting the basal septum alone is unlikely to completely relieve SAM, obstruction, and mitral regurgitation. When surgery is selected, myectomy is preferred over mitral replacement for relief of LVOT obstruction in HCM patients refractory to pharmacotherapy.

ALCOHOL SEPTAL ABLATION

Percutaneous Alcohol Septal Ablation (ASA) can be considered an alternative to surgical septal myectomy for patients at high operative risk and advanced age. It can be done only if there is suitable anatomy. This procedure offers the attractive promise of septal reduction without cardiopulmonary bypass and its complications. After placement of a temporary right ventricular pacing lead, a small diameter balloon catheter is placed in a selected left anterior descending (LAD) septal branch, and after inflating the balloon, angiographic contrast is injected to ensure that contrast does not reflux back into the LAD. Diluted echo contrast is then injected during transthoracic or transesophageal echocardiographic imaging. In 8% of such injections, contrast is seen to flow to structures where alcohol injection would be disastrous: posterior LV wall, RV free wall, mitral papillary muscles, or the entire septum. With this information, the operator searches for a septal branch that can be demonstrated to supply just the upper septum, preferably including and extending past the point of mitral–

septal contact. A dose of 1 to 3 mL of absolute alcohol is instilled into the septal branch. Optimally, a controlled myocardial infarction occurs. This is accompanied by typical chest pain, enzyme elevation, and risk for potentially lethal ventricular arrhythmia. The acute gradient reduction of ASA is caused by reduced ejection acceleration from the infarct and decreased hemodynamic force on the mitral valve decreasing SAM identically as in negatively inotropic medications. Late improvement stems from septal thinning owing to septal scar. ASA is associated with a risk of pacemaker dependency in 10% to 15% of cases, and an increase in ventricular arrhythmias has been reported. In addition, ASA does not offer as complete relief of obstruction compared with surgical myectomy.[28, 29]

DUAL-CHAMBER PACING

Dual-chamber pacing with complete ventricular preexcitation through a short atrioventricular (AV) delay to reduce outflow tract gradient is not considered primary therapy for obstruction.[30] Select older patients who are ≥65 years old may benefit with modest improvement on LVOT gradient and functional improvement.[30] Therapeutic effect is often incomplete; SAM persists with mean gradients of 30 to 55 mm Hg after 3 months of pacing. The mechanism by which pacing benefits SAM is unclear at this time. It may be because of the dyssynchrony caused by the right ventricular pacing, or because of the short AV delay. It is usually considered for patients who already have a dual-chamber pacemaker present with comorbid medical conditions or old age given in conjunction with disopyramide and a ***β***-blocker.

IMPLANTABLE CARDIOVERTER DEFIBRILLATOR

Although not a decision made solely in the CCU, the Implantable defibrillator has a role in the spectrum of care for HCM patients. Situations may arise in CCU patients that may prompt the recommendation of implantable cardioverter defibrillator (ICD) insertion. These include presentation with syncope or ventricular tachycardia—nonsustained or persistent. Other risk factors that are associated with higher risk for SCD and may prompt ICD include massive segmental wall thickening ≥30 mm, family history of SCD from HCM in a

young family member, and apical akinetic aneurysm owing to mid-LV obstruction.

MANAGEMENT OF ACUTE DECOMPENSATION OF PATIENTS WITH HCM

The initial step in the management of acute decompensated HCM patients with obstruction should be discontinuation of any possible offending agents such as vasodilators. The clinician should also keep in mind that positive inotropes in this setting of hemodynamic instability secondary to obstruction may be deleterious and should also be avoided. When hemodynamics stability is preserved, ***β***-blockers constitute the first line of treatment. If hemodynamic stability is compromised (systolic blood pressure <90 mmHg), increasing afterload and preload is in order. **Figure 15.9** shows the progression of management in these patients. In the event atrial fibrillation ensues, rate and rhythm control are imperative.

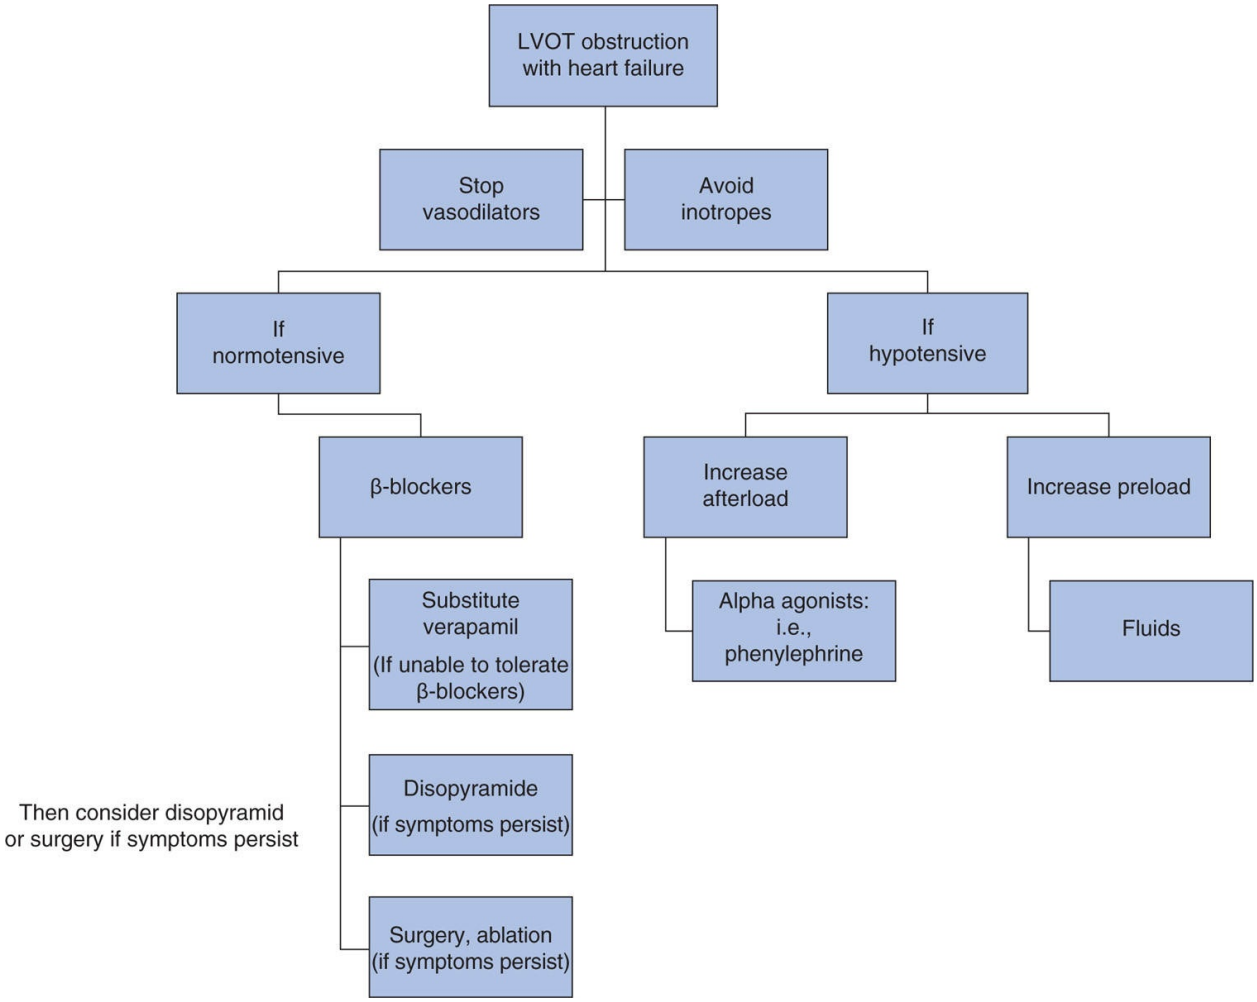

FIGURE 15.9 The management of patients being admitted into the cardiac care unit with heart failure symptoms secondary to left ventricular outflow tract obstruction is demonstrated above. Cessation of offending agents is the first step, and patients with hypotension should be treated with intravenous fluids and phenylephrine, if needed. Positive inotropes should be avoided because they can worsen obstruction. LVOT, left ventricular outflow tract.

The most common cause of acute decompensation in HCM patients is the acute onset of atrial fibrillation. The loss of the atrial kick and rapid heart rate on top of diastolic dysfunction can provoke heart failure symptoms. The first consideration should be whether the patient needs acute direct current cardioversion for severe heart failure or hemodynamic instability. For most other patients, slowing the ventricular rate with beta-blockade or nondihydropyridine CCBs is generally the best first treatment option. Verapamil may be used in nonobstructed patients but not in patients with resting obstruction because it has vasodilatory properties with a risk of pulmonary edema in severely obstructed patients. Amiodarone may be used to slow ventricular rate, but in non-

anticoagulated patients it should be used only in those who have recent (<48 hours) atrial fibrillation because the drug has the potential to restore sinus rhythm. Anticoagulation with parenteral heparin or low-molecular-weight heparin is indicated, because systemic embolism is very common in HCM patients. There should be a low threshold to refer patients for transesophageal echocardiogram (TEE) to exclude the presence of left atrial appendage thrombus before cardioversion. If there is no left atrial appendage thrombus noted, cardioversion may be performed either electrically or pharmacologically with a plan to continue warfarin or newer oral anticoagulants as an outpatient. The use of a newer oral anticoagulant agent should be considered, and although there are no data specifically looking at their use in this patient population, they are used in clinical practice with HCM patients who have atrial fibrillation. Frequent episodes of atrial fibrillation may warrant referral for catheter-based ablation, which may be an option for these patients. All patients with HCM and atrial fibrillation should continue long-term anticoagulation to reduce the risk of stroke and embolic events. In HCM patients who develop atrial fibrillation, the risk of embolic events is high (ie, incidence is 2.5%/year). Long-term anticoagulation regardless of CHADS–VASC score is indicated in these patients to reduce stroke and peripheral embolic events.[31]

ACUTE LVOT OBSTRUCTION AND TAKOTSUBO CARDIOMYOPATHY

Patients with HCM and latent obstruction may rarely present with acute, severe LV dysfunction consistent with apical ballooning, pulmonary congestion, and cardiogenic shock similar to Takotsubo cardiomyopathy. Besides apical ballooning and hypercontractile basal LV function, these patients are also noted to have SAM of the mitral valve and mitral–septal contact. Around 10% to 25% of Takotsubo cardiomyopathy cases have been documented showing SAM, with the etiology of this being unclear. It has been theorized that the hypercontractility of the basal myocardium narrows the LVOT, causes flow to course around the basilar septum posterior and laterally, and positions the mitral valve leaflets to be swept into the outflow tract by a Venturi or flow-drag mechanism.[32] Another proposed mechanism is that patients initially presenting with this variant of Takotsubo cardiomyopathy have underlying, undiagnosed HCM with latent obstruction. Severe increased afterload mismatch from SAM

can cause subendocardial ischemia with resulting LV dysfunction.[33] The complete reversal of these findings after relief of LVOT obstruction indicates that they were caused by the dynamic obstruction caused by SAM of the mitral valve and mitral–septal contact. These patients should be admitted to the CCU after cardiac catheterization to exclude severe coronary artery disease with a left ventriculogram (if able to be clinically tolerated). Intravenous fluids, beta-blockade, and phenylephrine should be administered so as not to exacerbate LVOT obstruction and for hemodynamic support.

Patient and Family Information for: HYPERTROPHIC CARDIOMYOPATHY

HCM is characterized by thickening of the left ventricle that occurs without clinical cause such as high blood pressure or aortic valve disease. It is marked by varying symptoms and abnormalities. HCM is the great masquerader of cardiology. It often masquerades as coronary artery disease because it presents with chest pain, but without significant coronary narrowings. It is particularly confusing when HCM may present with ECG abnormalities mimicking those found in coronary disease. HCM is characterized by thickening of the heart muscle, most commonly at the septum between the ventricles. This leads to stiffening of the walls of the heart and abnormal mitral valve function that may obstruct normal blood flow out of the heart. Many people with HCM have no symptoms or only minor symptoms and live a normal life. Other people develop symptoms that progress and worsen as heart function worsens. Symptoms of HCM can occur at any age and may include chest pain or pressure that can occur with exercise or physical activity or at rest as well. Shortness of breath especially with exertion and fatigue (feeling overly tired) are often experienced. Initial presenting symptom could be a fainting episode (syncope) caused by irregular heart rhythms or abnormal responses of the blood vessels. Some patients may experience palpitations (fluttering in the chest) because of abnormal heart rhythms (arrhythmias), such as atrial fibrillation or ventricular tachycardia. Sudden death may occur as the presenting symptom in a small number of patients with HCM. HCM can run in families as a dominant genetic trait, owing to a gene that is inherited in half of the first degree relatives. In other instances, the cause is unknown. HCM is diagnosed on the basis of medical history (symptoms and family history), a physical exam, and echocardiogram results.

Additional tests may include blood tests, ECG, chest X-ray, exercise stress test, cardiac catheterization, CT scan, and MRI. In a subset of patients, the site and extent of cardiac thickening and abnormalities of the mitral valve result in obstruction to LV outflow. LVOT obstruction is an important determinant of symptoms and is associated with adverse outcome. Obstruction is an important therapeutic target in HCM because relief of obstruction often leads to improved symptoms. The most common location of obstruction is in the LVOT, caused by SAM of the mitral valve and mitral–septal contact. The phenomenon of dynamic SAM is caused by a crucial anatomic overlap between the inflow and outflow portions of the left ventricle. There are five aspects of care that should be covered in the treatment of every HCM patient: (1) Risk of sudden death should be discussed, and individual stratification of risk should be done. The average risk of dying suddenly is 1%/year for HCM patient populations, but the risk may be higher or lower depending on other risk factors for sudden death that may be present. For patients deemed by their physicians to be at high risk, discussion of implantation of a defibrillator should be considered. (2) Treatment in hopes of alleviating symptoms should be initiated. (3) A discussion to avoid athletic competition and extremes of exertion should be conducted, as well as lifestyle modifications to avoid exacerbation of LVOT obstruction. (4) There should be an effort to detect and manage risk factors of coronary artery disease such as hypercholesterolemia, diabetes mellitus, and cigarette smoking (HCM and coronary disease have an adverse synergistic effect on prognosis). (5) Clinical screening (physical exam, transthoracic echocardiogram, and ECG) or genetic testing of first degree family members should be performed to assess who is at risk or has inherited the gene mutation. Although many aspects of this evaluation can wait until a patient is stabilized after the CCU stay, it must be remembered that HCM is a lifelong condition and that these issues need discussion and management when the dust clears. Lifestyle changes may alter the course of HCM. Simple things like drinking adequate amounts of fluids, and avoiding competitive sports are important. Regular visits with a cardiologist are highly important. Patients with HCM should seek at least one consultation with a cardiologist at a specialized HCM treatment center—such doctors treat many HCM patients, whereas the usual cardiologist will see few in his/her career. Patients with HCM may find themselves in a CCU setting because of acute onset of symptoms of chest pain, shortness of breath or syncope, or the new onset of atrial fibrillation, a rapid irregular heart rhythm. Pharmacologic therapy is the first line of treatment for symptoms of HCM. Drugs are used to treat symptoms

and prevent further complications of HCM. Medications are used to reduce the degree of obstruction in the heart so that it can pump more efficiently. ***β***-blockers, disopyramide, and CCB are medications that may be prescribed for obstruction. If there is an arrhythmia, medications to control heart rate or decrease the occurrence of arrhythmias may be prescribed. Certain medications may need to be avoided; these include nitrates (because they lower blood pressure and worsen obstruction in the heart) or digoxin, dopamine, and dobutamine (because they increase the force of the heart's contraction and worsen obstruction).

If fluid collection in the lungs occurs, treatment is aimed at controlling it through diuretics. Surgical procedures are used to treat HCM when pharmacologic therapy fails to improve symptoms and obstruction. The "gold standard" is surgical septal myectomy. During this open heart surgical procedure, the surgeon removes a small amount of the thickened septal wall of the heart to widen the outflow tract (the path the blood takes) from the left ventricle to the aorta. This highly effective operation is done at specialized centers with a surgical mortality of <1%. Another important complication is the need for permanent pacing because of interruption of the normal electrical pathway of the heart. Alcohol Septal Ablation is another approach that involves cardiac catheterization to locate the small coronary artery that supplies blood flow to the septum. Small amounts of pure alcohol are injected through the catheter, which kills the cells on contact, causing a small "controlled" heart attack. This therapy decreases the contractile force of the heart and decreases obstruction in that way acutely. Later, the septum shrinks back to a more normal size over the following months, widening the passage for blood flow. Most HCM centers reserve ASA for patients who have substantial complicating medical illnesses or old age and frailty because the procedural risks are comparable to surgical myectomy, but the results are overall not as satisfactory.

IMPLANTABLE CARDIOVERTER DEFIBRILLATORS

ICD are suggested for people at risk for life-threatening arrhythmias or SCD. The ICD constantly monitors the heart rhythm. When it detects a very fast, abnormal heart rhythm, it delivers small electric currents or shocks to the heart muscle to cause the heart to beat in a normal rhythm again. A small number of people with HCM have an increased risk of SCD. People at risk include the

following: (1) Patients with massive thickening of the left ventricle wall (exceeding 3 cm). (2) Those who have family members who have had SCD at a young age, thought to be because of HCM. (3) Young patients with HCM with fainting without cause. Generally, this is considered most important when blackout has happened within the last 6 months. (4) Adults who have a history of arrhythmia with a fast heart rate originating from the ventricles, called ventricular tachycardia. (5) Those with severe symptoms and poor contractile heart function. If risk factors are present, the strategy of the ICD is discussed with the patient, and the decision to implant depends on physician judgment and patient choice.

MANAGEMENT OF ACUTE DECOMPENSATION IN PATIENTS WITH HCM

The initial step in treating patients with acute decompensated HCM with obstruction involves discontinuing any medications that could dilate the peripheral vessels and cause the blood pressure to drop. The most common cause of acute decompensation in HCM patients is an arrhythmia called atrial fibrillation. This arrhythmia may speed up the heart rate. Usually, slowing it with medications is sufficient. However atrial fibrillation may cause the heart to fail, which translates into a dramatic drop in blood pressure. In this case, the arrhythmia might need to be stopped by performing a cardioversion. Anticoagulation with blood thinners such as heparin or low-molecular-weight heparin is indicated because emboli are very common in HCM patients. There should be a low threshold to refer patients for TEE to exclude the presence of thrombus prior to cardioversion. If there is no left atrial appendage thrombus noted, cardioversion may be performed either electrically or with medications with a plan to continue oral blood thinners, such as warfarin or other newer oral anticoagulants. Frequent episodes of atrial fibrillation may warrant referral for definitive treatment of the arrhythmia with procedures such as catheter-based ablations. In HCM patients who develop atrial fibrillation, the risk of embolic events is high (ie, incidence is 2.5%/year). All patients with HCM and atrial fibrillation should continue lifelong anticoagulation to reduce the risk of stroke and embolic events.

Cardiac Magnetic Resonance Imaging in the Cardiac Care Unit

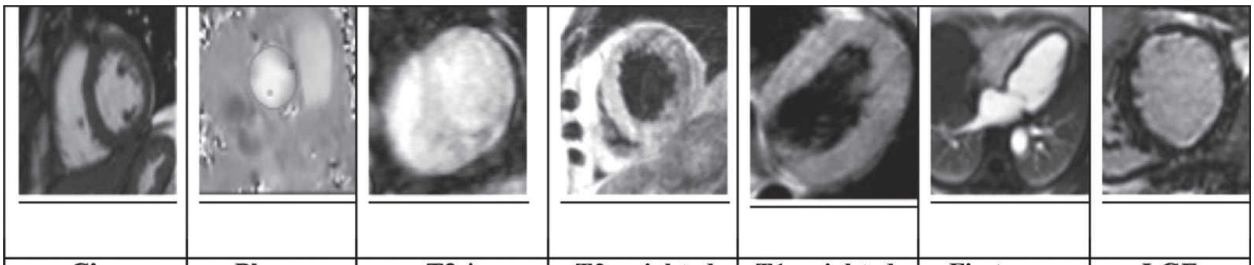
INTRODUCTION

The diagnosis and management of patients in the cardiac care unit (CCU) often requires the inclusion of data obtained by cardiac imaging. Although echocardiography and catheter-based coronary angiography are more commonly used, noninvasive cross-sectional imaging modalities such as cardiac computed tomography (CT) and cardiac magnetic resonance (CMR) are frequently necessary for clinical care as well. Without the use of ionizing radiation, CMR generates a signal (image) by altering the magnetic properties of hydrogen protons in the body through the application of radiofrequency pulses and magnetic gradients within a static magnetic field. The images generated can be very helpful in defining anatomy, function, and tissue characteristics of cardiac structures and the great vessels. In this chapter, we focus on CMR techniques and evaluations that would be relevant to the house staff who are on CCU rotation.

CARDIAC MAGNETIC RESONANCE SEQUENCES IN BRIEF

Different combinations of radiofrequency pulses and magnetic gradients,

generically termed sequences, enable acquisition of different types of images. Basic CMR sequences **(Figure 16.1)** include cine imaging, first-pass perfusion, phase-contrast, T1-, T2- and T2*-weighted imaging, early and late gadolinium enhancement (LGE) and magnetic resonance angiography (MRA).[1]



Cine	Phase Contrast	T2 *	T2 weighted	T1 weighted	First pass perfusion	LGE
Ventricular volumes, mass, ejection fraction, and wall motion assessment	Valvular stenosis and regurgitation, Qp/Qs	Iron deposition, intramyocardial hemorrhage	Presence of edema	Identification of fat, differentiation of chylous fluid and hemorrhage from simple fluid	Assessment of blood flow, microvascular obstruction	Assess for fibrosis/infarction

FIGURE 16.1 Common cardiac magnetic resonance sequences. LGE, late gadolinium enhancement.

- **Cine** imaging provides anatomic and functional details on chamber volumes and wall motion.
- **First-pass perfusion imaging** demonstrates perfusion defects, including microvascular obstruction (MVO).
- **Phase-contrast** imaging provides accurate data on the flow through the valves, including peak velocities, regurgitant volumes, and the ratio of pulmonary to systemic blood flows (Qp/Qs) as in the case of shunts.
- **T1- and T2-weighted** sequences assist with characterization of myocardial tissue, including myocardial edema, blood, thrombus, and fat. **T1- and T2-mapping** sequences provide more accurate and objective measures of tissue characterization compared to more subjective visual assessments. Although currently restricted largely to investigational use in the United States, these sequences are increasingly demonstrating abnormal myocardial parameters in various pathologies including, but not limited to, amyloidosis, cardiomyopathies, myocarditis, and autoimmune diseases.
- **T2*-weighted** sequences demonstrate the presence of myocardial iron and can

assist with identification of myocardial hemorrhage.

- **Early gadolinium enhancement** shows areas of no reflow and the presence of MVO, as well as increased myocardial signal intensity in myocarditis due to increased capillary leakage.
- **LGE** demonstrates areas of infiltration, necrosis, or fibrosis in characteristic patterns that can help diagnose the etiology of cardiac pathology.

MAGNETIC RESONANCE IMAGING SAFETY—PRACTICAL ASPECTS

CMR is a safe and valuable modality for the practicing cardiologist, but there are several important safety parameters to consider. To maximize image quality and minimize adverse events (which are rare), careful patient selection is crucial. The CCU patient will usually require an accompanying nurse and/or a physician for close monitoring and/or to administer medications as needed. The patient should be able to lie down flat for the duration of the examination up to 30 to 60 minutes, and he/she should ideally be able to follow breathing instructions. Typically, the patient is instructed to hold his/her breath for 10 to 15 seconds. Lack of cooperation can significantly impact image quality and even render the examination nondiagnostic. This may occur in patients who are in decompensated heart failure (HF) or who have underlying lung disease, altered mental status, or significant language barriers. The latter can be overcome by having a translator communicate with the patient from the control room. When patients are unable to the hold their breath, free-breathing alternatives such as real-time cine imaging often provide diagnostic image quality at the possible expense of a longer examination time.

A small proportion of patients (estimated around 2% to 4%) have significant claustrophobia. Of those, about half can be scanned by maximizing patient comfort with the use of blindfolds, appropriate lighting, and temperature control, or by having a family member available and maintaining verbal contact. Severe claustrophobia can be mitigated with a short-acting anxiolytic to be taken before the study (such as a low-dose benzodiazepine), avoiding oversedation that will impact cooperation with breathing instructions. Cardiac rhythm abnormalities are also important to consider. Tachyarrhythmias, including rapid atrial fibrillation/flutter and sinus tachycardia, can lead to blurry images, particularly on specific sequences. It may be helpful to control the heart rate with oral and/or intravenous (IV) beta-blocker before the examination, if medically appropriate. Frequent premature beats or bigeminy can have an impact on image quality. In

these cases, real-time cine imaging can also be helpful in improving image quality. While arrhythmias can reduce the accuracy of volumetric measurements, a diagnostic CMR study can be obtained in most cases.

The risks of CMR are primarily related to the generated static magnetic field, at a magnitude of 1.5 or 3.0 Tesla, representing 30,000 to 60,000 times the Earth's magnetic field strength. This can lead to ferromagnetic interactions causing motion or dislodgement of a ferromagnetic device or implant within the magnetic bore. Radiofrequency pulses can also result in local heating by concentrating energy around implanted wires or leads. Because of these risks, there are several devices that are categorized as unsafe because of their known hazard in all CMR environments. These are considered contraindicated and they include pacemakers (permanent or temporary), implantable cardioverter defibrillators (ICDs), and Swanz-Ganz catheters. A number of the newer pacemaker/ICDs are deemed magnetic resonance safe and are characterized as "MRI conditional" (magnetic resonance imaging conditional—meaning they can be scanned safely under specific conditions). Even though these devices are relatively safer, they can still produce significant artifacts that may render a cardiac scan nondiagnostic. Patients with these devices should be evaluated on a case-by-case basis and imaged at experienced CMR centers. Some of the transdermal medications (such as nitroglycerine patches) contain ferromagnetic components and should be removed before the CMR study. **Table 16.1** provides a comprehensive list of MRI-unsafe and MRI-safe or MRI-conditional devices.

TABLE 16.1 MRI Safety of Devices and Implants

MRI UNSAFE	MRI SAFE AND/OR CONDITIONAL (≤3.0 TESLA)
Permanent pacemakers[a]	Prosthetic heart valves
Implantable cardioverter defibrillators[a]	Intracoronary stents
Temporary transvenous pacemakers	Prosthetic joints
Insulin pumps	Dentures
Some medication patches	Implantable rhythm monitors[c]
Swan-Ganz catheters	Retained epicardial leads
Metal foreign bodies in the eyes	Occluder devices[d]

Brain aneurysm clips[b]	Peripheral stents[d]
Cochlear implants	Aortic aneurysm stents[d]
	Inferior vena cava filters[d]

[a]MRI-compatible pacemakers and implantable cardioverter defibrillators are now approved by the Food and Drug Administration and can be scanned under certain conditions at experienced cardiac magnetic resonance centers.
[b]More contemporary aneurysm clips are nonferromagnetic; however, confirmation with the implanting physician and manufacturer is absolutely required.
[c]Rhythm monitors can be conditional or unsafe, check with the manufacturer.
[d]If weakly ferromagnetic, it is recommended to wait 6 weeks post implantation.
MRI, magnetic resonance imaging.

One of the most significant (and avoidable) complications of contrast-enhanced CMR is nephrogenic systemic fibrosis (NSF). This occurs in patients with advanced renal insufficiency receiving gadolinium-contrast agents. Gadolinium is a lanthanide metal containing paramagnetic Gd^{3+} ions that enhances image contrast when administered intravenously. It is renally excreted with an elimination half-life of 60 to 90 minutes (18 to 34 hours in patients with renal insufficiency). NSF may occur in patients with advanced (stage 4 to 5) chronic kidney disease or acute kidney injury (AKI), particularly AKI of any severity in the setting of hepatorenal syndrome or in the liver peri-transplant period. It is characterized by fibrosis of skin, joints, eyes, and internal organs; approximately 5% of patients will have a debilitating course and, rarely, die.[2] Recommendations for NSF prevention are summarized in **Table 16.2**.

TABLE 16.2	MRI in Specific Patient Populations
Chronic kidney disease, renal insufficiency	eGFR <30 mL/min/1.73 m^2: use lowest possible dose (≤0.1 mmol/kg), avoid high-riska contrast agents
	ESRD: avoid contrast agents; if absolutely necessary, use lowest dose, avoid high-risk agents, consider hemodialysis 2 h afterward, and the following day
	AKI: avoid contrast agents (regardless of eGFR); if absolutely necessary, use lowest dose, avoid high-risk agents
Pregnancy	Gadolinium contrast agents should be avoided
	No evidence of teratogenic effects of noncontrast MRI studies

*High-risk contrast agents have a linear chemical structure, as compared with the safer macrocyclical contrast agents.
AKI, acute kidney injury; eGFR, estimated glomerular filtration rate; ESRD, end-stage renal disease; MRI, magnetic resonance imaging.

To enhance patient safety and selection for CMR, dedicated questionnaires that address all the important safety precautions have been developed. It is important to have a trained professional carefully administer these questionnaires and instruct the patient to provide accurate answers to all questions. It is also important to consider specific patient populations such as pregnant patients or patients with renal insufficiency **(Table 16.2)**.

CARDIAC MAGNETIC RESONANCE IN ACUTE CHEST PAIN

The differential diagnosis for acute chest pain (often with troponin elevation) is extensive and can be broadly divided into cardiac and noncardiac etiologies. In this chapter, we focus on the coronary causes of chest pain with troponin elevation in the acute and subacute phases as well as explore common noncoronary causes of chest pain and troponin elevation that are often seen in the CCU. **Table 16.3** briefly outlines some of the more common causes of chest pain, highlighting the disorders where CMR plays a significant role. It is important to realize that troponin elevation is sensitive but not specific for the detection of cardiac damage. It does not completely differentiate coronary from noncoronary causes of chest pain. Virtually any strain on the heart, whether from coronary occlusion, pulmonary embolism, or pneumonia, for example, can cause a troponin elevation. The decreased clearance of troponin in renal insufficiency can also lead to troponin elevation in nearly any setting.

TABLE 16.3 Differential Diagnosis of Chest Pain

CARDIAC	VASCULAR	GI	PULMONARY	OTHER

Takotsubo cardiomyopathy*		Cholecystitis		

Boerhaave syndrome

* Conditions in which CMR is potentially useful for diagnosis

ACUTE CORONARY SYNDROME

One of the most common presentations seen in the CCU is the acute coronary syndrome (ACS). Thankfully, the mortality and morbidity rates have consistently declined for acute myocardial infarction (MI), in large part because of better diagnostics and treatment, such as statin therapy and early invasive angiography. Although the incidence of ST-segment elevation myocardial infarction (STEMI) has decreased, as the population ages, the consequences of ACS will continue to grow.

Cardiac Magnetic Resonance in Acute Coronary Syndrome

For the patient with acute STEMI or non-STEMI (NSTEMI)/unstable angina with high-risk features, an early invasive approach is favored. The initial use of CMR in these patients is limited because any delay in revascularization can lead to worse outcomes. CMR after revascularization, however, can provide important prognostic information after an ACS. For stable patients without a diagnosed ACS, an imaging modality initially can be very beneficial in determining the etiology of symptoms. CMR may prevent unnecessary invasive angiography as well as identify patients who would receive greater benefit from an early invasive strategy. Kwong et al[3] studied 161 patients with chest pain and a nondiagnostic electrocardiogram (ECG) who had a CMR combining different sequences within 12 hours of presentation. The sensitivity and specificity for acute MI or unstable angina was 84% and 85%, respectively. CMR was far more sensitive than strict ECG criteria for ischemia, peak troponin-I, and thrombolysis in myocardial infarction (TIMI) risk score, and was more specific than an abnormal ECG.[3] Plein et al[4] showed that CMR, also by combining different sequences, can identify high-risk patients with significant coronary stenosis in patients with chest pain in the absence of STEMI. In a study with 72 patients with NSTEMI/unstable angina, a comprehensive CMR protocol predicted the presence of coronary stenosis with greater accuracy than did the TIMI risk score.[4]

Outside of the acute phase of presentation, CMR also adds significant information in determining the extent of MI, ventricular remodeling, the

presence of MVO, and the degree of viability. These parameters provide useful information that can assist with prognosis and treatment.

Functional Assessment

Using CMR to detect the presence and extent of wall motion abnormalities can be a helpful tool to determine patients most at risk, who would then benefit from more aggressive medical therapy and an early invasive strategy.

Subtle wall motion abnormalities that may be missed on echocardiography can often easily be seen on cine imaging in CMR because of its superior image quality**.** Wall motion abnormalities that correlate with a coronary distribution can further provide support for ACS in patients without STEMI.

In stable, low-risk patients who present with acute chest pain, CMR can be highly predictive of ACS in the near future. In one study, the presence of wall motion abnormalities on CMR, regardless of perfusion abnormalities and infarction, had greater sensitivity and specificity than did troponin elevation in predicting ACS or a positive stress test within 8 weeks.[3]

Common sequelae of ACS include left ventricular (LV) dilation **(Figure 16.2)**, wall motion abnormalities, and the formation of aneurysms. Cine imaging provides quantitative assessment of LV volumes, wall motion abnormalities, and LV and right ventricular (RV) function with greater accuracy and reproducibility than two-dimensional echocardiography. The degree of LV dilatation and reduction in left ventricular ejection fraction (LVEF), in addition to scar burden and MVO, significantly predicts patients at risk for future cardiovascular events.[5]

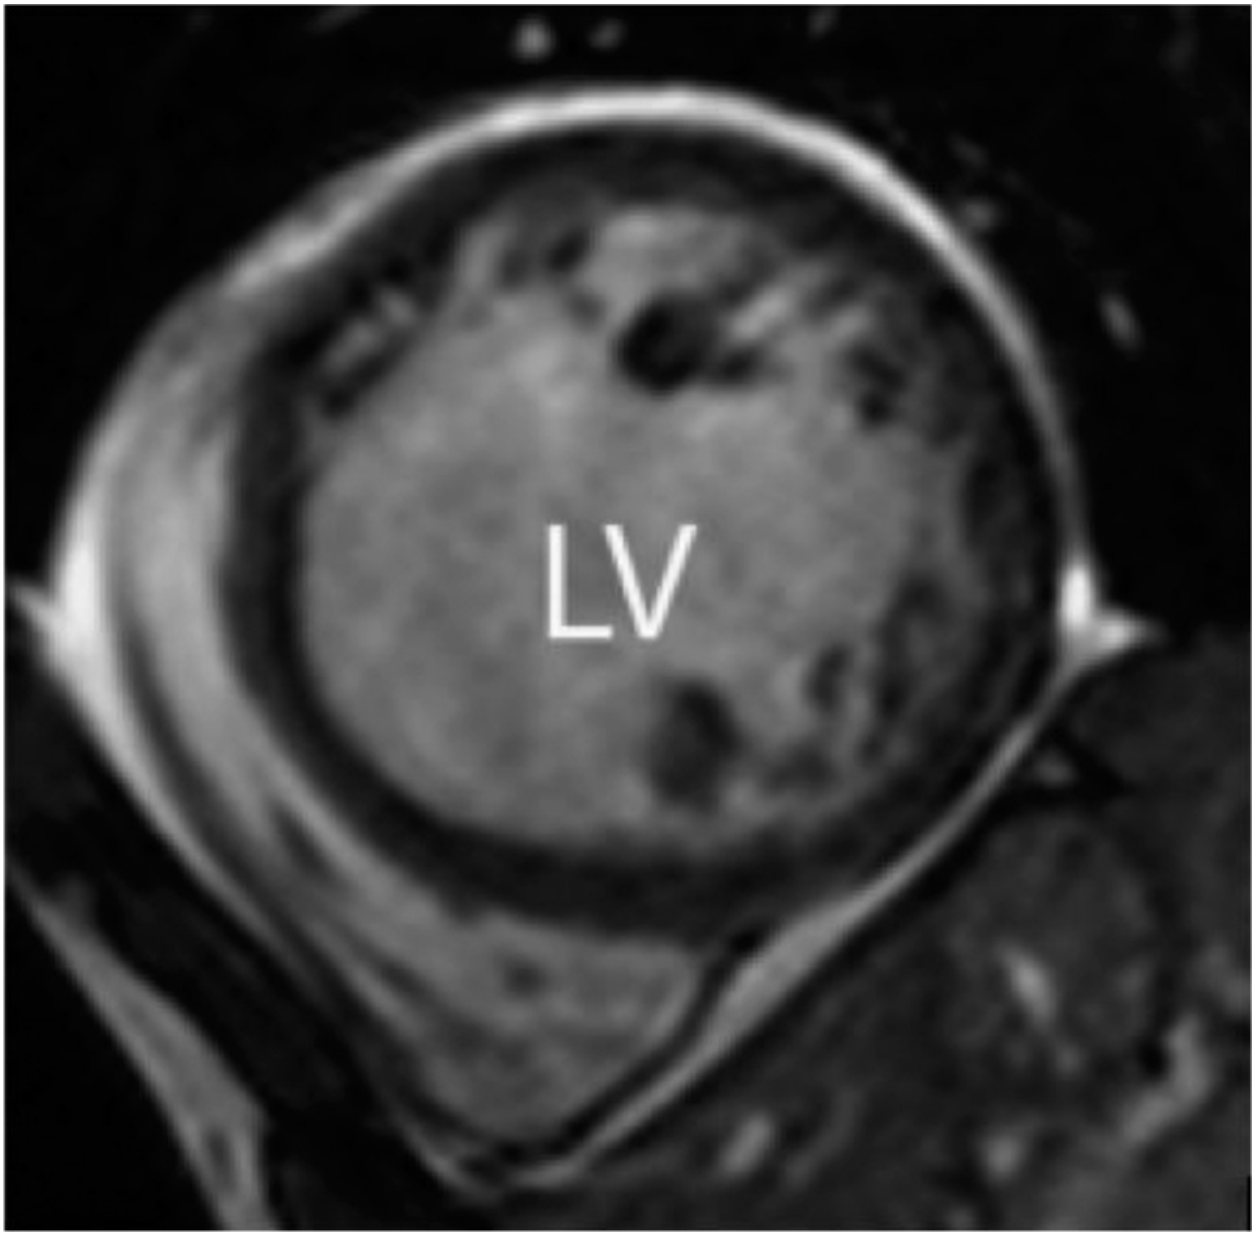

FIGURE 16.2 Short-axis view demonstrating a dilated left ventricle with a measured diastolic volume of 351 cc. LV, left ventricle.

Ischemia

The detection of ischemia on first-pass perfusion imaging can also reliably detect coronary disease even before wall motion abnormalities may be seen. Using a bolus of contrast with fast CMR sequences **(Figure 16.3)**, perfusion defects can become readily apparent. Normal myocardium will enhance, whereas relatively underperfused areas will appear dark for a certain amount of time.

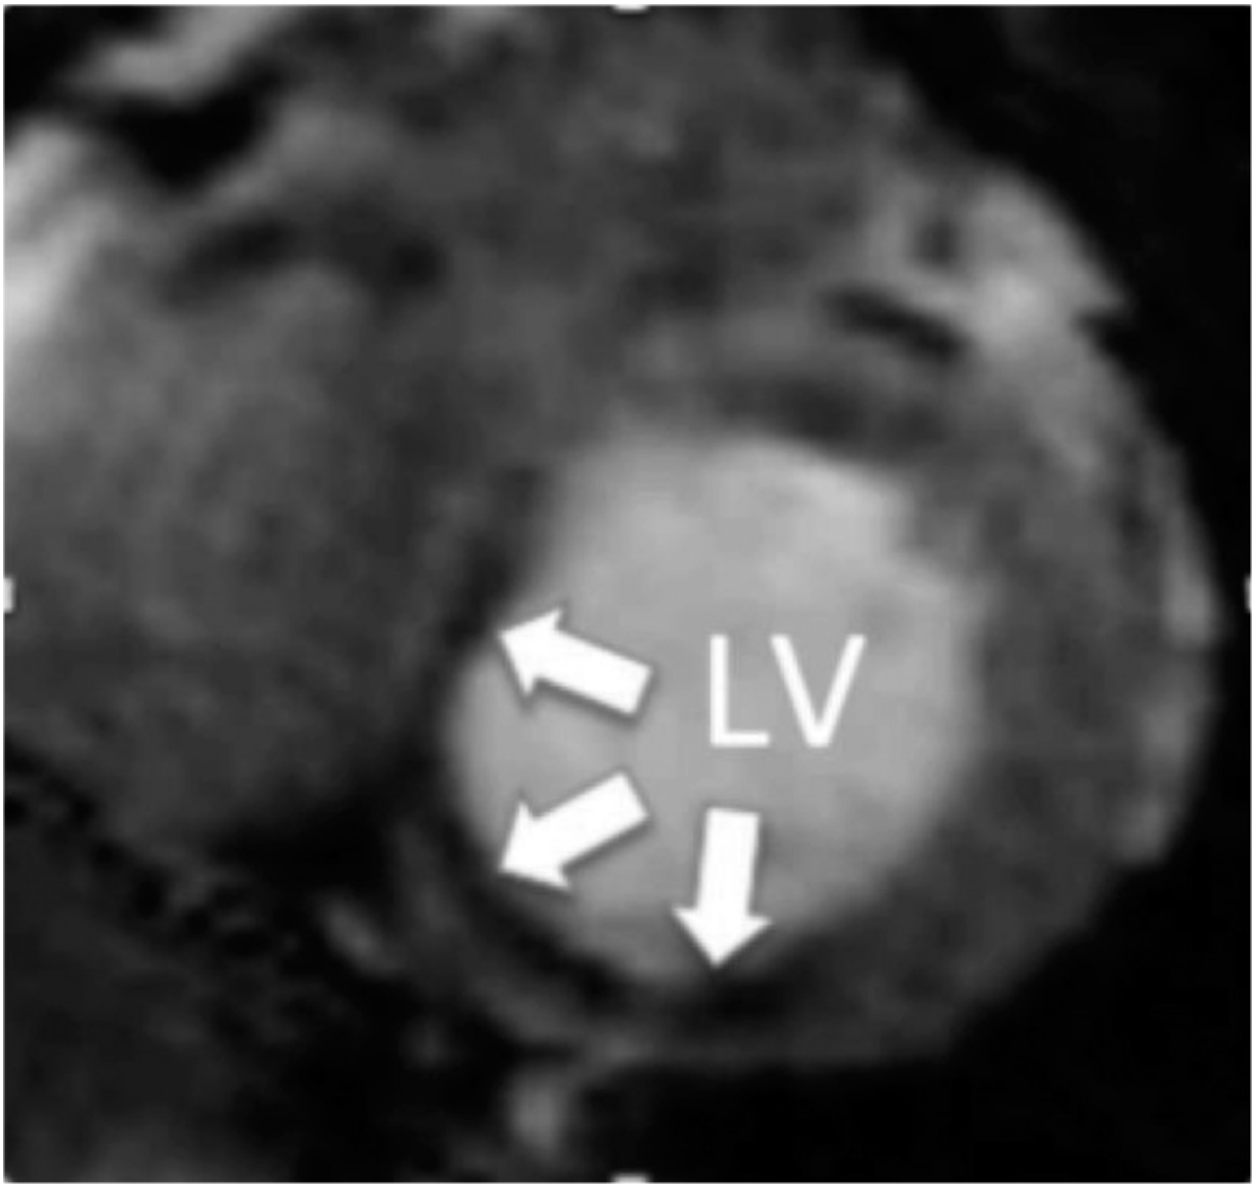

FIGURE 16.3 Short-axis view showing perfusion defects in the inferoseptal and inferior walls on first-pass perfusion imaging (white arrows). LV, left ventricle.

Myocardial Edema

Myocardial edema can be seen in many forms of myocardial injury and is not specific to acute MI. It can, however, be helpful in determining the acuity of an MI as well as the extent of injury. T2 relaxation time is a useful MRI parameter and is directly correlated to the percentage of free water. Myocardial edema in the setting of acute/subacute injury, myocyte swelling, and increased cell permeability in necrotic and ischemic areas accounts for the increase in free water and signal seen on T2-weighted imaging **(Figure 16.4)**. Of note, edema

after an ACS occurs in areas of both irreversibly and reversibly injured tissue and can overestimate the degree of myocardial necrosis. Myocardial edema may persist for weeks after infarction even after troponin levels have decreased to normal levels. A chronic infarct, on the other hand, will not have features of myocardial edema because water is resorbed and a fibrotic scar is formed, thus allowing CMR to distinguish between acute and chronic infarction. Cury et al[6] studied 64 patients presenting with chest pain, a normal ECG, and negative cardiac enzymes. Adding a T2-weighted sequence to cine imaging and LGE improved the specificity, positive predictive value, and accuracy in detecting ACS before a rise in serum biomarkers.[6]

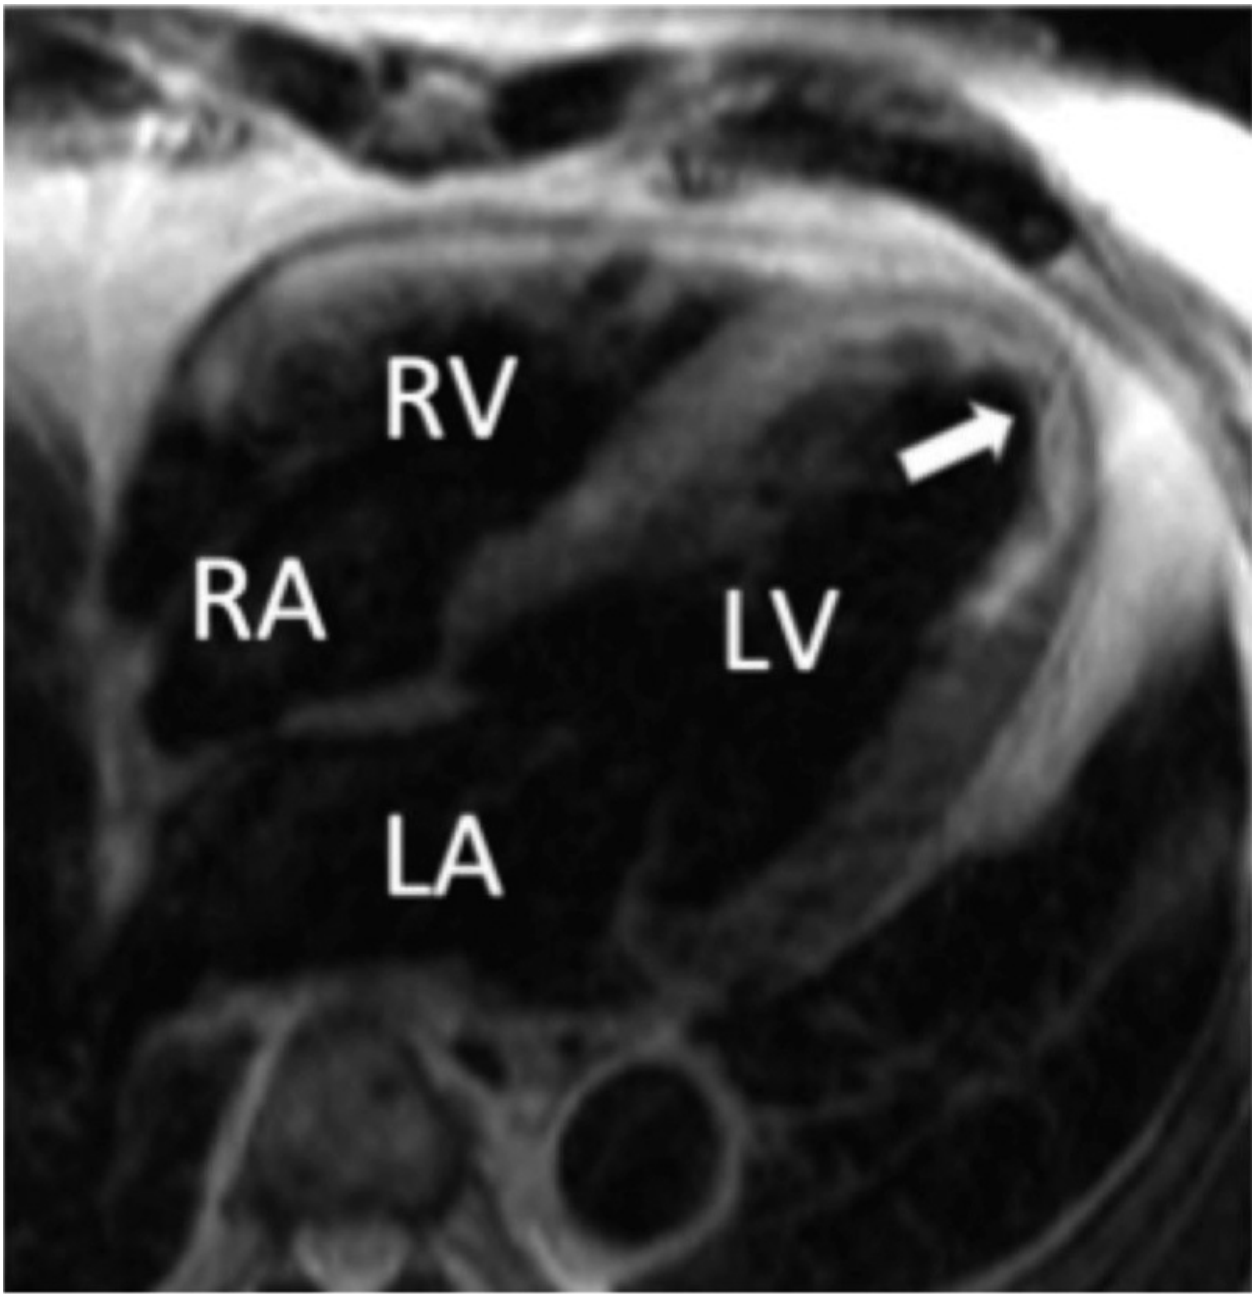

FIGURE 16.4 T2-weighted imaging demonstrating the presence of myocardial edema in the apical, apical lateral, and apical septal walls (*white arrow*) after acute myocardial infarction. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

In addition, combining T2-weighted imaging with LGE, a myocardial salvage index (MSI) can be calculated as the difference between the T2-intense region (area at risk) and final infarct (LGE), and used to predict outcomes after STEMI. Eitel et al[7] studied 208 patients with STEMI who had angioplasty within 12 hours of symptom onset and demonstrated that CMR-derived MSI can predict

long-term clinical outcomes, including major adverse cardiovascular events (MACE) and mortality.

Myocardial Infarction (Late Gadolinium Enhancement)

Gadolinium-contrast agents accumulate in extracellular space and do not enter healthy cells. In the acute MI phase, degradation of myocardial cell membranes allows contrast to enter the damaged cells if given enough time, appearing bright on LGE imaging. In the chronic setting, the contrast accumulates temporarily in the enlarged interstitial space occupied by fibrotic tissue **(Figure 16.5)**. Assessment of scar and viability is discussed subsequently**.**

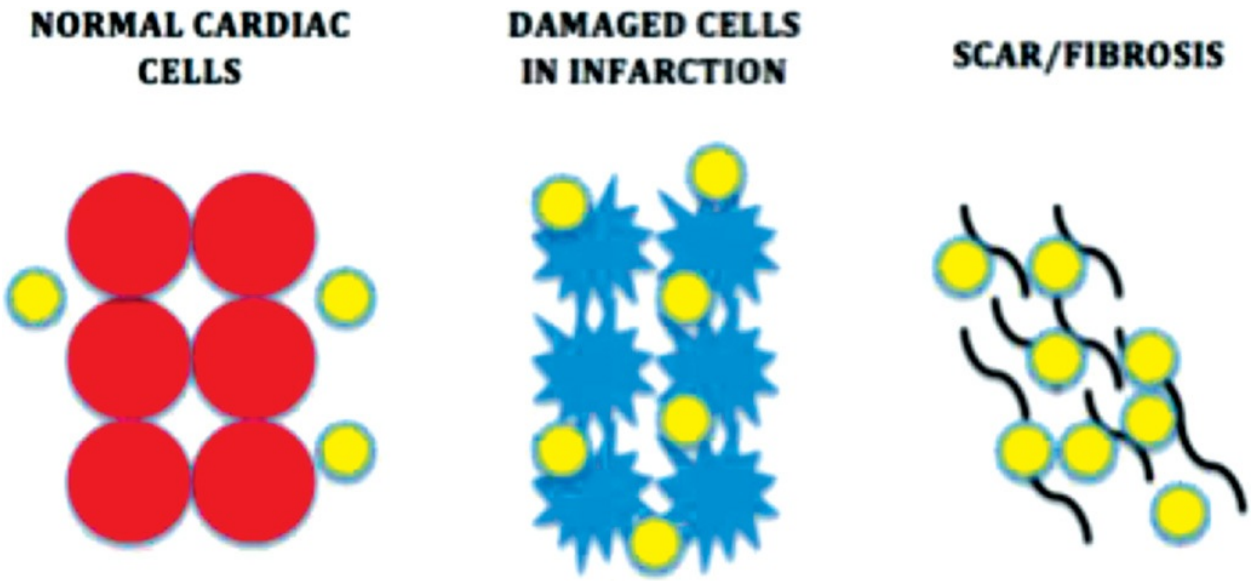

FIGURE 16.5 Deposition of gadolinium-contrast agents. Red—healthy cells; blue—acutely damaged cells; black—scar/fibrosis; yellow—gadolinium contrast.

Multiple studies have demonstrated the close correlation between LGE and histopathologic specimens of necrotic tissue. LGE is capable of detecting infarctions as small as 1 g due to the outstanding spatial resolution of CMR**.** Other imaging modalities are limited in their ability to differentiate small infarctions because of lower spatial resolution. The right ventricle, in particular, is poorly imaged by echocardiography, and acute RV infarction is more often demonstrated by LGE on CMR **(Figure 16.6)** than with the combination of ECG and echocardiography.

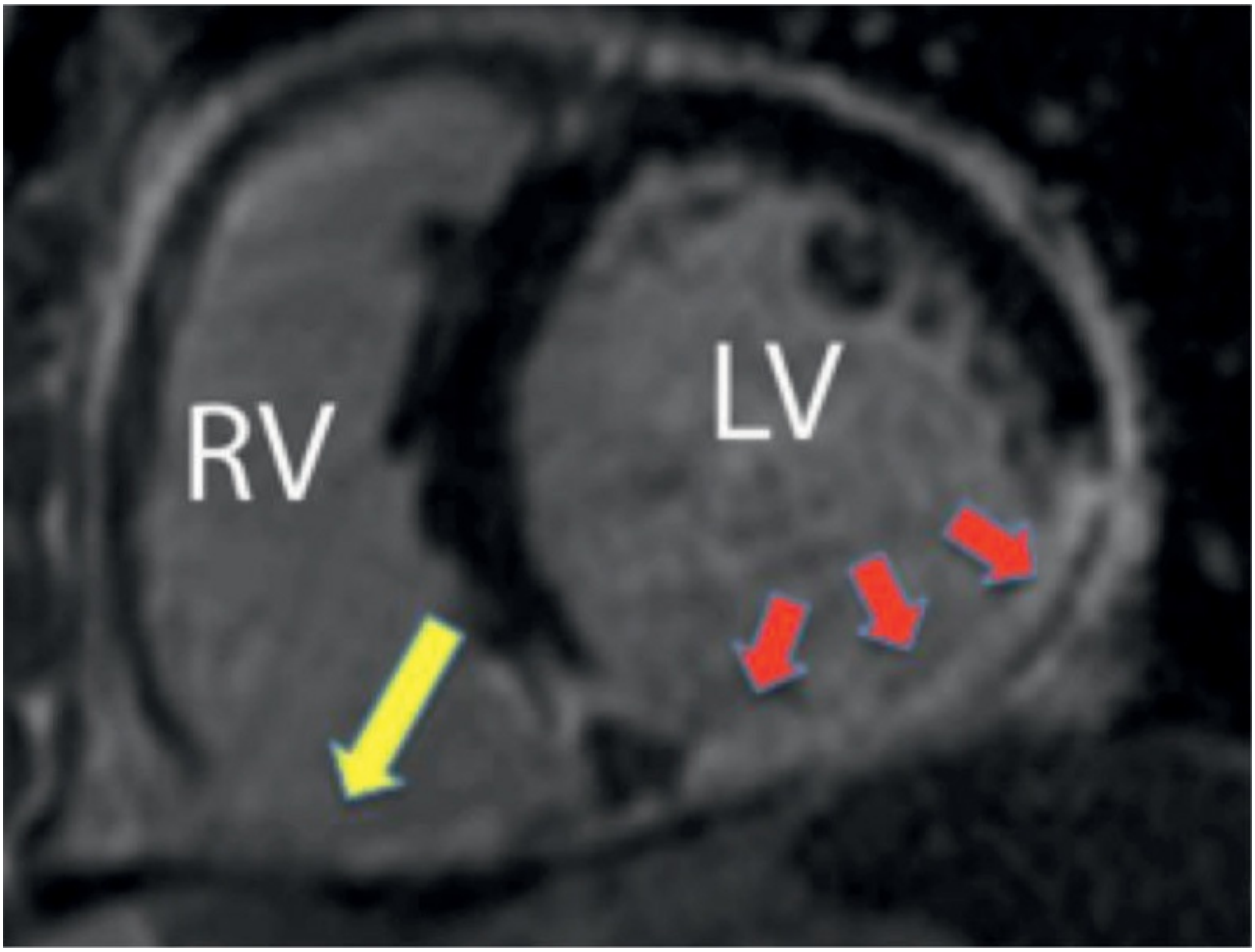

FIGURE 16.6 Short-axis view in delayed enhancement images demonstrating near transmural infarction of the inferior and inferolateral walls of the left ventricle (LV; *red arrows*) and near-transmural infarction of the inferior wall of the right ventricle (RV; *yellow arrow*). LV, left ventricle; RV, right ventricle.

Microvascular Obstruction and Intramyocardial Hemorrhage

Despite successful revascularization of their coronary arteries, subsets of patients have MVO**.** First-pass perfusion, early gadolinium enhancement, and/or LGE imaging can delineate these areas as a region without enhancement within the infarct core **(Figure 16.7)**, as a consequence of the lack of blood flow depositing contrast in these areas.

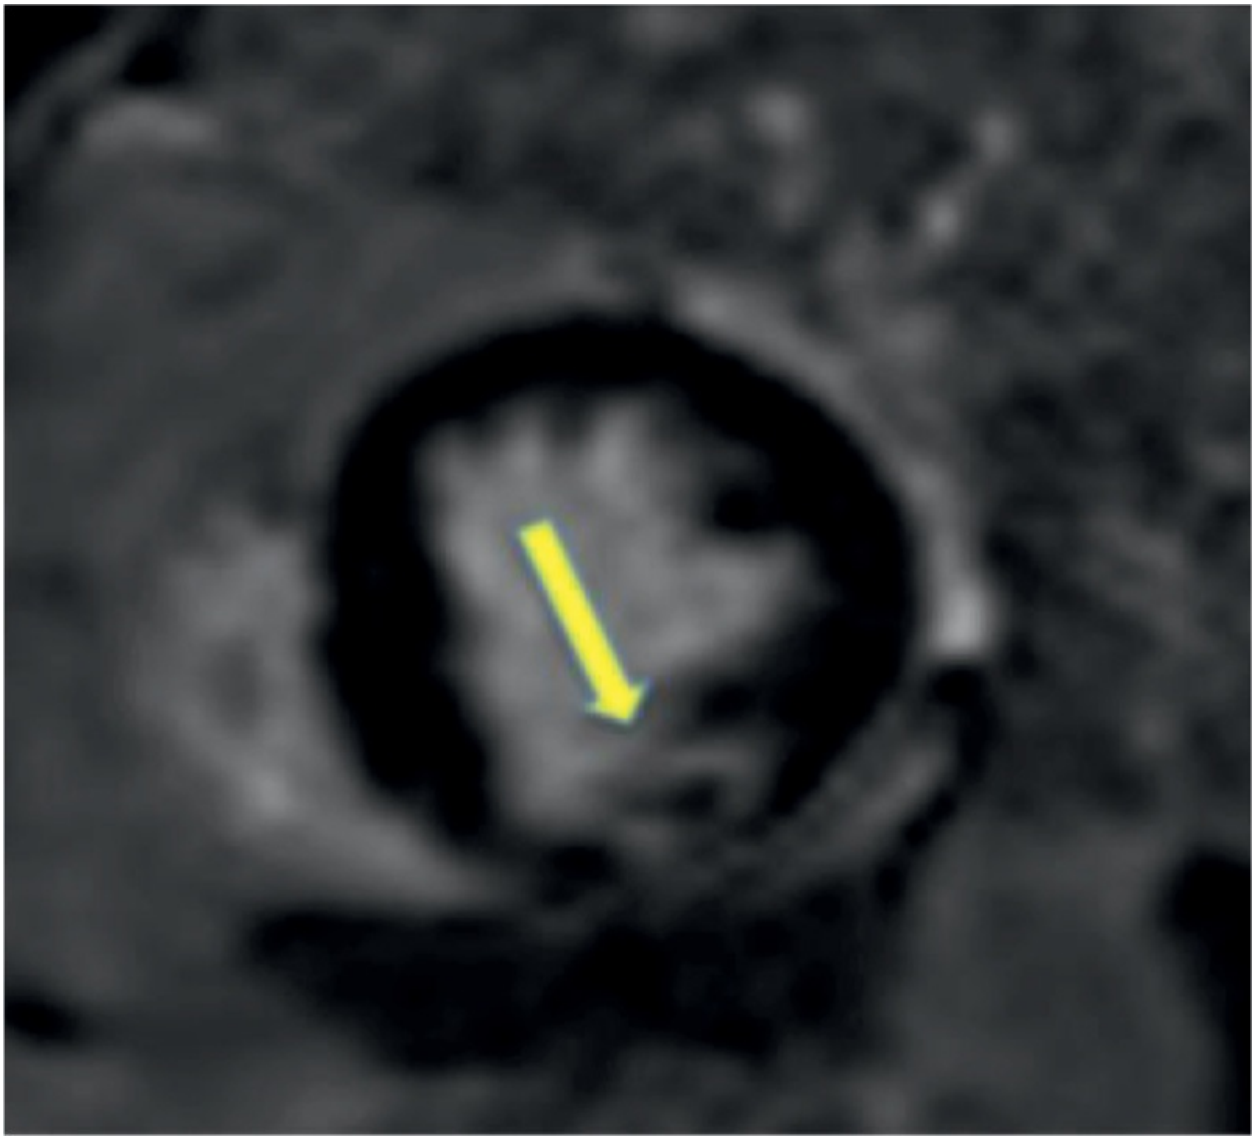

FIGURE 16.7 Short-axis view demonstrating a central hypointense core within an area of enhancement (*arrow*), signifying the presence of microvascular obstruction.

The presence of MVO has been demonstrated as an independent predictor of adverse LV remodeling and MACE. Hombach et al[5] studied 89 patients within 10 days of acute MI and concluded that, in addition to LV end-diastolic volume and LVEF, persistent MVO was a significant predictor of MACE.[5]

Viability

LGE is a useful tool to evaluate viability after ACS as well as provide prognostic information. The extent of the fibrosis is assessed by measuring the number of segments affected using a 17-segment model, as well as the percentage of

thickness involved in each segment. Segments with a small amount of fibrosis are often viable and can recover spontaneously if stunned and with revascularization in hibernating myocardium. Conversely, segments that have near transmural or transmural fibrosis are unlikely to recover. This can be a very helpful tool in determining which patients will benefit from revascularization.[8] Subendocardial enhancement that can progress to full transmural enhancement is characteristic of ischemic coronary disease. This is easily differentiated from nonischemic patterns of scar **(Figure 16.8)** that are described in more detail in section "Cardiac Magnetic Resonance in Heart Failure."

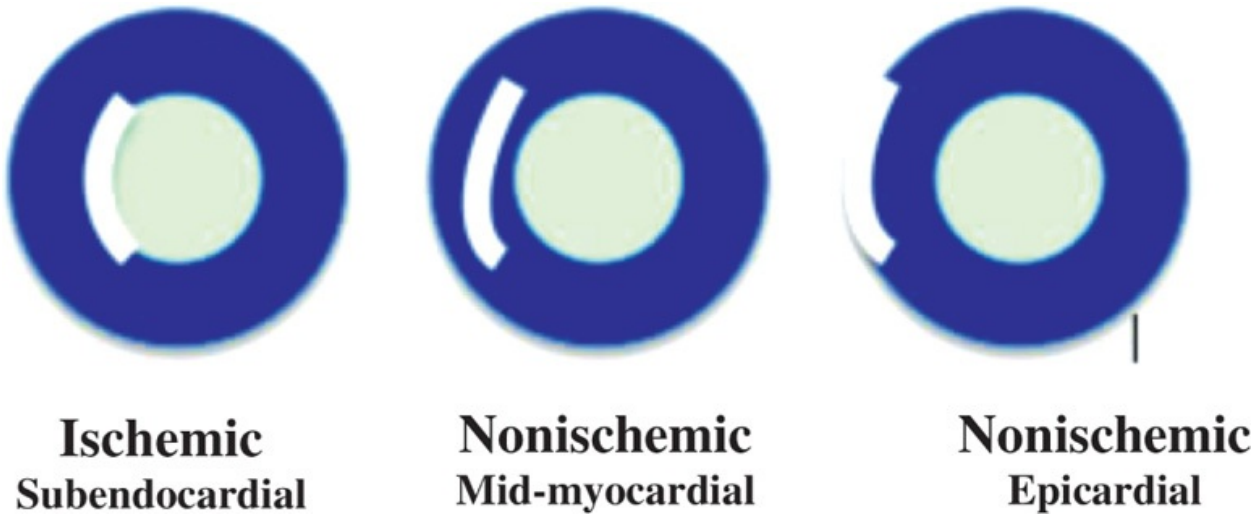

FIGURE 16.8 Fibrosis patterns in ischemic cardiomyopathies compared to nonischemic cardiomyopathies. Green—left ventricular (LV) cavity; blue—myocardium; white—fibrosis.

Cardiac segments with LGE evident in less than 25% to 50% thickness **(Figure 16.9)** are likely to regain function after revascularization, whereas segments with ≥75% enhancement **(Figure 16.10)** are most likely scarred and unlikely to benefit from further intervention. In addition, the amount of transmural infarction on LGE also predicts adverse LV remodeling.

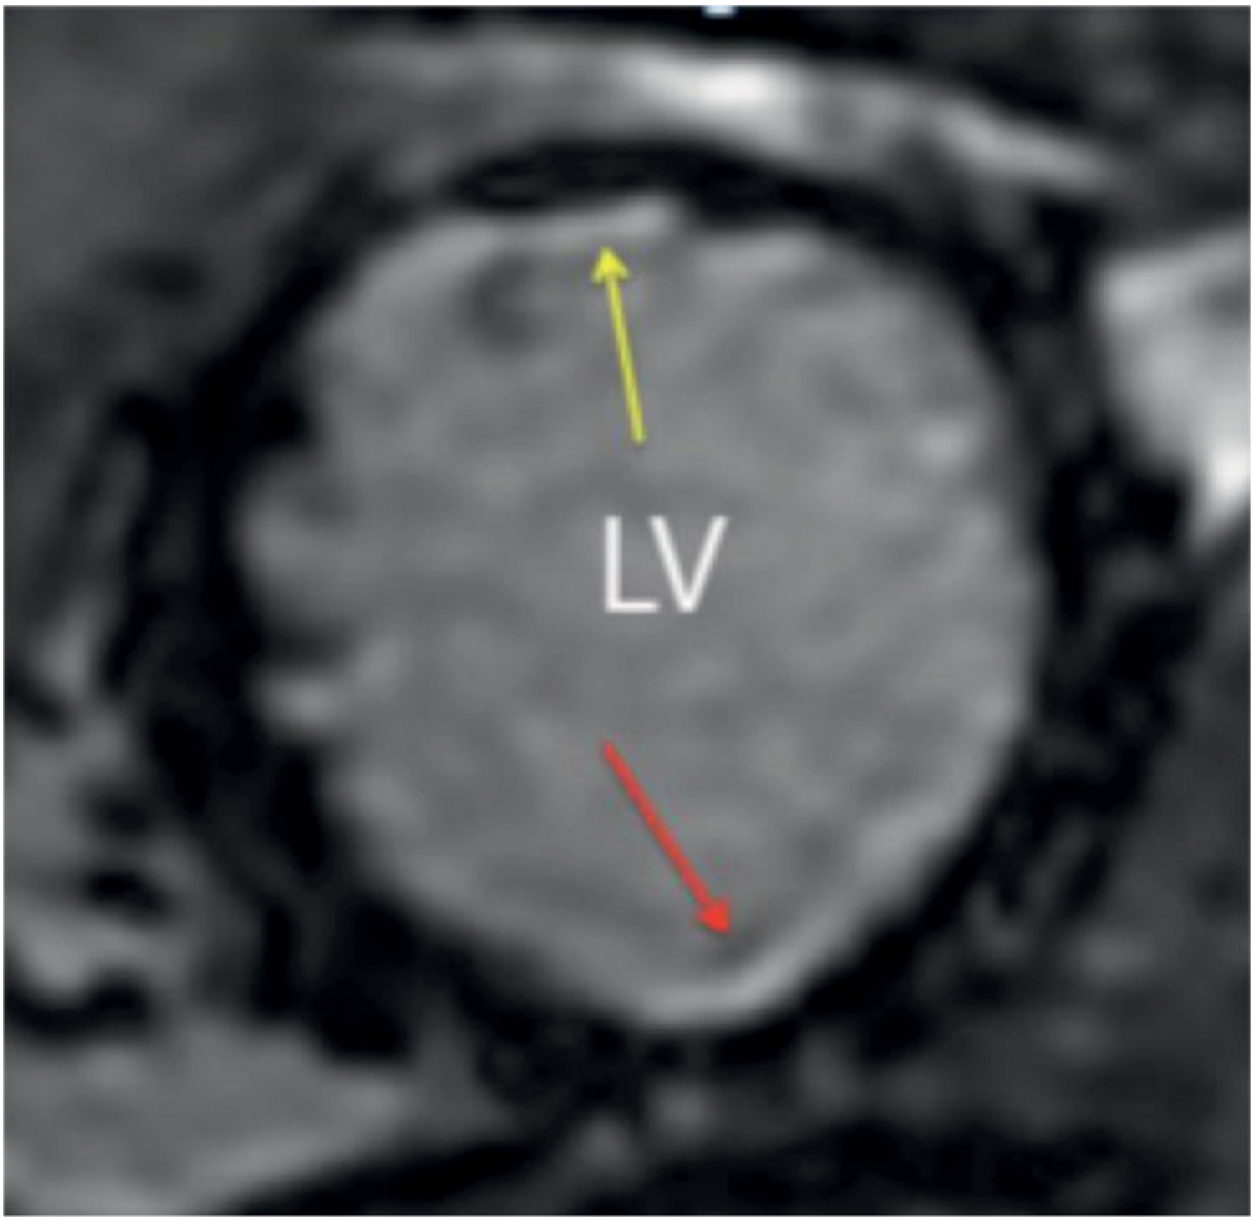

FIGURE 16.9 Short-axis view showing subendocardial infarctions of the anterior wall (*yellow arrow*) and inferior wall (*red arrow*) with a large area of preserved myocardium. LV, left ventricle.

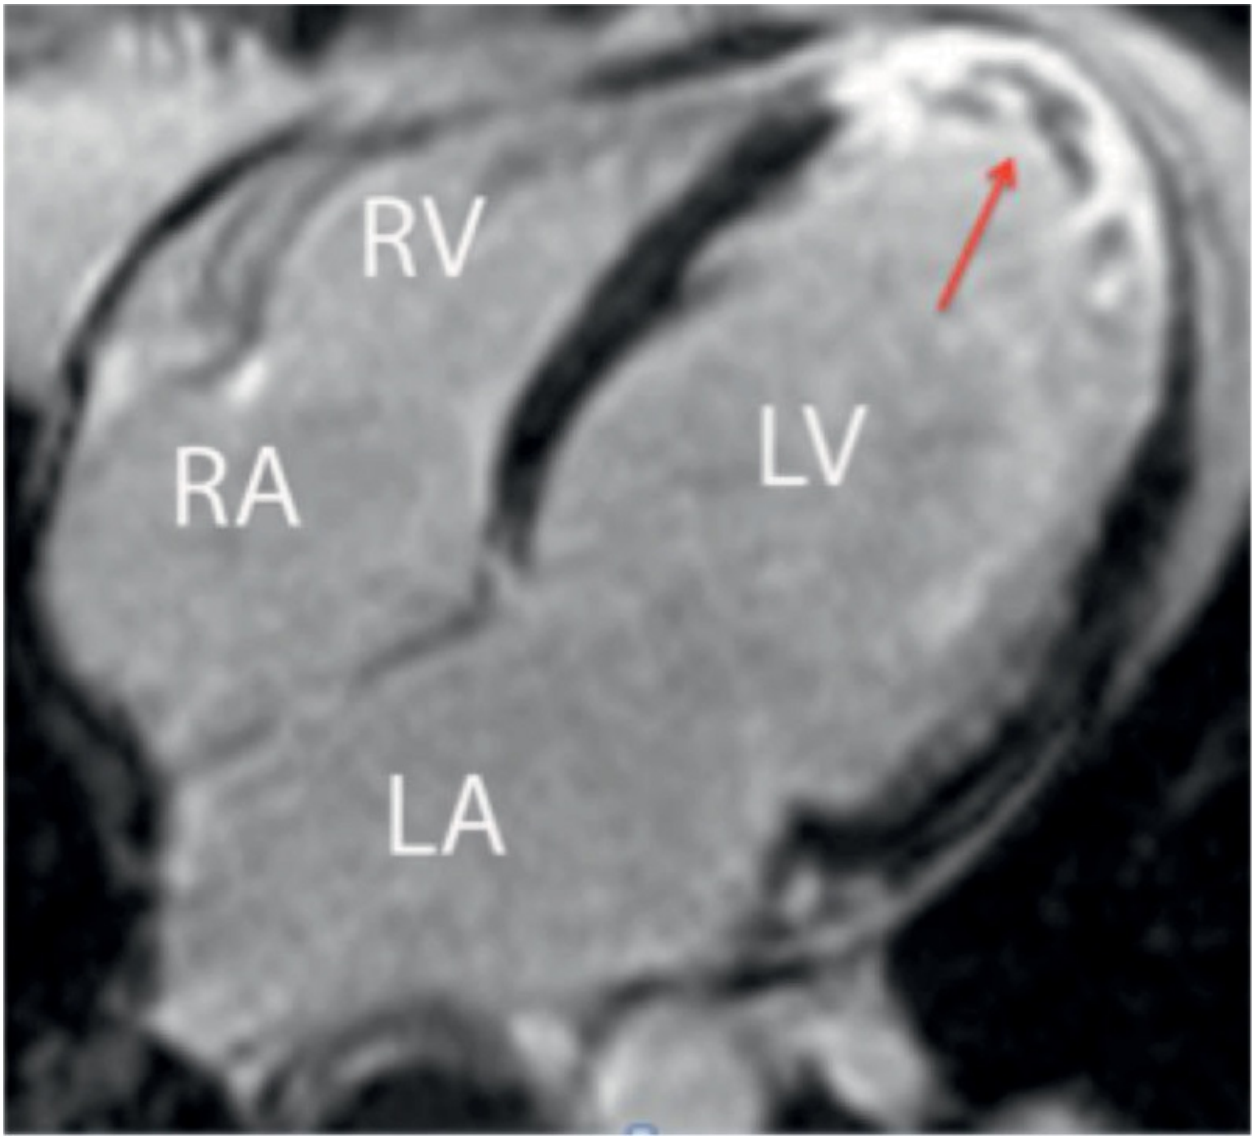

FIGURE 16.10 Four-chamber view demonstrating a large area of transmural infarction involving the LV apex, apical septal, and apical lateral walls (*arrow*). Note the central hypointensity within the area of enhancement, indicating the presence of microvascular obstruction. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

The peri-infarct region (also known as “gray zone” or “border zone”) on LGE imaging, is defined as an area with signal intensity above that of normal myocardium but less than dense scar. It has been recognized as a marker of arrhythmia risk. Whether the peri-infarct zone, overall scar amount, or LVEF alone are better predictors of spontaneous ventricular arrhythmias remains a question. Gouda et al[9] studied 48 patients post MI, half of whom had sustained monomorphic ventricular tachycardia (VT), and evaluated total scar, scar core, mean infarct transmurality, peri-infarct zone, and number of segments with LGE.

In multivariable analysis, total infarct size as percentage of LV mass was the only significant independent predictor of spontaneous and inducible VT.[9]

Post–Myocardial Infarction and Procedural Complications

With the advent of early percutaneous coronary intervention, the incidence of post-MI complications has dramatically decreased. When patients present late after onset of coronary occlusion, there is a greater risk (albeit still small) of dangerous post-MI complications. It is important to be aware of these phenomena because they are often acute and any delay in diagnosis can be fatal. Given the rapidity in onset and clinical deterioration, portable echocardiography is typically the most useful tool. However, if the patient is stable enough, post-MI complications can be more accurately assessed utilizing CMR.

Left Ventricular Thrombus

One of the most common complications of MI is the development of LV thrombus. Thrombus is most common in large anterior infarcts but can develop even in small isolated apical infarctions, as well as in other locations, particularly the septal and inferolateral walls.

Diagnosis by echocardiography, even with contrast administration, is far less sensitive than detection by CMR. Using simple CMR techniques, an LV thrombus can rapidly be distinguished from normal adjacent myocardium. Although contrast echocardiography significantly increased detection of thrombi compared to noncontrast echocardiography, LGE more accurately detected smaller and/or mural thrombi **(Figure 16.11)**.[10] Differentiation between thrombi and other cardiac masses is discussed in section “Miscellaneous.”

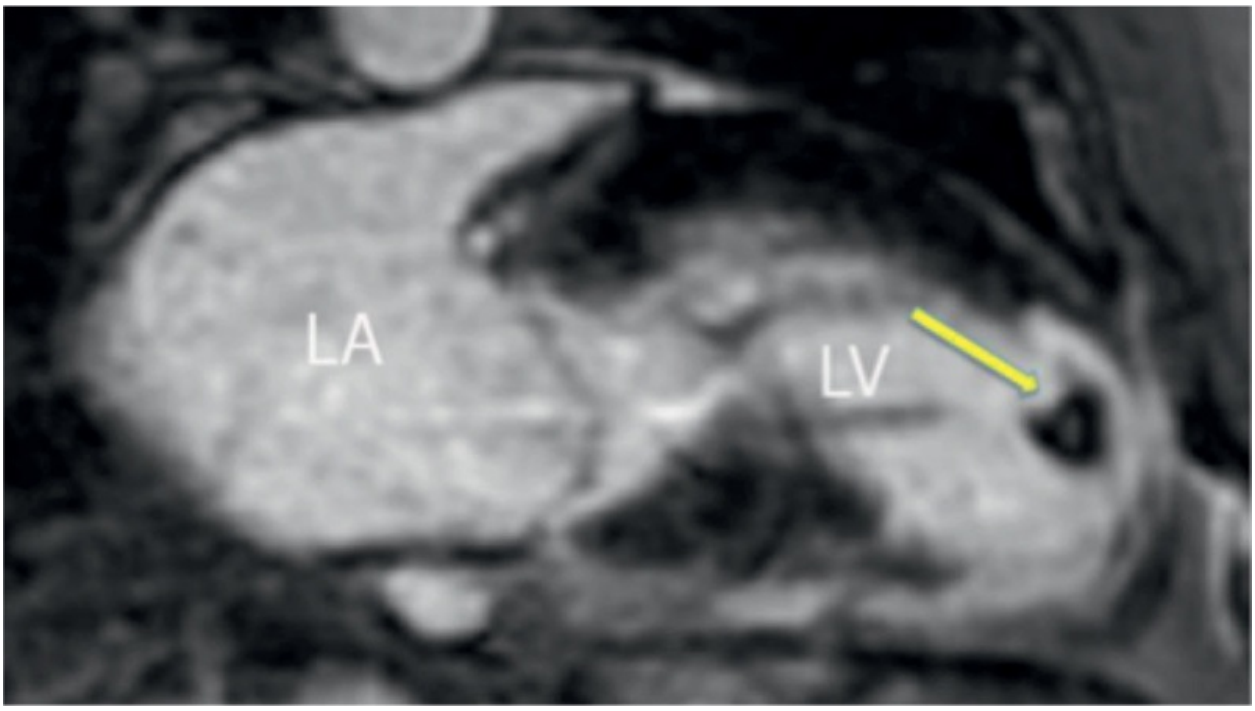

FIGURE 16.11 Two-chamber view demonstrating hypointense LV thrombus (*yellow arrow*) on late gadolinium enhancement imaging. LA, left atrium; LV, left ventricle.

Left Ventricular Aneurysm

Another common complication of acute MI is the development of an LV aneurysm. Typically, an infarcted, thin-walled left ventricle that has remodeled extensively causes the formation of aneurysms. Persistent ST-segment elevations on an ECG in the absence of chest pain or acute MI can indicate the presence of an LV aneurysm. Cine imaging and/or LGE sequences **(Figure 16.12)** can demonstrate the extent of aneurysm formation and clearly delineate the wide orifice that is characteristic of them.

FIGURE 16.12 A, Short-axis view in cine images demonstrating a large aneurysm of the anterolateral wall. B, Short-axis late enhancement view demonstrating near-transmural infarction of the aneurysmal myocardial territory. LV, left ventricle; RV, right ventricle.

Left Ventricular Pseudoaneurysm/Free Wall Rupture

Less common, but more urgent, is the diagnosis of pseudoaneurysm/contained wall rupture. A true aneurysm contains all three layers of myocardial tissue (subendocardial, endocardial, and epicardial), whereas a pseudoaneurysm wall is constituted only by pericardium and fibrotic/inflammatory tissue (in essence, a contained free wall rupture) and is at high risk of losing that containment. A pseudoaneurysm typically has a narrow neck.

Uncontained free wall rupture is another rare post-MI complication that can be rapidly fatal. When suspected, immediate diagnosis with portable echocardiography and surgical intervention is often the only chance of survival. Patients are rarely, if ever, stable enough to have a CMR. In the rare case that a patient has a contained free wall rupture, CMR can provide detailed anatomic assessment of the rupture, including site, orifice, material containing the rupture, and other important parameters **(Figure 16.13)**.

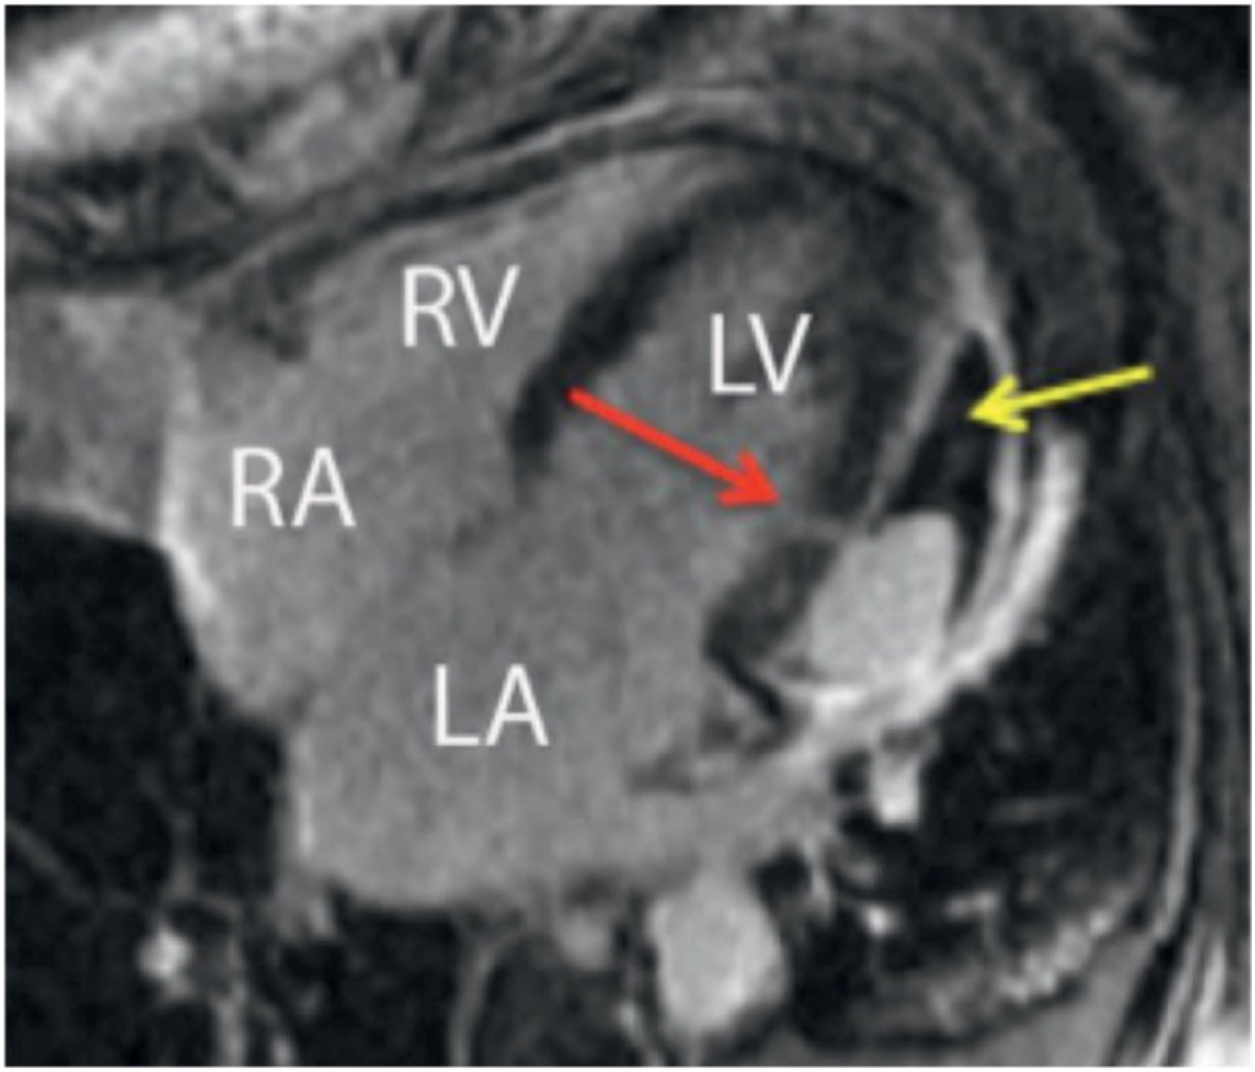

FIGURE 16.13 Free wall rupture contained only by thrombus (*yellow arrow*) and pericardium. Note the narrow neck at the point of rupture (*red arrow*). (Image courtesy of Jiwon Kim, MD, Weill Cornell Medical Center, New York, NY.) LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Ventricular Septal Defect

Ventricular septal defect (VSD) is another rare but potentially fatal complication that typically occurs within 1 week of acute MI. Patients typically present with a new holosystolic murmur, biventricular failure, and cardiogenic shock. Rapid diagnosis and surgical intervention are key to ensuring a patient's survival. Echocardiography is the diagnostic imaging modality of choice when VSD is suspected because of its portability and rapid image acquisition. Very rarely will a patient be stable enough to acquire a CMR to assist with diagnosis. If the patient is stable and there are poor acoustic windows on echocardiography, CMR

can provide excellent anatomic detail of the VSD and calculate the Qp/Qs for shunt quantification.

CARDIAC MAGNETIC RESONANCE IN NONCORONARY CAUSES OF ACUTE CHEST PAIN (WITH OR WITHOUT TROPONIN ELEVATION)

The most common cardiac causes of chest pain and troponin elevation in patients with nonobstructive coronary artery disease are myocarditis, myopericarditis, Takotsubo cardiomyopathy, and acute aortic syndromes.

Myocarditis

Myocarditis (both acute and chronic) remains a diagnostic challenge in clinical cardiology. Myocarditis should be considered in any patient with chest pain, elevated cardiac biomarkers, and normal coronary arteries. In addition, cardiomyopathy may result from chronic inflammatory disease in patients with inadequate immune response. Endomyocardial biopsy (EMB) with immunohistology is the “gold standard” for the diagnosis of myocarditis, but it is an invasive procedure with risks of complications.

CMR has been increasingly used as an aid in the diagnosis of myocardial inflammation in patients with suspected myocarditis. The International Consensus Group on CMR Diagnosis of Myocarditis was founded to establish recommendations on CMR techniques for myocarditis.[11] Infections are one of the most common etiologies of myocarditis, predominantly viral infections or post-viral immune-mediated reactions. Myocardial inflammation may also be triggered by reversible or irreversible toxic, ischemic, or mechanical injury, drug-related inflammation, transplant rejection, or some other immune response.[11] No single clinical or imaging finding confirms the diagnosis of myocarditis. The diagnostic approach should be an integrated synopsis of history, physical examination, noninvasive and invasive testing (LV function and volume as well as CMR tissue characterization) to guide medical therapy.

CMR has the ability to characterize inflammatory tissue changes. One approach is the Lake Louise Criteria (LLC): edema with T2-weighted imaging, hyperemia, or capillary leak with early gadolinium enhancement, and irreversible cell injury with LGE (besides other nonspecific findings such as LV dysfunction and pericardial effusion).[11] These CMR imaging techniques are used to determine the presence of edema, hyperemia, and myocardial

necrosis/fibrosis, which are part of the pathological process seen in myocarditis **(Figure 16.14)**. Several patterns of LGE may be seen in myocarditis, which usually follows a nonischemic pattern. Focal signal intensity may be seen in a subepicardial or intramyocardial pattern and can involve part or the entire extent of the myocardial wall **(Figures 16.15** and **16.16)**.

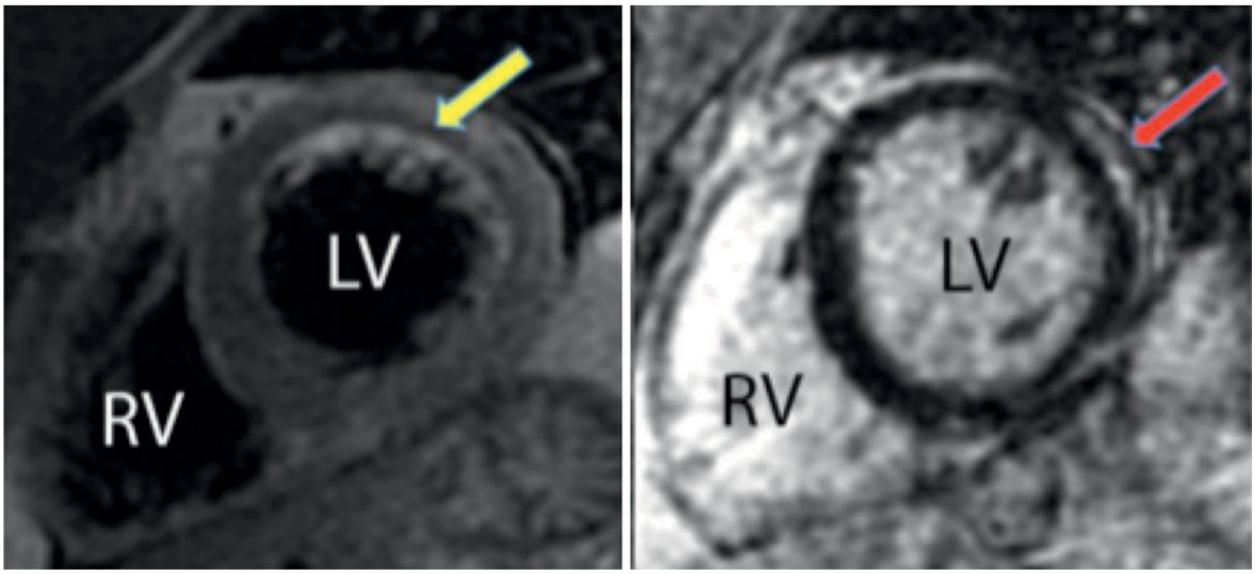

FIGURE 16.14 Myocardial edema on T2-weighted imaging (*yellow arrow*) and subepicardial late gadolinium enhancement (*red arrow*) in a patient with myocarditis. LV, left ventricle; RV, right ventricle.

Panel (B) demonstrates positron emission tomography (PET) imaging of the same patient. Panel (C) demonstrates fused PET magnetic resonance imaging (MRI): noteice the inflammatory activity in the area of LGE, consistent with active myocarditis. LV, left ventricle; RV, right ventricle. (Figure courtesy of Zahi Fayad, PhD, Maria Giovanna Trivieri, MD, and Phil Robson, PhD, Icahn School of Medicine, Mount Sinai Medical Center, New York, NY.)

More recently, T1 and T2 mapping with quantification of extracellular volume have provided additional information in the CMR diagnosis of myocarditis. Myocardial T1- and T2- relaxation times are significant parameters of active inflammation and edema in patients with acute myocarditis, as well as during the convalescent stage of the disease. In a recent publication, the MyoRacer Trial, Lurz et al[12] compared the diagnostic performance of CMR using T1 and T2 mapping versus the reference standard, EMB. They noted that in patients with acute myocarditis symptoms, T1- and T2-mapping techniques were even superior to the LLC (which have a sensitivity of 82% and a specificity of 98% for acute myocarditis). Therefore, T1 and T2 mapping may add useful information over T1- and T2-weighted imaging in the diagnosis of myocarditis.[12]

In summary, in patients suspected of having acute myocarditis, a comprehensive quantitative CMR is a useful tool that can reliably detect inflammatory alterations in the myocardium and should be implemented early if myocarditis is suspected.

Acute Pericarditis

Inflammation of the pericardium often presents as acute chest pain, with possible troponin elevation if there is concomitant myocardial involvement. The causes

of acute pericarditis are vast and include infectious (viral, bacterial, fungal, and mycobacterial), rheumatologic (eg, scleroderma, lupus, and rheumatoid arthritis), sequelae of radiation therapy, post-MI (ie, Dressler syndrome), trauma, and uremia.

Although systematic evaluation of the role of CMR in acute pericarditis is lacking, T2-weighted and LGE imaging can respectively demonstrate edema and enhancement of the pericardium **(Figure 16.17)** when there is ongoing inflammation.[13]

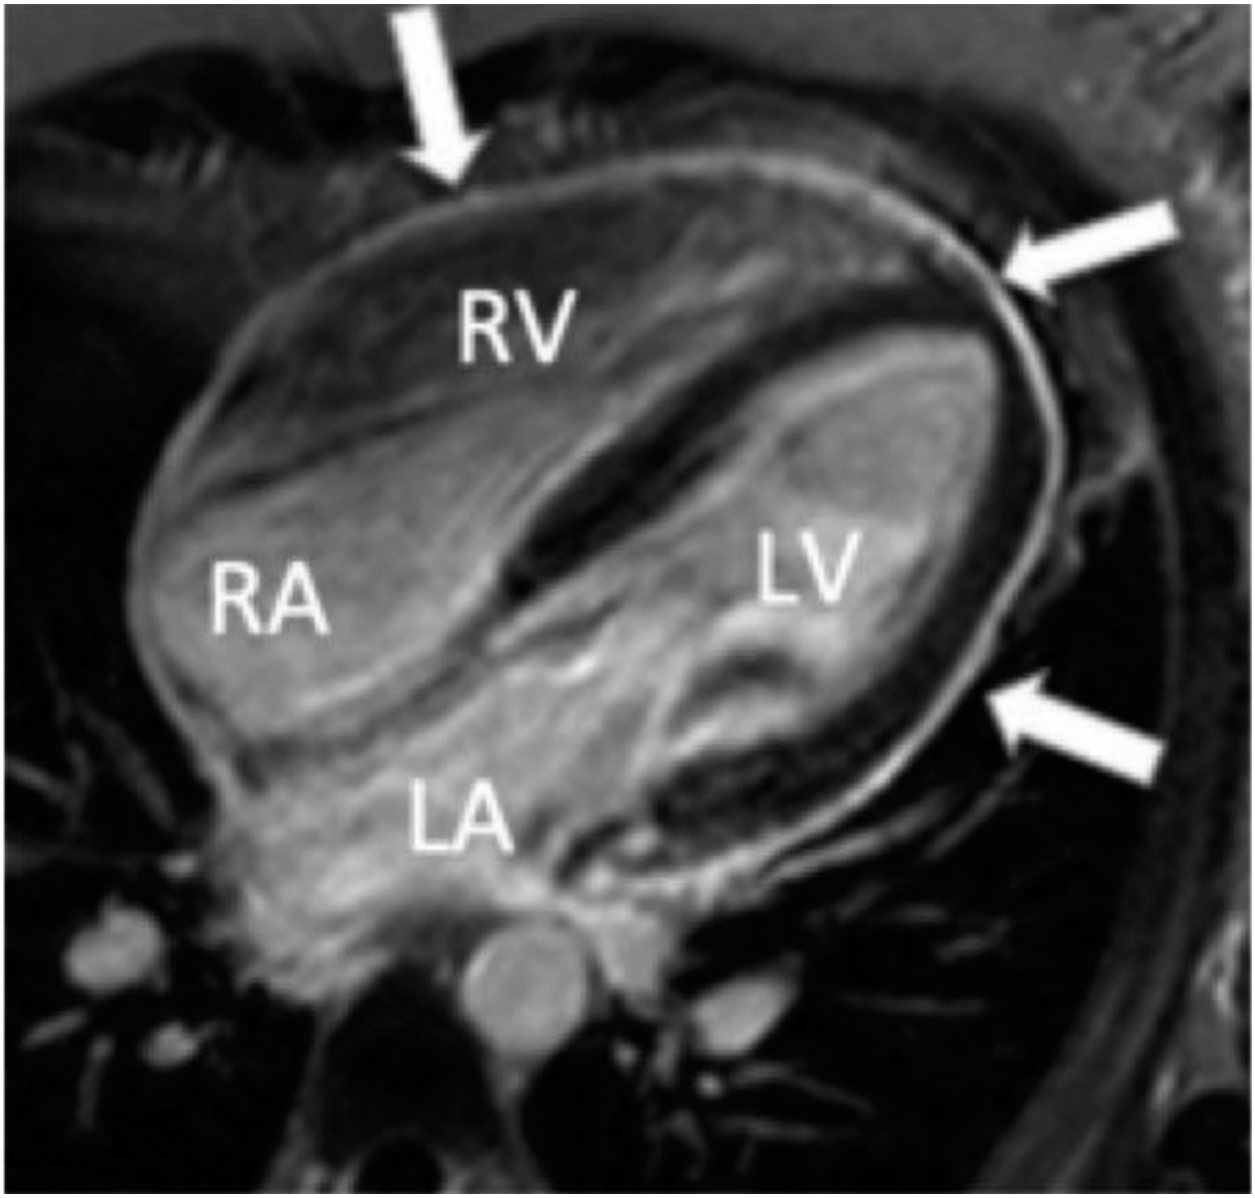

FIGURE 16.17 Diffuse delayed enhancement of the pericardium (*arrows*) in a patient with acute pericarditis. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Takotsubo Cardiomyopathy

Takotsubo cardiomyopathy, also known as “apical ballooning syndrome” or “stress-induced cardiomyopathy,” is a unique syndrome that often presents similarly to an ACS or myocarditis **(Table 16.4)**. Among the hallmarks of the syndrome are wall motion abnormalities that do not correlate with a single coronary arterial territory. Takotsubo cardiomyopathy is classically described as a consequence of severe emotional stress, but virtually any stress, emotional or physical, can lead to this clinical entity. In some cases, no inciting event can be identified.

TABLE 16.4 Comparison of MRI Findings in Takatsubo Cardiomyopathy, Myocardial Infarction, and Myocarditis

	Takotsubo	Myocardial Infarction	Myocarditis
WMA in a coronary distribution	No	Yes	No
Edema	Yes (typically in areas of WMA)	Yes (typically in areas of WMA)	Yes (subepicardial/midmyocardial or transmural)
Late gadolinium enhancement	No or low intensity	Yes (subendocardial to transmural)	Yes (subepicardial/midmyocardial or “patchy”)
Resolution or follow up to 3 months	Majority = Yes	No	Majority = Yes

WMA, wall motion abnormality.

As of yet, the pathophysiology of Takotsubo cardiomyopathy is not well understood; theories range from multivessel spasm to catecholamine toxicity. Patients with Takotsubo cardiomyopathy often present with chest pain, ST-segment changes such as ST elevation or diffuse ST depression and prolongation of the QT interval. The classic wall motion abnormalities described are LV basal segment hyperkinesis with severe hypokinesis of the apical segments, and hence the term “apical ballooning.” Multiple variants of Takotsubo have been described including reverse Takotsubo with hyperkinesis of the apex and severe hypokinesis of the mid segments and a mid-wall variant where only the mid segments are hypokinetic.

Takotsubo cardiomyopathy remains a diagnosis of exclusion. The diagnosis is only in the absence of coronary artery disease on invasive or noninvasive angiography that matches with wall motion abnormalities. CMR is emerging as a

useful tool to readily distinguish between other causes of ACS and Takotsubo cardiomyopathy.

Cine imaging on CMR can accurately depict wall motion abnormalities that do not correlate with a coronary territory **(Figure 16.18)**. Myocardial edema on T2-weighted imaging, as described earlier, is often prominent in areas of wall motion abnormality. Edema and wall motion abnormalities can also be seen in the right ventricle.

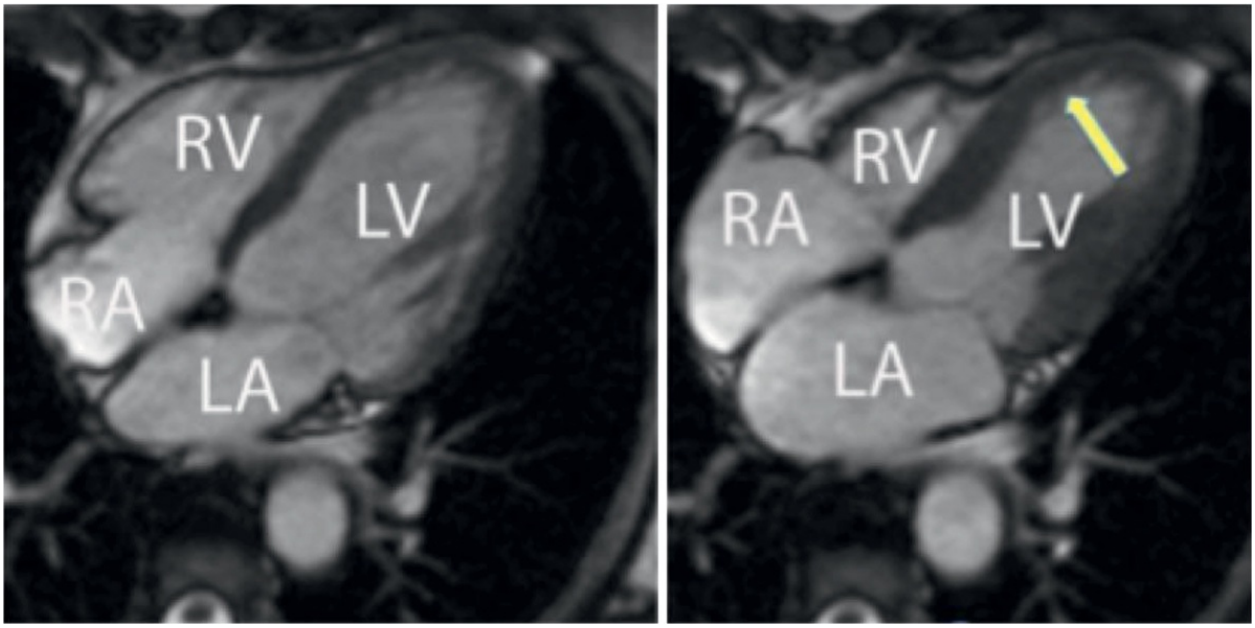

FIGURE 16.18 Four-chamber cine view (left: diastole; right: systole) demonstrating wall motion abnormalities in a patient with Takotsubo cardiomyopathy. Note the lack of movement of the mid-distal segments (*arrow*) compared to the basal segments. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

The lack of significant LGE in the areas of wall motion abnormality confirms the absence of MI**.** The degree of enhancement is almost never to the extent of a true MI and is sometimes termed “low-intensity LGE” **(Figure 16.19)**.[14]

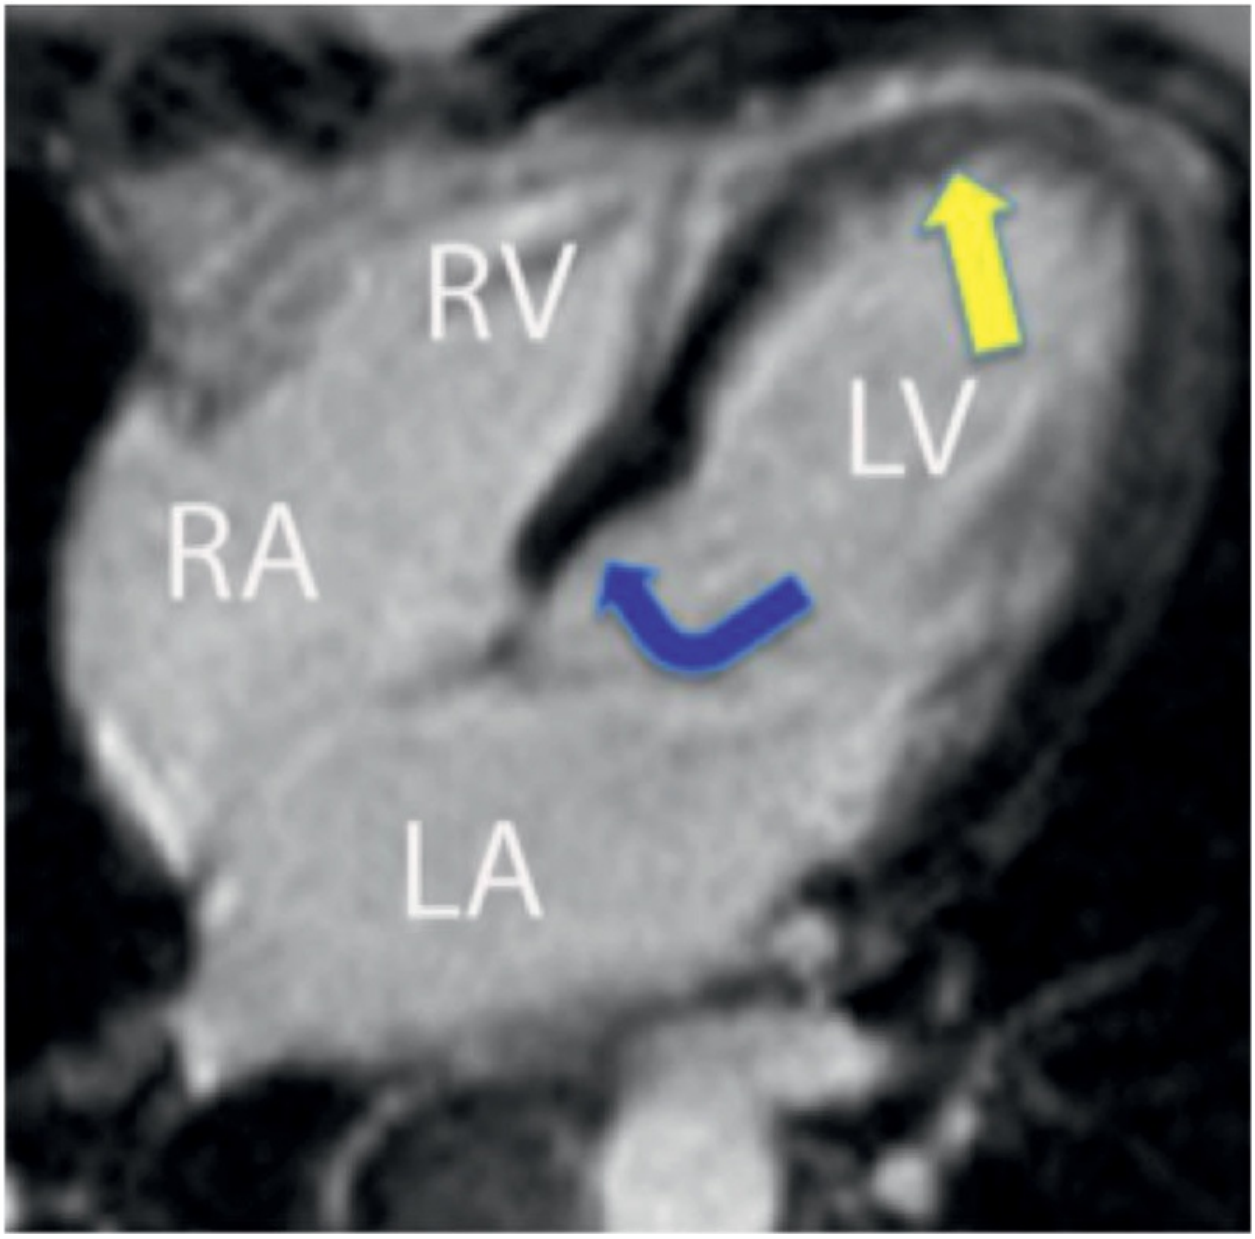

FIGURE 16.19 Four-chamber view demonstrating low-intensity late gadolinium enhancement (LGE) (*yellow arrow*) compared to normal myocardium (*blue arrow*) in the same patient as in the previous figure with Takotsubo cardiomyopathy. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

This constellation of findings (wall motion abnormalities beyond a coronary distribution, myocardial edema, and the lack of intense LGE) can assist in the diagnosis of Takotsubo cardiomyopathy. Patients often have a good prognosis, with the majority recovering LV function at 3 months.

Acute Aortic Syndromes

MRI can play an important role in determining the location and extent of involvement in patients with aortic dissection. When utilized, MRI provides a complete anatomic assessment of the intimal flap **(Figure 16.20)**, aortic valve morphology and severity of insufficiency, the presence of hemopericardium indicating impending aortic wall rupture, branch involvement of the great vessels, and the presence of an MI due to dissection into a coronary artery (usually the right coronary). MRI is also one of the most valuable imaging techniques for imaging aortic dissections after surgical intervention. Images are highly reproducible, making it an excellent modality for serial examinations. Residual dissection, thrombosis of the false lumen, suture dehiscence, and anastomotic leaks can be easily identified and help guide further management.[15]

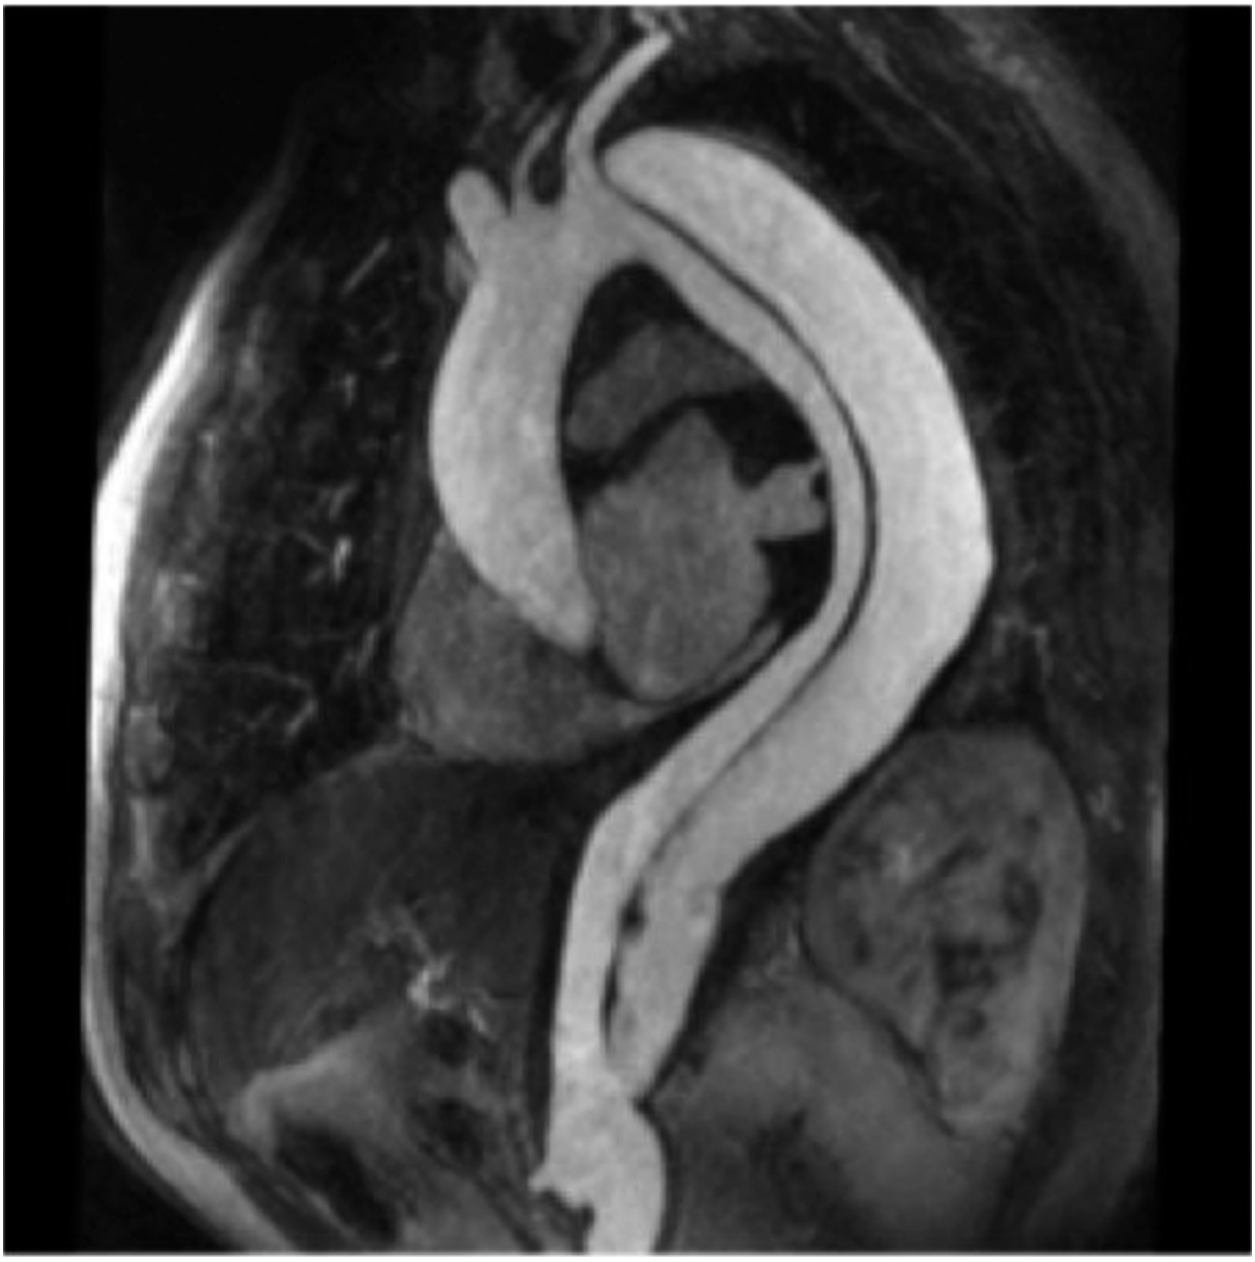

FIGURE 16.20 Contrast-enhanced aortic magnetic resonance angiography (MRA) demonstrating a type-B dissection flap extending from the origin of the left subclavian artery to the abdominal aorta.

CARDIAC MAGNETIC RESONANCE IN VENTRICULAR ARRHYTHMIAS

Sudden cardiac death (SCD) has been the leading cause of death in North America. It has been well documented that severely depressed LVEF (<35%) has been associated with SCD. Ventricular fibrosis or myocardial “scar” is the nidus

or “anatomic substrate” for ventricular arrhythmias in patients with ischemic cardiomyopathy (ICM) and nonischemic cardiomyopathy (NICM). In multiple randomized, controlled trials, with inclusion based on LVEF, the use of an ICD has reduced mortality. These studies are the basis of our current guidelines in primary prevention. However, only a fraction of patients (approximately 30%) receiving an ICD for primary prevention of SCD get appropriate therapy. The use of LVEF solely as the marker for ICD implantation is not ideal. SCD can occur also in patients with normal and mildly depressed LVEF. Therefore, a more in-depth need for risk stratification for primary prevention in patients with ICM and NICM (ie, myocarditis, sarcoidosis, and arrhythmogenic right ventricular cardiomyopathy [ARVC]) is necessary. CMR with LGE can be used to detect myocardial scar size and heterogeneity. Because myocardial scar is an important substrate for developing VT, CMR may be useful in predicting future ventricular arrhythmias.[16] CMR with contrast can be used to assess myocardial scar characteristics including scar transmurality, the border zone, and variations in the density of scar tissue and heterogeneity versus homogeneous scar appearance.

Disertori et al[16] performed a meta-analysis to evaluate the predictive value of LGE in CMR for ventricular tachyarrhythmia in ventricular dysfunction. Nineteen studies enrolling 2850 patients with ICM and NICM were included in the meta-analysis. The study demonstrated that LGE is a powerful predictor of ventricular tachyarrhythmic events in patients with ventricular dysfunction of ischemic and nonischemic etiology. The prognostic power of LGE for ventricular arrhythmias is particularly strong in patients with severely depressed LVEF (≤30%).

Regions of viable tissue within the gray zone detected by three-dimensional LGE-CMR correspond to conduction channels on endocardial voltage mapping and, therefore, may play a role in arrhythmia management and therapy.[16] As discussed also in section “Cardiac Magnetic Resonance in Heart Failure,” the presence or absence of fibrosis or, particularly, mid-wall fibrosis in NICM are indicators of high versus low risk of arrhythmic events.

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy (HCM) remains the most common cause of SCD in young adults. Contrast-enhanced CMR with LGE has emerged as an in vivo marker of myocardial fibrosis and perhaps a marker for ventricular arrhythmias

and SCD **(Figure 16.21)**.[17]

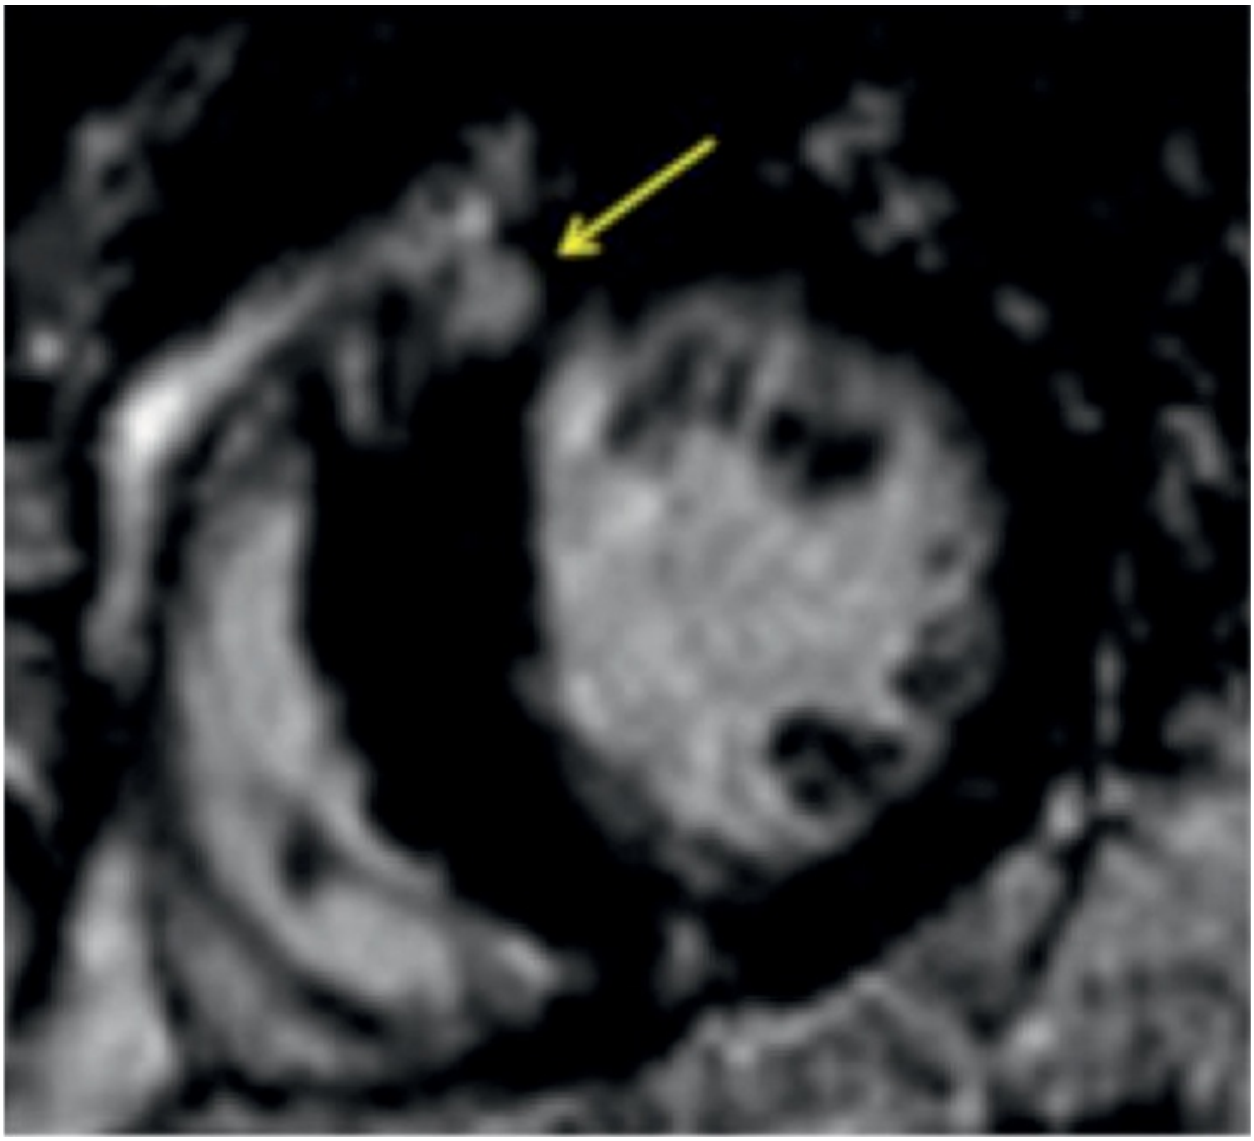

FIGURE 16.21 Short-axis view demonstrating mid-wall septal fibrosis at the right ventricular insertion point (*yellow arrow*), a characteristic pattern seen in hypertrophic cardiomyopathy.

In a recent publication by Chan et al,[17] the correlation between LGE and cardiovascular events were assessed in over 1200 patients with HCM. SCD events occurred in 37 patients (3%). The extent of LGE was associated with an increased risk of SCD events. LGE ≥15% of LV mass demonstrated a 2-fold increase in SCD event risk in those patients otherwise considered to be at lower risk. Performance of the SCD event risk model was enhanced by LGE (net reclassification index, 12.9%; 95% confidence interval, 0.3 to 38.3).[17] Absence

of LGE was associated with lower risk for SCD events in these patients.

CARDIAC SARCOIDOSIS

Inflammatory cardiomyopathies can be associated with ventricular arrhythmias at any time throughout their clinical course. Myocarditis is discussed in section "Cardiac Magnetic Resonance "Acute Chest Pain." Another potential cause of inflammatory cardiomyopathy is sarcoidosis, a systemic non-necrotizing granulomatous disease. This CD4+-mediated disease has multiorgan system involvement. The lungs are affected in more than 90% of patients, and the disease can also involve the heart, liver, spleen, skin, eyes, parotid gland, or other organs and tissues. An estimated 20% to 25% of patients with pulmonary or systemic sarcoidosis have asymptomatic cardiac involvement.[18] This finding was initially established on the basis of autopsy studies, which estimated the prevalence of cardiac involvement to be at least 25% among patients with sarcoidosis. These autopsy findings are consistent with recent data using LGE-CMR technology.

Cardiac involvement can include atrioventricular conduction disorders, atrial and life-threatening ventricular arrhythmias, and biventricular HF. Approximately 60% to 70% of patients with sarcoid-related deaths have evidence of intramyocardial infiltration. Although rare, isolated cardiac sarcoidosis does exist. Between 16% and 35% of patients presenting with complete atrioventricular block (age <60 years) or VT of unknown etiology have previously undiagnosed cardiac sarcoidosis as the underlying etiology.[18] EMB is considered to be the gold standard when positive. EMB is highly specific, but it is an invasive procedure. As cardiac involvement is not homogeneous and lesions are usually in a patchy distribution, EMB has poor sensitivity with a diagnostic yield as low as 19%. Thus, CMR is becoming the imaging modality of choice for the diagnosis of cardiac sarcoidosis and to guide the EMB to active intracavitary inflammatory lesions to increase the yield of biopsy.

There is no specific pattern of LGE on CMR that is diagnostic for cardiac sarcoidosis, although usually it is patchy and multifocal, with sparing of the endocardial border. CMR is increasingly utilized for assessment of clinically silent cardiac sarcoidosis, in view of its ability to identify small regions of myocardial damage, even in subjects with preserved LV systolic function.[18] In a recent meta-analysis including 760 patients, Coleman et al[19] noted that the presence of LGE on CMR imaging is associated with increased odds of both all-

cause mortality and arrhythmogenic events compared to those without myocardial involvement on LGE.

Positron emission tomography (PET)/CMR, which enables concurrent imaging of the two stages of the disease (inflammation and fibrosis/scar), has been also used recently in the diagnosis and management of cardiac sarcoidosis **(Figure 16.22)**.

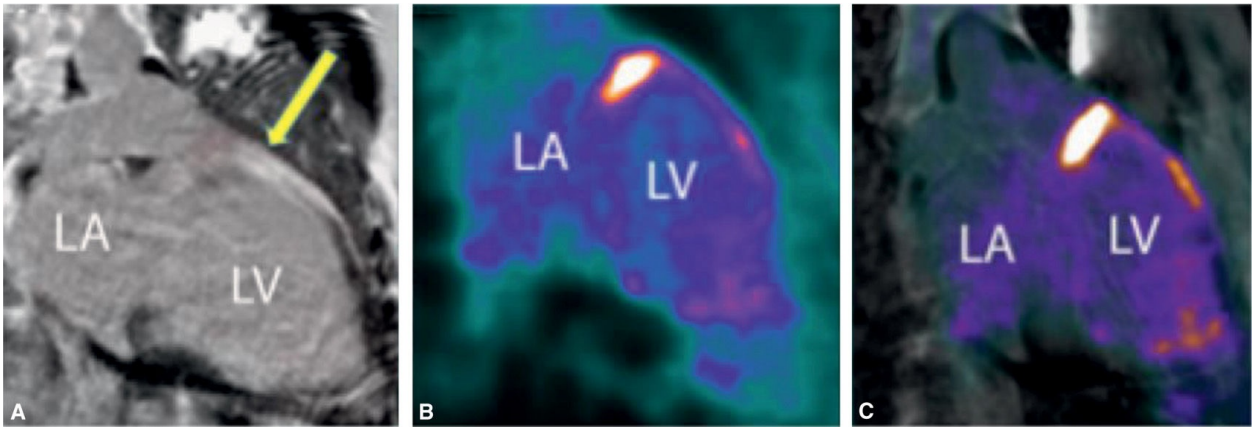

FIGURE 16.22 A, Two-chamber cardiac magnetic resonance (CMR) view of the LV with subepicardial (nonischemic) pattern of late gadolinium enhancement (LGE) in the basal to mid-anterior wall in a patient with known pulmonary sarcoidosis. B, **Positron** emission tomography (PET) imaging of the same patient. C, PET-CMR imaging: notice the inflammatory activity in the area of LGE consistent with active cardiac sarcoidosis. LA, left atrium; LV, left ventricle. (Image courtesy of Zahi Fayad, PhD, Maria Giovanna Trivieri, MD, and Phil Robson, PhD, Icahn School of Medicine, Mount Sinai Medical Center, New York, NY.)

The clinical situations where immunosuppression should be considered in patients with known cardiac sarcoidosis and myocardial inflammation include Mobitz II or third-degree heart block, frequent ventricular ectopy or nonsustained ventricular arrhythmias, sustained ventricular arrhythmias, and LV dysfunction.[18]

An electrophysiological study for SCD risk stratification may be considered in patients with LVEF >35% despite optimal medical therapy. ICD implantation should be considered when LVEF is <35% despite optimal medical therapy.[18] Patients with cardiac sarcoidosis have a worse prognosis than patients without cardiac involvement. Cardiac death is due to progressive HF or SCD. In patients with clinically manifest disease, the extent of LV dysfunction is the most important predictor of survival.

ARRYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY

Also known as arrythmogenic right ventricular dysplasia, ARVC is an inherited cardiomyopathy characterized by fibrofatty infiltration predominantly involving the right ventricle but that can also affect the left ventricle. Both can predispose patients to life-threatening ventricular arrhythmias. ARVC has a prevalence of 1 in 2000 to 5000 people, but can be as high as 1 in 1000 in certain regions because of underdiagnosis. Genetic testing for ARVC has developed over the past decade with associated mutations in desmosomal genes and non-desmosomal genes. Inheritance varies depending on the genes involved but most commonly is autosomal dominant with incomplete penetrance and variable expressivity.[20] Over the past decade, CMR has emerged as the gold standard imaging modality for in-depth evaluation of RV morphology, function, and tissue characterization.[20]

The diagnosis of ARVC is challenging and is based on the International Task Force criteria.[21] The Task Force set out to establish the major and minor CMR criteria for ARVC. Liu et al[21] evaluated the revised 2010 criteria in 968 consecutive patients referred for CMR with clinical suspicion for ARVC. The revised criteria in 2010 resulted in a reduction of total patients meeting any diagnostic CMR criteria for ARVC from 22.7% to 2.6% compared to the 1994 Task Force criteria.[21] This reinforced that perhaps ARVC was originally overdiagnosed before the 2010 revision. The new CMR major criteria include regional RV akinesia or dyskinesia plus RV enlargement (RV end-diastolic volume ≥110 ml/m^2 in males and ≥ 100 ml/m^2 in females) or RV ejection fraction ≤ 40% **(Table 16.5)**. Microaneurysms can also be present in the RV wall and are best seen on CMR cine imaging **(Figure 16.23C)**.

TABLE 16.5 Revised Imaging Task Force Criteria for the Diagnosis of ARVC[22]

2010 TASK FORCE CRITERIA
MAJOR CRITERIA
Two-dimensional echocardiographic criteria
Regional RV akinesia, dyskinesia, or aneurysm Plus one of the following (end-diastole): • PLAX RVOT ≥32 mm (corrected for body size [PLAX/BSA] ≥19 mm/m^2) • PSAX RVOT ≥36 mm (corrected for body size [PSAX/BSA] ≥21 mm/m^2) or fractional area change ≤33%

MRI imaging criteria
Regional RV akinesia, dyskinesia, or dyssynchrony Plus one of the following: • ratio of RV end-diastolic volume to BSA ≥110 mL/m^2 (male) or ≥100 mL/m^2 (female) • or RV ejection fraction ≤40%
RV angiographic criteria
Regional RV akinesia, dyskinesia, or aneurysm
Minor criteria
Two-dimensional echocardiography criteria
Regional RV akinesia, dyskinesia, or aneurysm Plus one of the following (end-diastolic): • PLAX RVOT ≥29 to <32 mm (corrected for body size [PLAX/BSA] ≥16 to <19 mm/m^2) • PSAX RVOT ≥32 to <36 mm (corrected for body size [PSAX/BSA] ≥18 to <21 mm/m^2) or fractional area change >33% to ≤40%
MRI criteria
Regional RV akinesia, dyskinesia, or dyssynchrony Plus one of the following: • ratio of RV end-diastolic volume to BSA ≥100 to <110 mL/m^2 (male) or ≥90 to <100 mL/m^2 (female) • or RV ejection fraction >40% to ≤45%

ARVD, arrythmogenic right ventricular dysplasia; MRI, magnetic resonance imaging; RV, right ventricular.

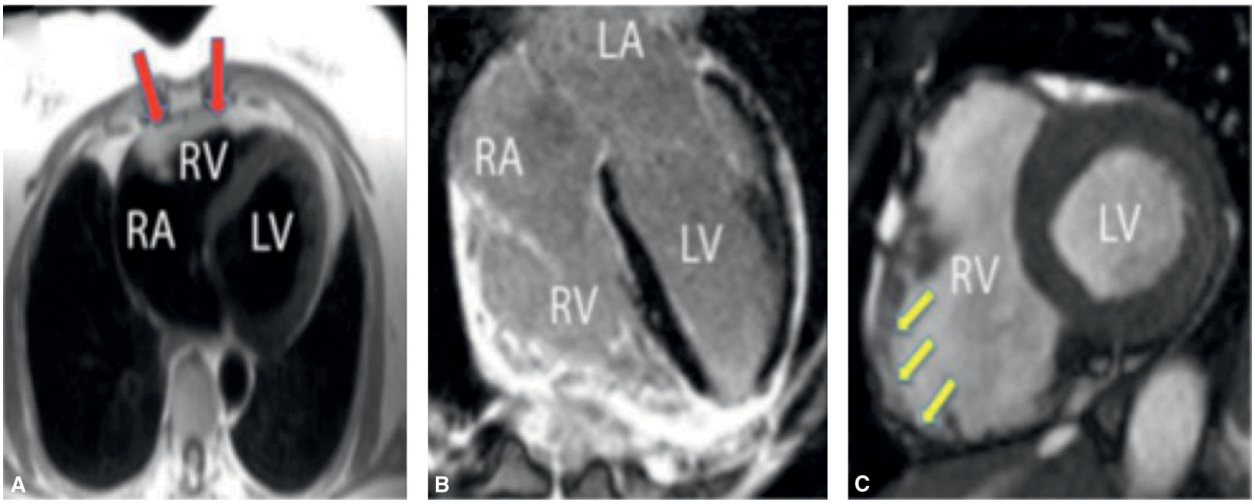

FIGURE 16.23 Axial black-blood imaging demonstrating fatty infiltration of the right ventricle (*red arrows*, A). Four-chamber view showing extensive late gadolinium enhancement (LGE) of the right ventricular free wall and apex (B). Short-axis cine view of the left and right ventricles with a large focal aneurysm of the right ventricular free wall (*yellow arrows*, C). LA, left atrium; LV, left ventricle; RA, right

atrium; RV, right ventricle.

Infiltration of fat in the right ventricle can be seen on T1-weighted CMR imaging, which is demonstrated as regions of increased signal intensity in the myocardium **(Figure 16.23A**). Fat–water separation imaging can further aid in the diagnosis of the fibrofatty infiltration. In addition, LGE of the RV myocardium can sometimes be seen **(Figure 16.23B**). New CMR sequences including high-resolution T1 mapping are evolving tools that may detect early and subtle changes in the right ventricle. In addition, quantification of RV regional wall motion abnormalities and evaluation of inter- and intraventricular dyssynchrony can provide novel tools for early detection of ARVC. Genetic testing using comprehensive cardiomyopathy panels and whole exome sequencing are also likely to significantly impact the diagnosis of ARVC and prevention of SCD. The diagnosis of ARVC with CMR is difficult and requires experienced imaging specialists for accurate diagnosis of the disease.

CARDIAC MAGNETIC RESONANCE IN HEART FAILURE

The presence of HF is a common indication of admission in the CCU. As discussed previously, CMR is most commonly reserved for the stable patient who is able to tolerate a decubitus position. The main roles of CMR include providing accurate quantification of biventricular size and function, and characterization of the myocardium for the presence of scar, necrosis, infiltration, or edema. Although reduced LVEF as measured with a variety of imaging modalities is a well-known marker of risk in HF, during the past few years, the presence of myocardial scar as demonstrated by LGE has emerged as an important powerful prognosticator independent of LVEF. In a series of 857 consecutive patients with HF, survival free from death or heart transplantation was similar in patients with severe LV dysfunction but no scar compared with those with preserved LVEF but evidence of LGE.[23] These findings, subsequently confirmed in other studies, suggest that myocardial scarring may be as powerful a prognosticator as measures of LV dysfunction.

For the purpose of the discussion, this section is divided into predominantly left-sided or right-sided HF, although there is certainly overlap between the two syndromes and their underlying etiologies. Additional information that can be obtained from CMR includes pericardial involvement, valvular disease severity,

or quantification of systemic to pulmonary shunts. It must be emphasized that data on CMR diagnostic and prognostic ability in HF has been obtained largely from stable cohorts and not from patients admitted to the CCU.

LEFT-SIDED HEART FAILURE

Dilated Cardiomyopathy

One of the most common causes of left-sided HF is dilated cardiomyopathy (DCM). DCM of specific etiologies, such as ischemia or sarcoid, have been discussed in section “Cardiac Magnetic Resonance in Ventricular Arrhythmias,” so here we address mainly DCM of unknown cause. In idiopathic DCM, two patterns of LGE are commonly observed: absent (approximately 65% to 70%) or nonischemic (approximately 20% to 25%). As described in sections “Cardiac Magnetic Resonance in Acute Chest Pain” and “Cardiac Magnetic Resonance in Ventricular Arrhythmias,” nonischemic LGE refers to areas of scar with a predominantly intramyocardial or subepicardial location, or transmural or subendocardial areas that do not conform to a coronary territory. Occasionally (around 10% of cases), “ischemic” LGE can be seen in patients with DCM and normal or nonobstructive coronary artery disease, raising the possibility of an ischemic etiology despite the absence of significant coronary stenoses (ie, embolization, vasospasm, thrombus autolysis, etc). A pattern of nonischemic, linear intramyocardial LGE in the interventricular septum can be often seen in idiopathic DCM and has received particular attention **(Figure 16.24)**.

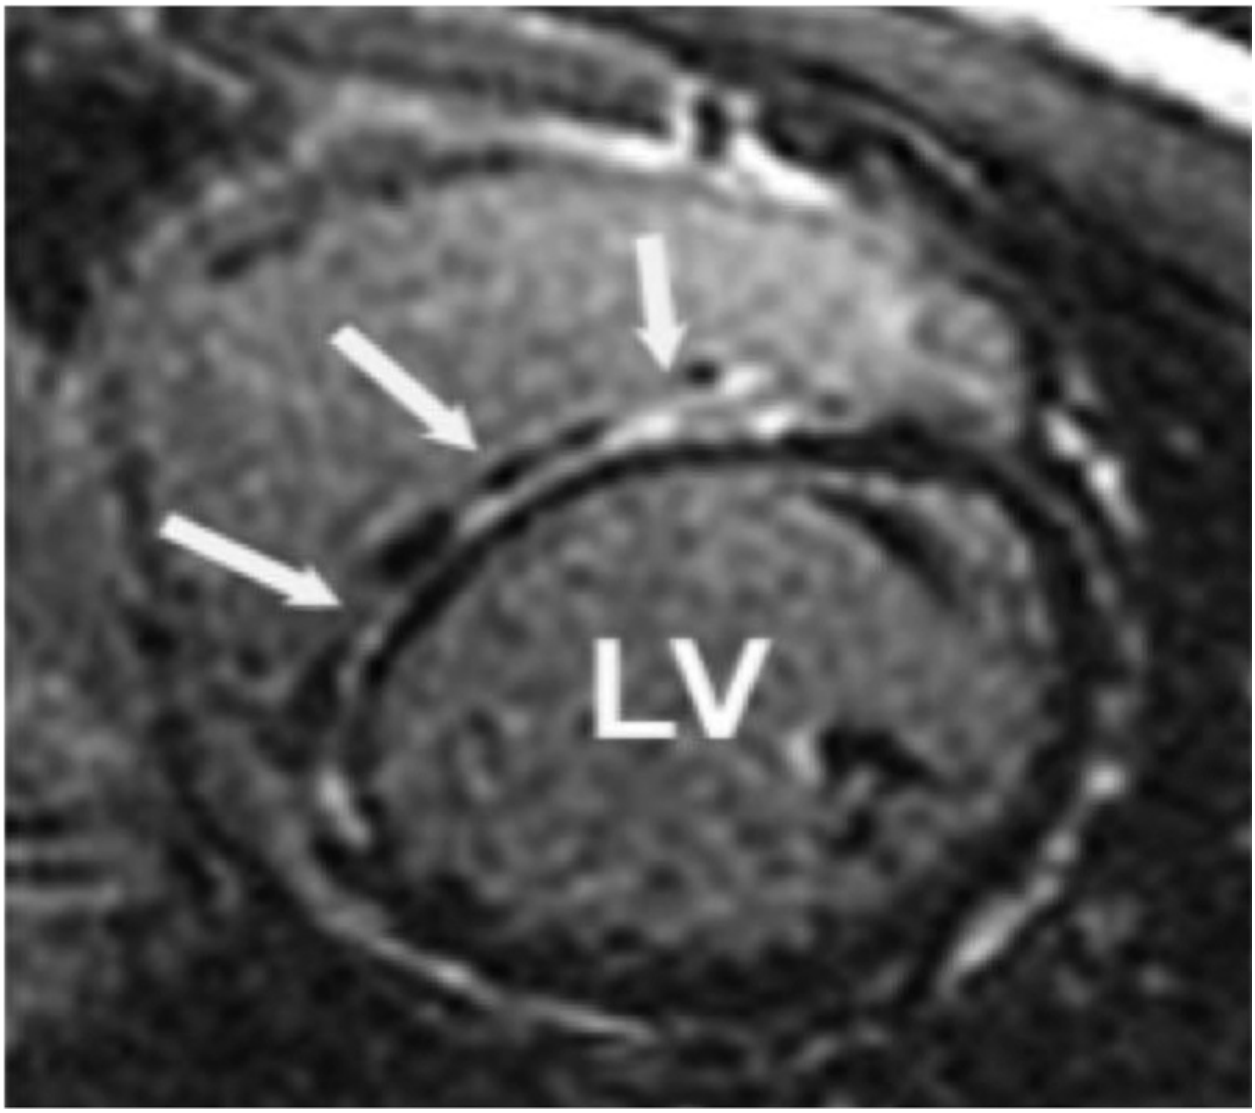

FIGURE 16.24 Short-axis image demonstrating linear intramyocardial late gadolinium enhancement (*arrows*) in a patient with idiopathic dilated cardiomyopathy. LV, left ventricle.

In a meta-analysis of nine studies including ≈1500 patients,[24] this pattern was associated with increased midterm risk of mortality (odds ratio = 3.27), malignant ventricular arrhythmias (odds ratio = 5.32), or HF hospitalization (odds ratio = 2.91; P <0.001 for all), independent of other conventional risk markers including LVEF. RV ejection fraction is also of prognostic value in these patients.

HEART FAILURE WITH PRESERVED EJECTION FRACTION

Many cases of HF do not have reduced LVEF, a situation commonly referred to

as heart failure with preserved ejection fraction (HFpEF). HFpEF is a multifactorial syndrome in which diastolic LV dysfunction is believed to represent a common pathophysiologic pathway. The role of CMR in HFpEF is not well defined because diastolic function is often better evaluated with echocardiography, although preliminary data suggest an association between localized scar (using LGE) or diffuse myocardial fibrosis (using novel T1-mapping sequences) with abnormalities in LV stiffness and impaired outcomes.[25]

RIGHT-SIDED HEART FAILURE

Restrictive Cardiomyopathy

CMR plays an increasingly important role in the evaluation of restrictive cardiomyopathy, one form of HFpEF associated with congestive symptoms, related to infiltrative heart disease. In developed countries, the most common cause of restrictive cardiomyopathy is cardiac amyloidosis. The typical features of amyloidosis include increased ventricular wall thickness in the absence of electrocardiographic hypertrophy, relatively preserved LVEF, biatrial enlargement, thickening of the mitral and tricuspid leaflets as well as of the interatrial septum, and pericardial and pleural effusions. These features are specific but have low sensitivity. Cardiac amyloid is associated with a typical pattern of diffuse LGE, more prominent toward the base of the heart, with a predominantly intramyocardial and subendocardial distribution **(Figure 16.25)**.

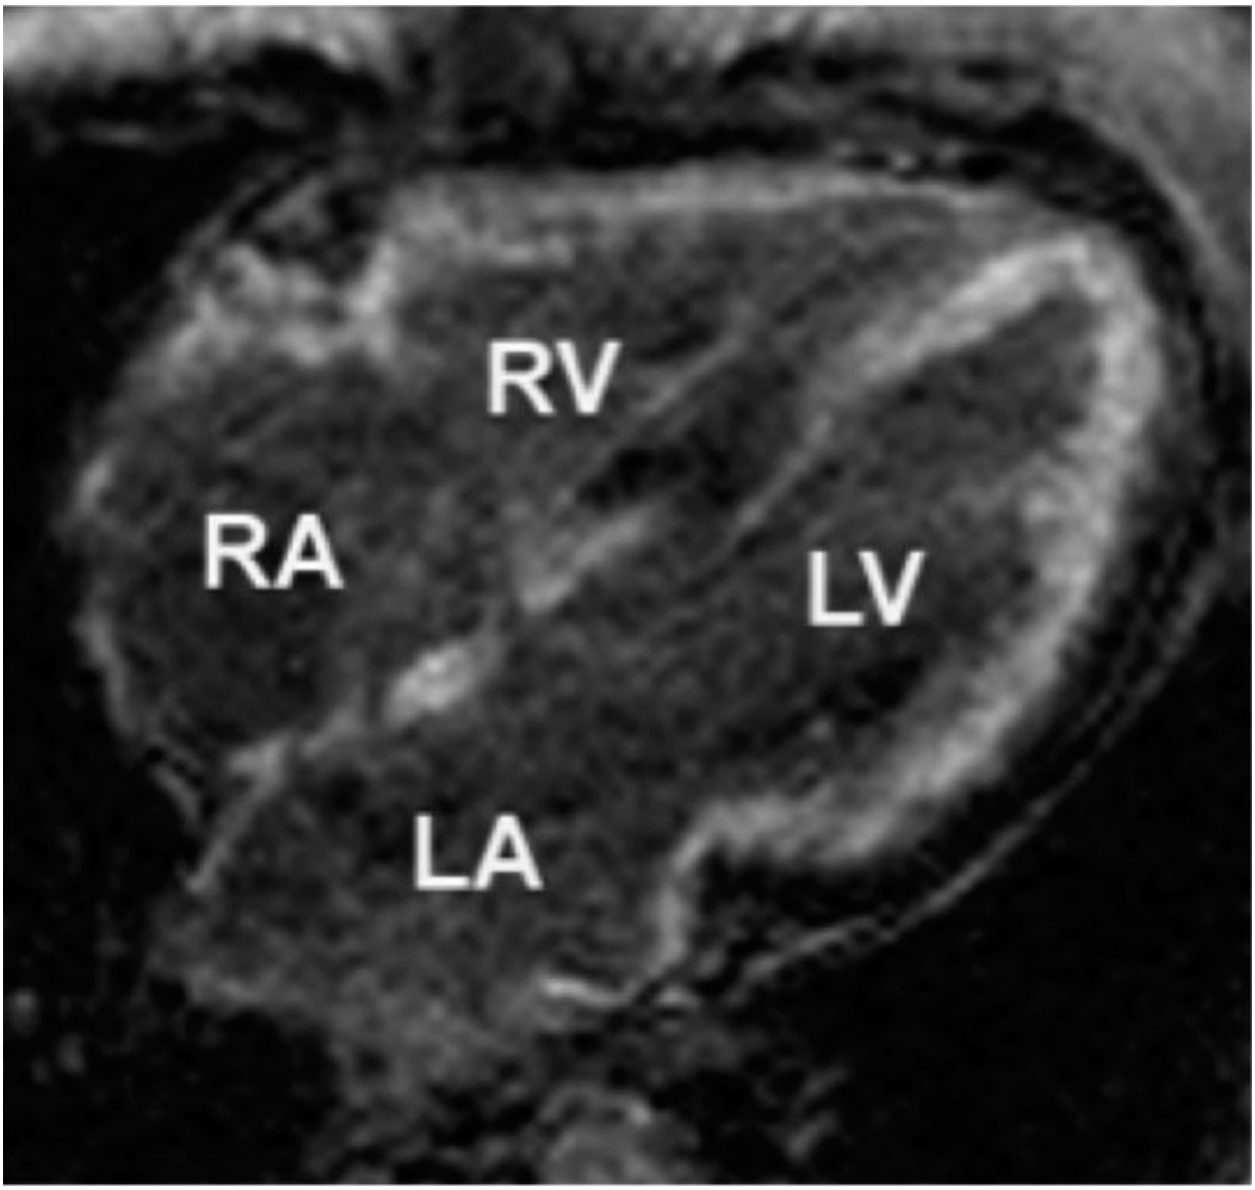

FIGURE 16.25 Four-chamber view demonstrating diffuse, predominantly subendocardial late gadolinium enhancement (LGE) in the LV of a patient with cardiac amyloidosis. LGE also noted in the RV and both atria. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

In addition, abnormal contrast kinetics between the blood and the myocardium can be observed and quantified. This pattern is highly specific to cardiac amyloidosis and, importantly, has been associated with increased mortality (hazard ratio = 5.2; P <0.001) after adjusting for LV systolic and diastolic function, LV mass index, and N-terminal pro-brain natriuretic peptide.[26] Some distinguishing CMR features may help in the differential diagnosis between light-chain and transthyretin amyloid, which has both prognostic and therapeutic

implications. Other less common etiologies of restrictive heart disease such as iron deposition or endomyocardial fibrosis **(Figure 16.26)** can also be accurately identified with CMR.

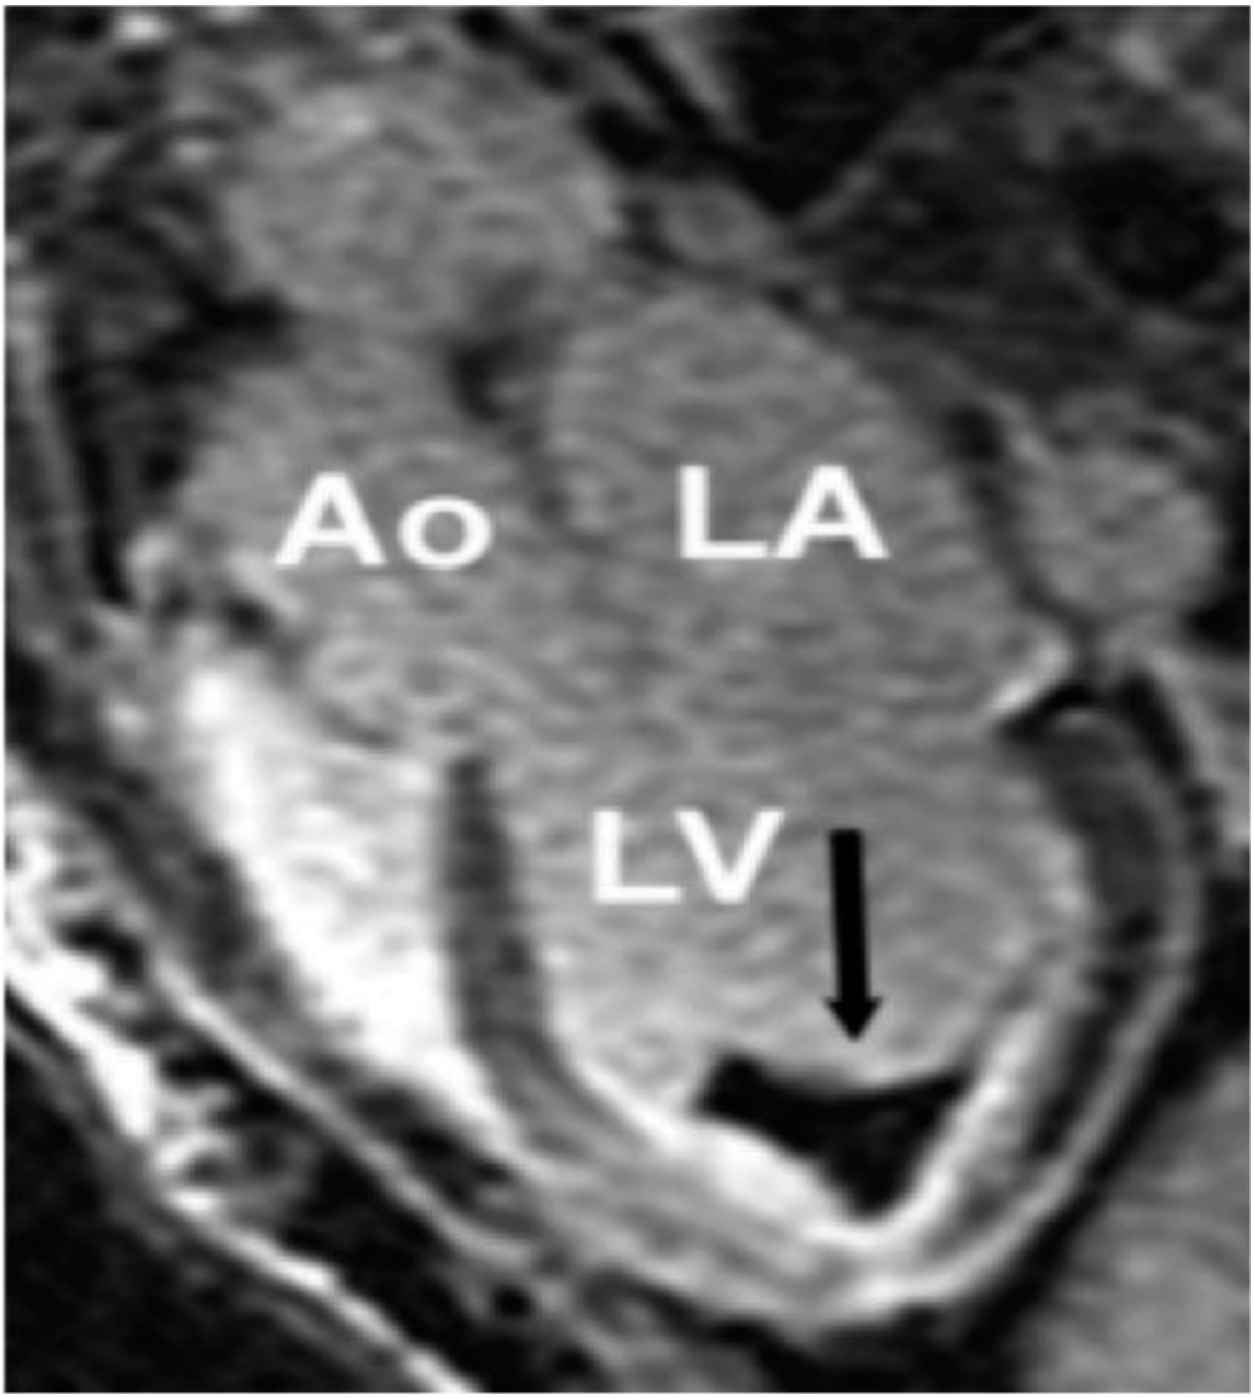

FIGURE 16.26 Three-chamber view in a patient with endomyocardial fibrosis demonstrating apical late gadolinium enhancement with superimposed thrombus (*arrow*). Ao, aorta; LA, left atrium; LV, left ventricle.

Constrictive Pericarditis

Constrictive pericarditis can be idiopathic as well as the end result of virtually any progressive inflammatory pericarditis process. The diagnostic standard of pericardial constriction is equalization of end-diastolic pressures in all cardiac chambers due to the pressure exerted by the thickened, and/or inflamed pericardium as well as increased ventricular interdependence. It is important to distinguish this entity from restrictive cardiomyopathies, which can present similarly, because patients with constrictive pericarditis, unlike those with restrictive cardiomyopathy, may benefit from pericardiectomy or anti-inflammatory therapy. CMR can assess the thickness of the pericardium; the presence of pericardial edema, effusion and inflammation; as well as demonstrate exaggerated ventricular interdependence. Other sequelae of constriction that support the diagnosis may also be seen, such as a dilated inferior vena cava and pleural effusions.

CMR is well suited for direct quantification of pericardial thickness **(Figure 16.27)**. Normal pericardial thickness in CMR (due to limitations in spatial resolution) is 1 to 2 mm. A thickness of 3 mm is considered borderline, whereas ≥4 mm is considered definitely abnormal.[13] Increased pericardial thickness can be focal or diffuse. The most common pattern of thickening includes prominence over the right heart as well as the atrioventricular groove. It is important to realize that constriction can occur with normal pericardial thickness in the presence of focally inflamed pericardium that significantly impairs filling. Similarly, the presence of pericardial thickening is not synonymous with constriction. Constrictive physiology can be assessed with CMR as increased ventricular interdependence with respiration, manifested by marked inspiratory flattening of the interventricular septum during free-breathing cine imaging **(Figure 16.28)**.[13]

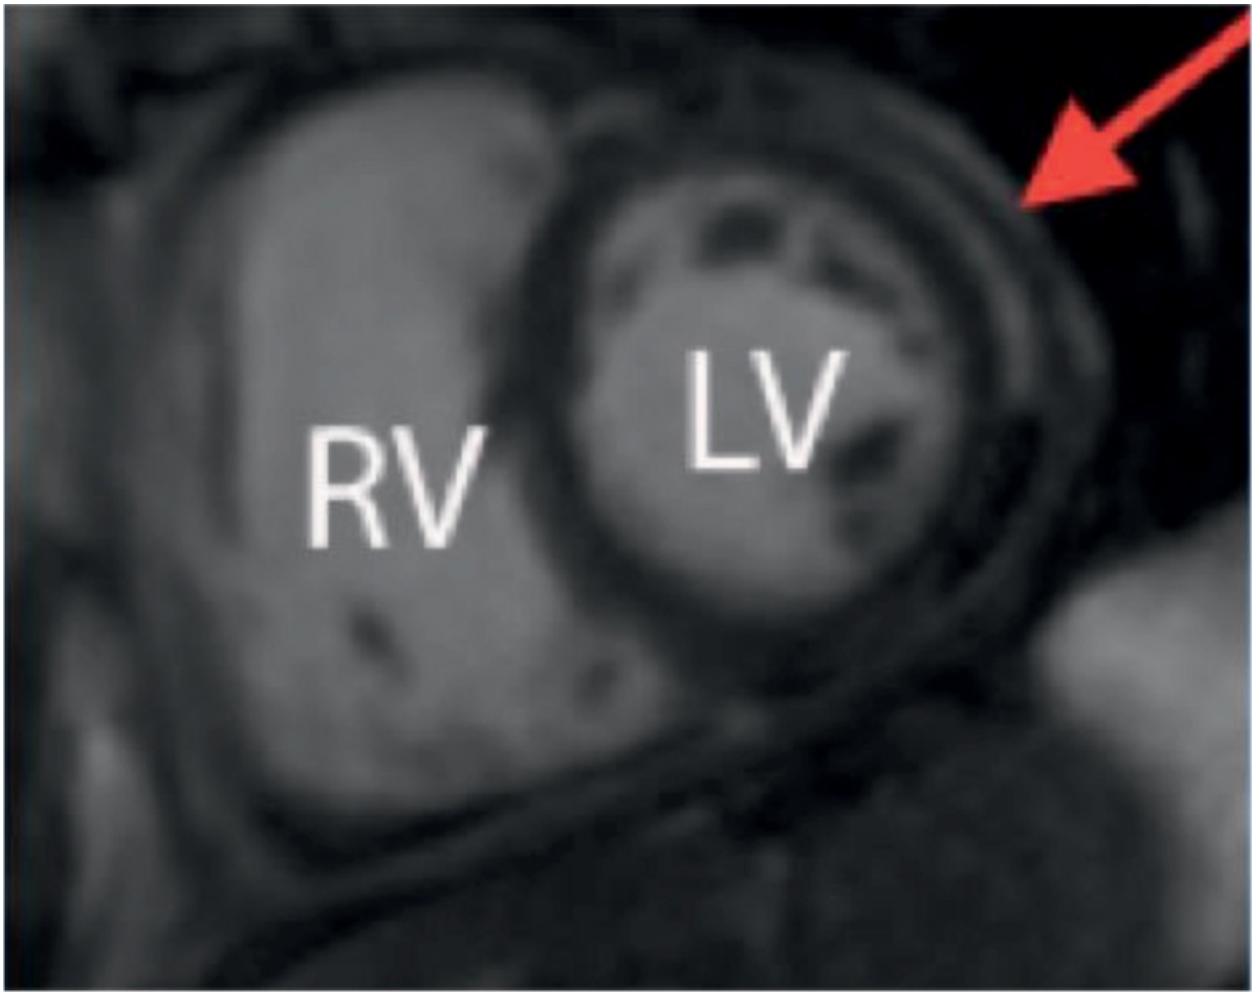

FIGURE 16.27 Short-axis view with prominent pericardial thickening (*arrow*) in a patient with constrictive pericarditis. LV, left ventricle; RV, right ventricle.

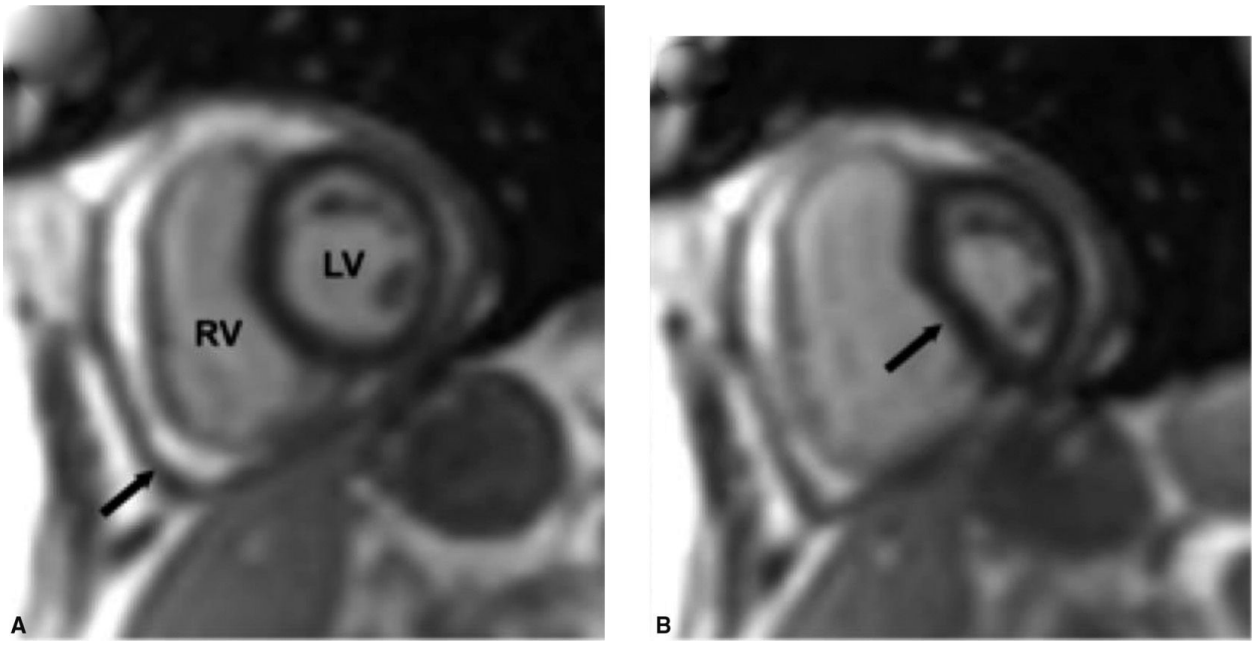

FIGURE 16.28 Expiratory (A) and inspiratory (B) short-axis views in a patient with pericardial constriction, demonstrating prominent flattening of the interventricular septum (*arrow* in B) with inspiration. Note also the thickened pericardium (*arrow* in A). LV, left ventricle; RV, right ventricle.

As in the case of acute pericarditis (see section “Cardiac Magnetic Resonance in Acute Chest Pain”), increased T2 signal intensity (compatible with edema) and post-contrast LGE in the pericardium **(Figure 16.29)** are indicative of active inflammation and can be seen in constrictive effusive pericarditis. Zurick et al[27] studied 25 patients with constrictive pericarditis who underwent pericardiectomy, imaging them with CMR and examining the histopathology of the pericardial specimens. They found that a subset of patients with LGE had more chronic inflammation and fibroblastic proliferation. These patients often had increased pericardial thickness compared to patients with a fibrotic, less inflamed pericardium. These findings may help guide treatment and identify patients who may benefit from anti-inflammatory therapies in lieu of immediate surgical treatment.[27]

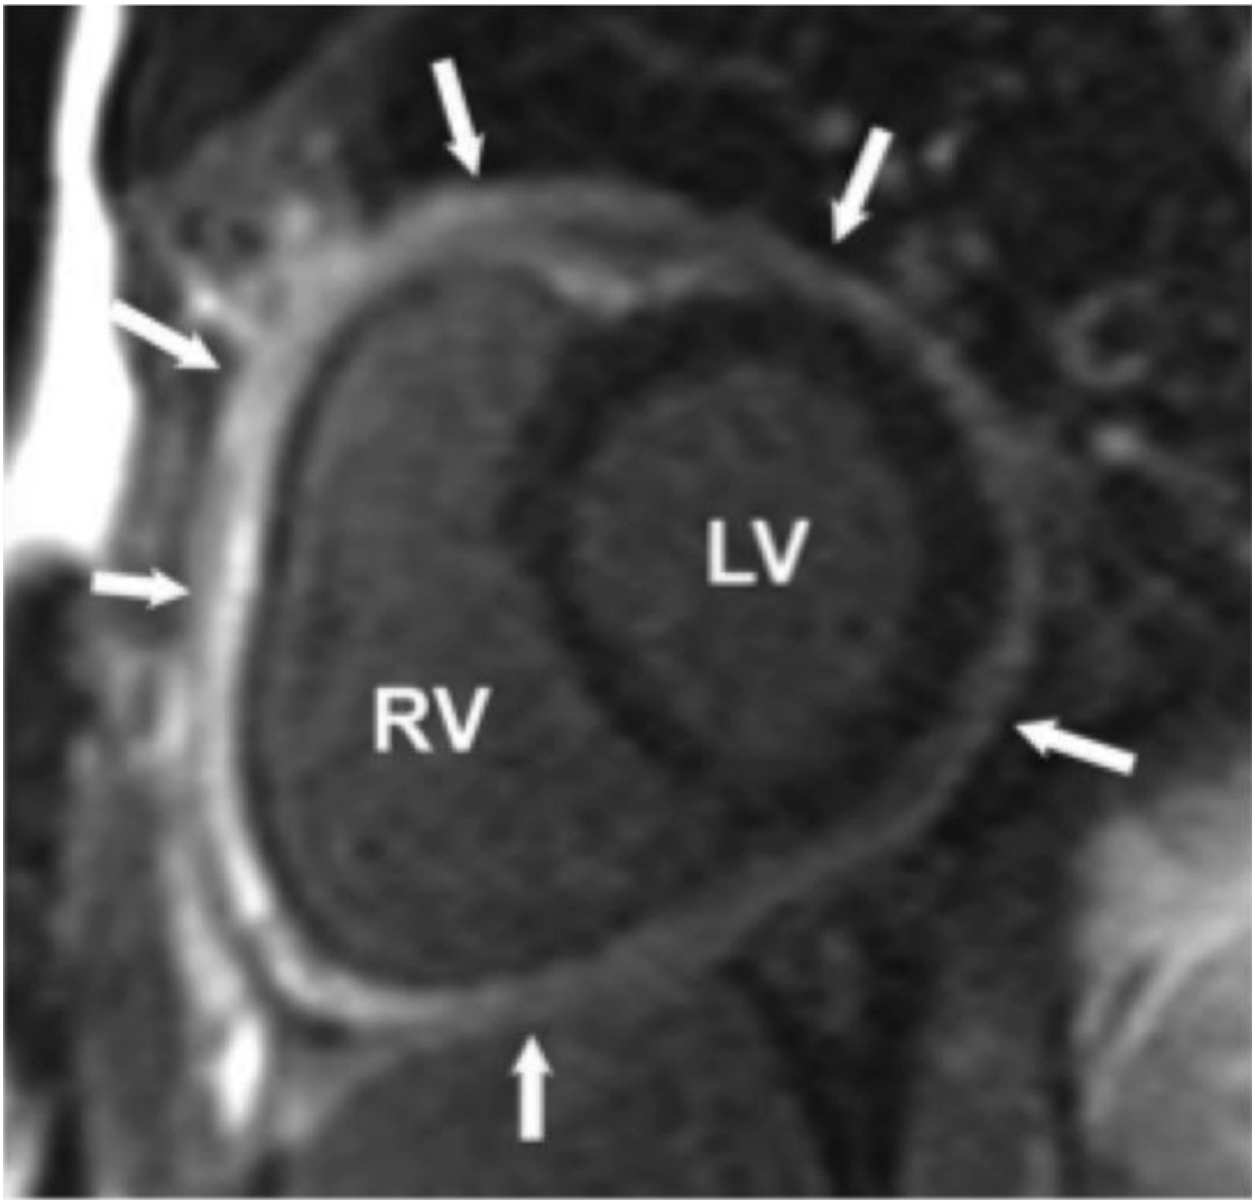

FIGURE 16.29 Short-axis image demonstrating extensive pericardial late gadolinium enhancement (*arrows*) in a patient with constrictive pericarditis. LV, left ventricle; RV, right ventricle.

CMR can help not only diagnose constriction but also provide important prognostic information. Aquaro et al[28] studied 70 patients with clinical suspicion of constrictive hemodynamics on echocardiography and/or catheterization. Constrictive pericarditis was present in 53 patients, whereas 12 had active inflammation, suggestive of a transient constrictive process. LGE was correlated with adverse events.[28]

Right Ventricular Dilatation

Dilatation involving only or predominantly the RV can be seen in ARVC (see section “Cardiac Magnetic Resonance in Ventricular Arrhythmias”), and in RV pressure or volume overload. In RV pressure overload (pulmonary hypertension, stenosis, and embolism), RV dilatation, hypertrophy (if chronic), predominantly systolic septal flattening and, eventually, reduced RV ejection fraction can all be identified with CMR and have been linked to impaired outcome.[29] Although identification of pulmonary embolism with MRA is feasible, CT is usually preferred for this application because of increased accuracy and speed of acquisition. RV volume overload is characterized by RV dilatation and dysfunction without hypertrophy and predominantly diastolic flattening of the interventricular septum. A common cause of RV volume overload is right-sided valvular regurgitation, such as can be seen in carcinoid heart disease. Both pulmonary and tricuspid insufficiency can be accurately quantified with CMR. If no valvular regurgitation is present, a systemic-to-pulmonary shunt should be suspected. CMR is well suited to depict shunts that may not be readily identified with echocardiography such as some ventricular and atrial septal defects, anomalous pulmonary vein drainage, or patent ductus arteriosus. CMR is the most accurate noninvasive modality for the quantification of shunt severity, which is accomplished by measuring systemic (aortic) and pulmonary output using phase-contrast imaging as described here.

FLOW IMAGING—VALVULAR HEART DISEASE

Phase-contrast (or flow) imaging is a technique that can quantify blood velocity and flow within a vessel and that, when applied to the pulmonary artery or the aorta, can respectively provide right- and left-sided stroke volume/output **(Figure 16.30)**.

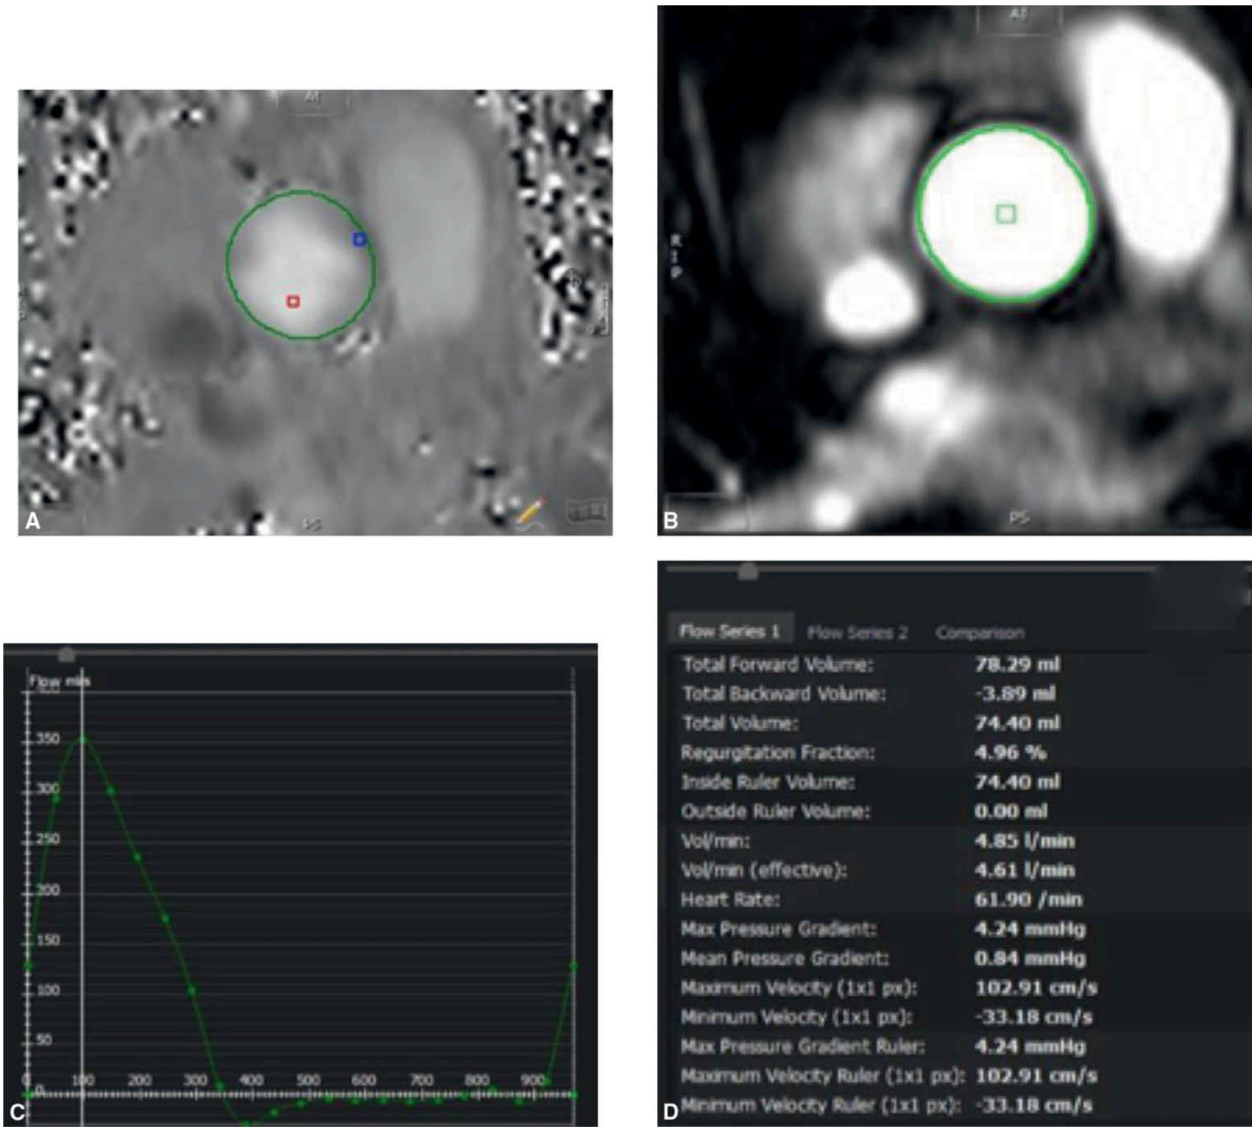

FIGURE 16.30 Phase-contrast imaging demonstrating a cross-section of the ascending aorta (*green contours*) in both the (A) velocity map and (B) anatomic reconstruction. C, Integration of the velocities within the aortic area enables determination of flow throughout the cardiac cycle and (D) quantification of parameters such as output, stroke volume, or degree of regurgitation. For example, the regurgitant fraction in this case is 5%.

As indicated, the difference between the two is used in congenital abnormalities to calculate the Qp/Qs. In addition, phase-contrast imaging in the same locations can be employed to assess valvular heart disease. Evaluation of valvular abnormalities is rarely the primary indication for CMR, so a detailed description of available techniques is beyond the scope of this chapter. Nonetheless, valvular assessment is appropriate if the patient is undergoing CMR for other reasons, or in situations where test results are discordant or

echocardiography may be limited (eg, quantification of pulmonary regurgitation, differentiation of bicuspid from trileaflet valves, identification of sub- or supravalvular stenoses, etc). Pulmonary and aortic regurgitation are measured as the difference between anterograde and retrograde flows in the pulmonary artery and ascending aorta, respectively (as illustrated in **Figure 16.30**). Mitral and tricuspid regurgitation are graded on the basis of the difference between the LV or RV stroke volume calculated with cine imaging, and the stroke volume in the aorta or pulmonary artery measured by phase contrast. Preliminary data indicate meaningful prognostic value of CMR-based indices of aortic and mitral regurgitation, although further confirmatory studies are needed. Finally, valve stenosis severity can be quantified by direct valve planimetry or measuring peak transvalvular gradients in a manner comparable to Doppler ultrasound (although gradients tend to be underestimated with CMR).

MISCELLANEOUS

CARDIAC CAUSES OF HYPOTENSION—BEYOND HEART FAILURE

In the reasonably stable patient with unexplained hypotension, and in the appropriate clinical scenario, CMR may be helpful to investigate potential underlying etiologies. A possible cause of unexplained hypotension in the CCU patient includes pericardial effusion and tamponade. Although this is more readily and efficiently evaluated with ultrasound, localized effusions or pericardial hematomas such as those seen after cardiac surgery may be difficult to identify on echocardiography. In addition, if CMR is performed in a patient with pericardial effusion, fluid signal characteristics can provide gross characterization on whether fluid is simple (ie, transudate) or complex (hemorrhagic, purulent, etc).[13]

Dynamic LV outflow tract obstruction can also cause hypotension, particularly in the postoperative settings after mitral valve replacement, or in patients with HCM, hypovolemia, and/or increased inotropic state. This complication is again usually identified with echocardiography, but CMR can be considered as an alternative if the ultrasound is not diagnostic.

ADULT CONGENITAL HEART DISEASE

Although a relatively uncommon indication for admission in the CCU, the increasing population of adults with surgically corrected complex congenital

heart disease is likely to result in an increasing number of patients presenting with decompensated HF, arrhythmias, or thromboembolic disease.

As mentioned in section “Cardiac Magnetic Resonance in Heart Failure,” CMR can be used to quantify the severity of systemic-to-pulmonary shunting, including Eisenmenger physiology, in simple and complex disorders. Additional important roles of CMR in these patients include the quantification of the volumes and function of the RV or the systemic ventricle, the evaluation of patency of surgical baffles and conduits, and the assessment of extracardiac structures such as the pulmonary arteries that can be difficult to study with echocardiography.

Regarding some specific malformations, Ebstein anomaly can present with right-sided HF, and the abnormal insertion of the tricuspid leaflets into the RV can be characterized with echocardiography and/or CMR. Patients with a repaired tetralogy of Fallot often develop RV dilatation and systolic dysfunction secondary to significant pulmonary insufficiency. CMR can provide absolute quantification of regurgitation severity, and guide the optimal timing of surgical or percutaneous pulmonary valve implantation before irreversible RV deterioration occurs. In addition, the presence of an RV scar has been linked to an increased risk of HF and ventricular arrhythmias. Patients with corrected transposition may develop dilatation and dysfunction of the systemic right ventricle in cases of atrial baffles, or narrowing of the pulmonary and reimplanted coronary arteries after arterial switch operations. Finally, in patients with a single-ventricle physiology, CMR can be used to determine ventricular performance (including dilatation, dysfunction, and LGE), patency of the Fontan circulation, and presence of cardiac or venous thrombi that is a common complication of associated chronic venous stasis.

CARDIAC MASSES

CMR can be very useful in the diagnostic evaluation of a cardiac mass, and in the differentiation between benign and malignant tumors. The most common primary cardiac tumors are benign, and they include myxomas, lipomas, and papillary fibroelastomas. Myxomas are mobile, pedunculated masses commonly in the atria and frequently attached to the interatrial septum **(Figure 16.31).**

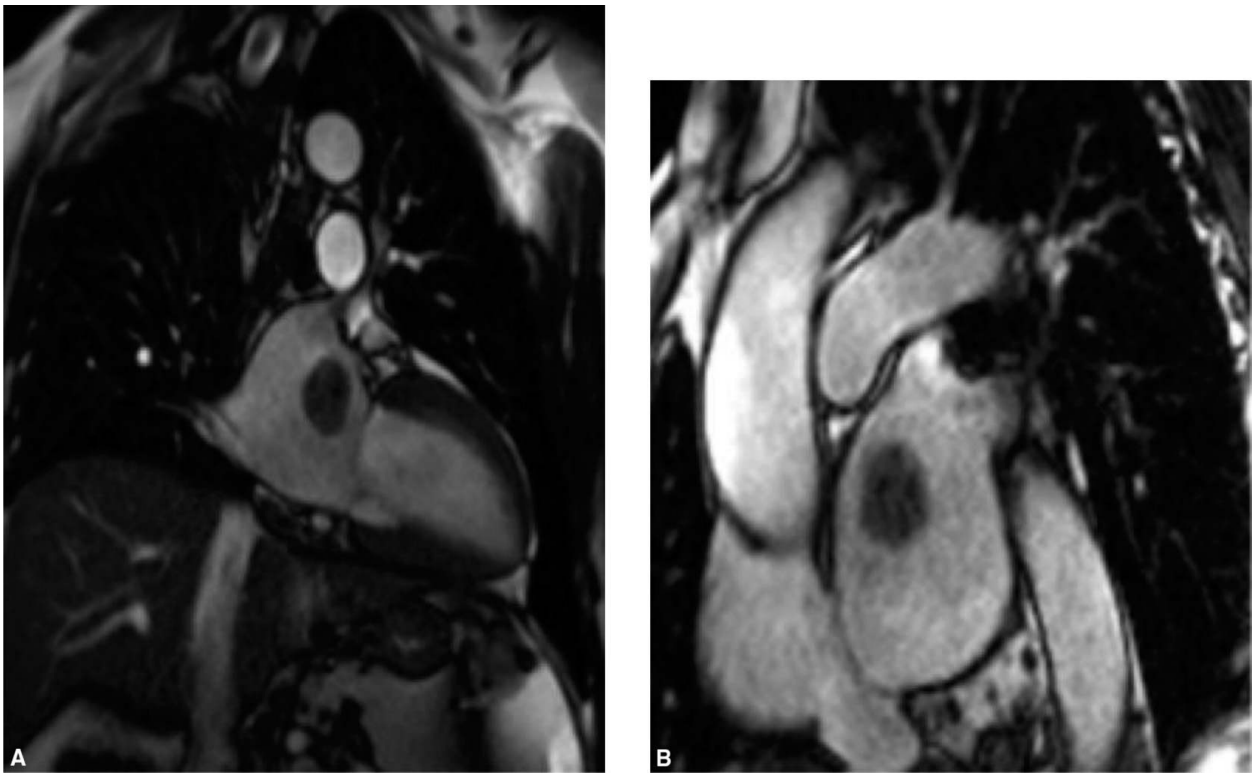

FIGURE 16.31 Two-chamber view demonstrating a left atrial myxoma (A). Short-axis stack at the level of the atria showing the large mass in the left atrium (B). Pathology confirmed the diagnosis of myxoma.

Fibroelastomas are valvular tumors that are small (<1 cm) and commonly involve the aortic side of the aortic valve. Cardiac lipomas are usually in the epicardial space, slow growing, and should be distinguished from the more prevalent lipomatous hypertrophy of the interatrial septum. The most common primary malignant cardiac mass is angiosarcoma, which classically involves the right atrium with extension into adjacent structures (pericardium, with associated pericardial effusion). Secondary tumors are much more common than primary cardiac tumors, and they involve the heart or pericardium either via direct invasion (lung and renal cell carcinoma) or by hematogenous spread (breast cancer, melanoma).

CMR offers several advantages in the imaging of cardiac masses over echocardiography. The combination of high resolution with a wide field of view can help define anatomy of the mass, attachment site, and adjacent structures. For example, the presence of a large pericardial effusion, lymphadenopathy, or involvement of more than one cardiac chamber or other mediastinal structures is consistent with a malignant process. The high temporal resolution of CMR (albeit less than that of echocardiography) can help assess mobility of the mass.

Most importantly, CMR can delineate tissue characterization with the use of T1-weighted, T2-weighted, and fat-saturation sequences. With IV contrast administration and evaluation of first-pass perfusion, CMR can demonstrate vascularity of a mass, and LGE allows further tissue characterization **(Figure 16.32)**. The post-contrast inversion time (TI) scout images are also helpful, and a combination of these findings can narrow the differential diagnosis (see subsequent text).

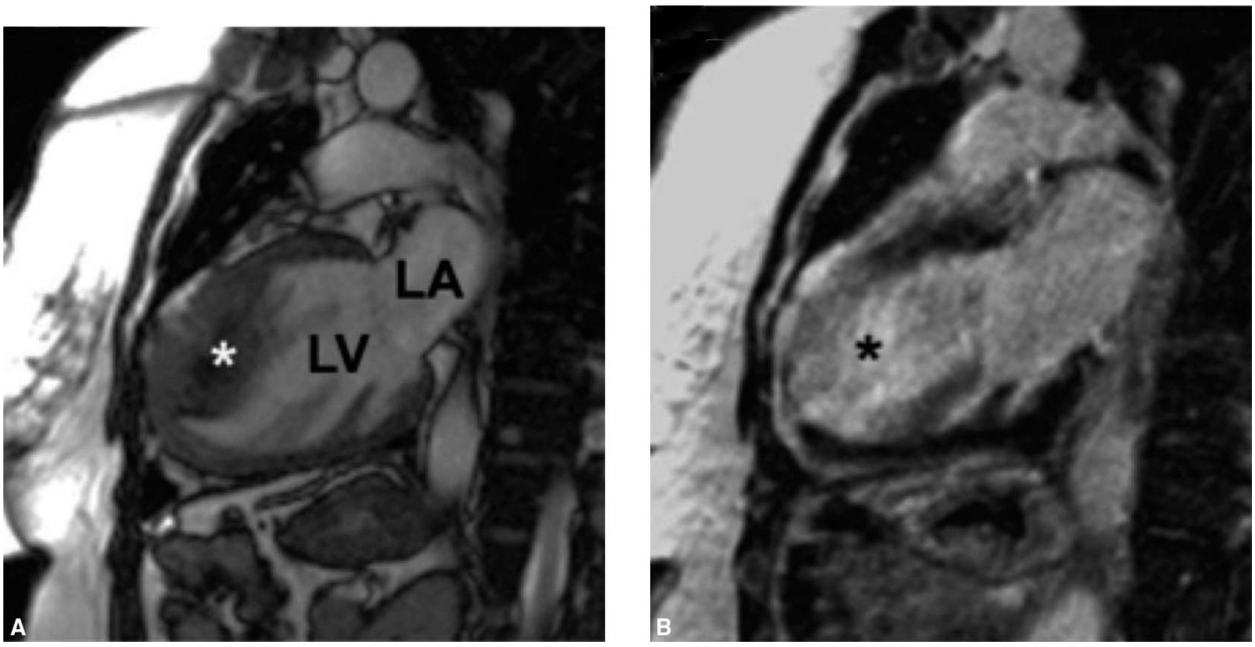

FIGURE 16.32 Two-chamber view demonstrating a mass in the left ventricular apex (*white asterisk*, A). Two-chamber view illustrating that the mass is a vascular structure on long TI imaging (B). Contrast this with the avascular thrombus in Figure 16.11. Pathology was consistent with a hamartoma. LA, left atrium; LV, left ventricle.

In the CCU setting, one of the most relevant applications of CMR for cardiac masses is the differentiation between tumor and thrombus. This is important in patients who present with ischemic cardioembolic stroke with underlying atrial fibrillation, prior MI (see section “Cardiac Magnetic Resonance in Acute Chest Pain”), LV aneurysm, rheumatic heart disease, or DCM. In such patients, several findings can identify thrombus with reasonable accuracy, as demonstrated in a recent retrospective CMR analysis of 116 patients with a definite cardiac mass.[30] In this study there were 84 thrombi, 17 benign tumors, and 25 malignant tumors. In comparison to benign or malignant tumors, thrombi were more often smaller, more homogeneous and less mobile. On the other hand, tumors were more often

hyperintense on T2-weighted imaging, first-pass perfusion, and LGE imaging when compared to thrombi. A key distinguishing characteristic with 95% accuracy was demonstrated on the TI scout images, where thrombi appeared hyperintense or isointense with short TI, and hypointense with long TI, whereas tumors demonstrated the opposite behavior.[30]

CONCLUSION

As demonstrated in this chapter, CMR is an increasingly useful imaging modality that can help diagnose and direct treatment in patients in the CCU. CMR can assist in the diagnosis of ACS, provide excellent tissue characterization, lend insights into HF etiology, precisely quantify LV and RV volumes and ejection fractions, demonstrate intracardiac shunts with precision, and assist with the identification of extracardiac structures, among other capabilities. Although not available at all cardiac centers because of its expense, it is a valuable tool when performed and read by experienced physicians.

Patient and Family Information for: CARDIAC MAGNETIC RESONANCE IMAGING

MRI stands for magnetic resonance imaging. Cardiac MRI is a safe and painless imaging modality that uses a strong magnet to create pictures of the inner structures of the heart and help the referring physician determine many aspects of heart health. Unlike other types of imaging, MRI does not use harmful ionizing radiations such as X-rays or gamma rays. It can accurately determine the function of both sides of the heart, identify problems with valves, assess the presence of scar tissue in the heart, and provide information on many more structural and functional aspects of the heart.

PREPARATION FOR THE PROCEDURE

Some imaging facilities request that patients do not eat or drink anything before the procedure. It is important to check with the imaging facility to determine what their pre-MRI dietary guidelines are.

The magnetic field of an MRI machine extends beyond its physical boundaries and usually includes the room where the machine is placed. Any metallic object placed inside or close to the magnetic field can interfere with its function. As a result, jewelry and metal accessories, cell phones, electronic devices, and wallets containing credit or debit cards should be removed before the examination and preferably left at home.

A few types of metal implants are not safe for cardiac MRIs. Certain types of metal coils in brain aneurysms, cochlear implants (hearing aid implants placed inside the inner ear), “Triggerfish” contact lenses, insulin pumps, defibrillators,

and pacemakers are not MRI compatible. Virtually any metal-containing material can interfere with an MRI. These include, but are not limited to, bullets or shrapnels left in place and metallic rods, plates, or screws used in fixing fractured bones. All implantable and external devices should be reported to the physician before undergoing a cardiac MRI.

The examination requires that patients are able to lie flat for 30 to 60 minutes and hold their breath for 10 to 15 seconds multiple times over the course of the examination. If a patient has any difficulty lying flat or is unable to hold his/her breath, the referring physician should be informed.

Some patients will need injectable contrast with the examination depending on the clinical indication. The contrast used in cardiac MRI examinations is a gadolinium-based agent, which is distinctly different from the contrast used in CT scans. It should not be used if the patient's kidney function is very low. Gadolinium-based contrast agents have a much lower incidence of allergic reactions compared to iodinated contrast agents used in CT scans. If the patient has had an allergy to the iodinated contrast used in CT scans and has any other allergies, the physician should be informed to determine the best course of action.

If the patients have claustrophobia, which is a fear of being in enclosed spaces, they should alert their physician because some MRIs can appear to the patients as small and enclosed. In some cases, the physician may prescribe a medication to help with the claustrophobia.

Patients who are pregnant or think that they may be pregnant should alert their physician before having an MRI. There have been limited studies to determine the safety of an MRI in pregnant patients. The decision to do the examination is made individually in each case after careful consultation between the physician conducting the MRI and the referring physician.

THE DAY OF THE EXAMINATION

MRI units vary in size but are often quite large, with a cylinder-shaped tube where the patient will lie down. Some MRI units are open on the sides, "open MRI," whereas others are closed. Closed MRIs can make some patients claustrophobic. Many imaging facilities have headphones and some have videos that the patient can watch during the examination to ease the claustrophobia. The patients are given a handheld device that they can squeeze if they feel

uncomfortable at any point during the examination. This device alerts the technician to stop the examination and come into the room to check on the patient. The MRI technician will be able to speak with, and hear, the patient from the control room. While the patient will be alone in the MRI room, the control room is immediately adjacent to the MRI room with large windows so that the technician can see the patient at all times.

The patients will have stickers attached to their chest that will connect to a monitor to observe the heart rate and correlate the imaging with the cardiac cycle to obtain the best possible images. The examination has many sequences that require the patient to hold his/her breath for 7 to 8 seconds at a time. The breath-holding instructions will be clearly given by the technician. If the patient becomes tired with the breath holding, some sequences can be obtained with normal breathing, but this may affect the quality of the images.

Some patients will have an IV line placed if they need contrast. A series of images are often taken before the contrast is given, with another series of images taken afterward. The gadolinium-based contrast is usually well tolerated, but may make some patients feel warm, nauseous, and/or leave them with a metallic taste in their mouth. If the patient experiences any itching, hives, difficulty breathing, he/she should immediately press the handheld button and alert the technician.

The entire examination typically lasts between 30 and 60 minutes depending on the sequences that need to be obtained and whether contrast is being used.

AFTER THE EXAMINATION

After the examination, the patients can go about their normal day as long as they did not get any sedating medications. If they were given medication to ease anxiety, they should be accompanied by another person who would be able to safely take the patient home and monitor them for a few hours. The radiologist or cardiologist interpreting the examination will analyze the images and send a report to the referring physician. The referring physician will share the results with the patient. The time of reporting varies according to the policies at each imaging facility.

Mechanical Circulatory Support in the Cardiac Care Unit

Cardiogenic shock refers to the disorder where cardiac dysfunction results in inadequate end-organ perfusion. The classic condition involves systemic hypotension and symptoms or signs of organ hypoperfusion despite adequate intravascular volume. Initial management is focused on treatment of reversible causes such as revascularization when appropriate in acute coronary syndromes. Following this or simultaneously, inotropic and vasopressor agents are administered to improve hemodynamics. Despite these measures, adequate perfusion to prevent end-organ dysfunction is often not restored or able to be maintained. As a result, morbidity and mortality from this disorder remain high, with a 30-day mortality, across many studies, exceeding 40%.[1] This has led to the development of mechanical circulatory support (MCS) devices that have been proven to reverse the poor hemodynamic profile of cardiogenic shock. It is important to note that although use of MCS clearly improves hemodynamics, data demonstrating a mortality benefit are lacking.

The decision to initiate MCS must not be taken lightly. Its use demands substantial resource allocation and carries tremendous cost. In addition, there is a high rate of serious complications when MCS is employed. Appropriate patient selection is of utmost importance. It is imperative that patients for whom temporary MCS is considered are thought to have a long-term option for

survival, because temporary MCS is merely a bridging therapy. Therefore, the medical providers must have a high index of suspicion that survival with the capacity for meaningful recovery of end-organ function and quality of life is possible. This may be accomplished by eventual improvement of native cardiac function, by placement of long-term MCS or through cardiac transplantation.

The MCS devices currently available differ in several ways, including the level of support provided, hemodynamic effects, site of vascular access, vessel size required for delivery, and associated complications (**Table 17.1**). In this chapter, we will discuss the most commonly used devices and highlight their important distinctive features.

TABLE 17.1 Characteristics of Mechanical Circulatory Support Devices

DEVICE	MECHANISM	HEMODYNAMIC SUPPORT (L/min)	DEVICE SIZE (Fr)	INSERTION
IABP	Pneumatic	0–1	8	Percutaneous: femoral or axillary artery
TandemHeart	Centrifugal	4	Inflow 21 Outflow 12–17	Percutaneous: inflow femoral vein (to left atrium via transseptal puncture), outflow femoral artery
Impella 2.5	Axial	2.5	13	Percutaneous: femoral artery
Impella CP	Axial	4	14	Percutaneous: femoral artery
Impella 5.0	Axial	5	23	Surgical cutdown: femoral or axillary artery
Impella RP	Axial	4	22	Percutaneous: femoral vein
VA-ECMO	Centrifugal	>4.5	Inflow 18–21 Outflow 15–22	Percutaneous ± cutdown: inflow femoral vein, outflow femoral artery
Durable LVAD	Axial or Centrifugal	>7	NA	Surgical: inflow from LV, outflow ascending aorta

Fr, French; IABP, intra-aortic balloon pump; LV, left ventricular; LVAD, left ventricular assist device; L/min, liters per minute; VA-ECMO, venoarterial-extracorporeal membrane oxygenation.

INTRA-AORTIC BALLOON PUMP

The intra-aortic balloon pump (IABP) was the first mechanical device developed, and its use has become widespread since its inception in the 1960s. It is placed in the descending thoracic aorta and acts by balloon inflation during diastole and active deflation in systole (see **Figure 17.1**). This results in a higher perfusion pressure in the coronary arteries during diastole and a reduction in left ventricular afterload during systole. The hemodynamic effects are variable and depend on the position in the aorta, heart rate, rhythm, aortic compliance, and systemic resistance. Overall, the potential hemodynamic effects include an increase in cardiac output (CO) of approximately 500 cc minute, an increase in mean arterial blood pressure (MAP), and a reduction in left ventricular end-diastolic pressure (LVEDP) with a resulting decrease in left ventricle (LV) wall stress and myocardial oxygen demand. Given the mechanism of action already described, the use of IABP has generally been studied in patients with cardiogenic shock resulting from myocardial infarction. The largest randomized trial evaluating the use of IABP in this group of patients was the IABP-SHOCK II Trial.[1] Six hundred patients with cardiogenic shock complicating acute myocardial infarction expected to undergo early revascularization were randomly assigned to IABP or usual care. No difference in the primary end point of 30-day all-cause mortality was found. Several smaller studies and meta-analyses have failed to show convincing evidence of a mortality benefit with the use of IABP in this setting. Of note, some benefit has been demonstrated with the use of an IABP in patients with myocardial infarction complicated by shock treated with thrombolytic therapy.[2, 3]

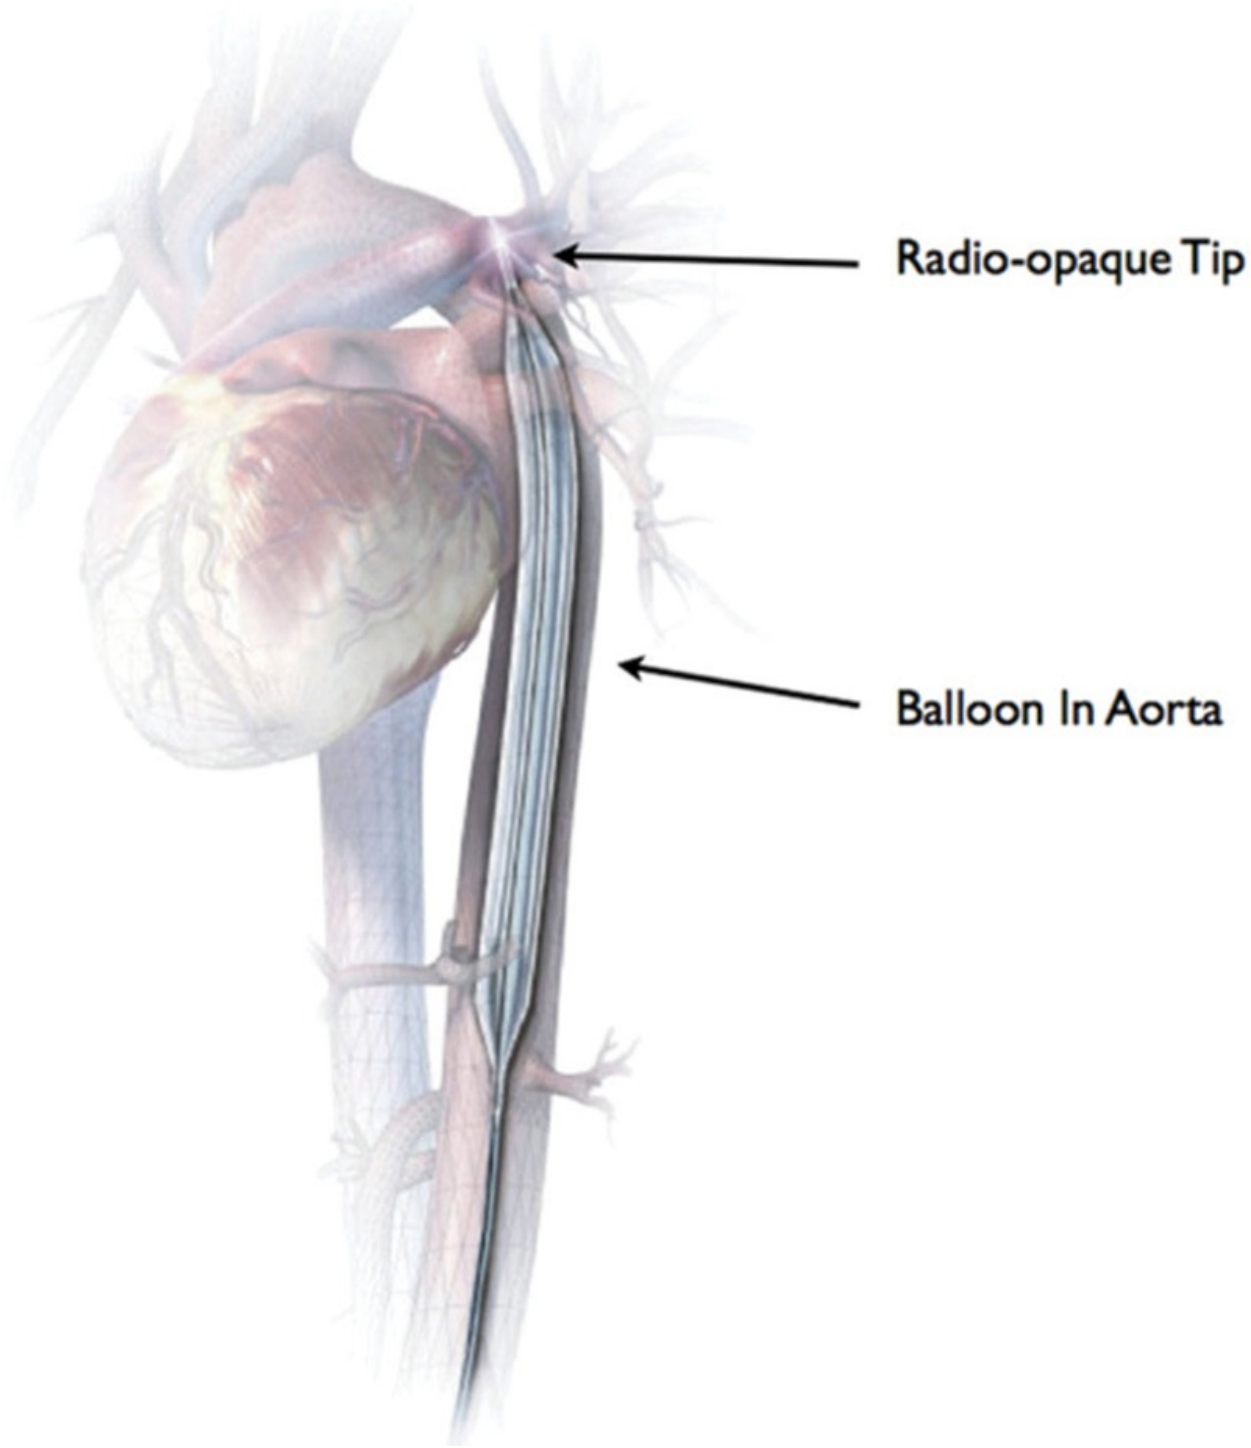

FIGURE 17.1 Intra-aortic balloon pump. It is shown placed in the descending thoracic aorta below the aortic knob. The radio-opaque tip is used to assess placement by X-ray.

CLINICAL USE

The IABP is typically placed in the femoral artery, although placement in the left

axillary/subclavian artery has been used when long-term support is planned. Its tip is advanced to the descending thoracic aorta up to the level of the carina and at least 2 cm below the aortic knob. An IABP should not be placed in patients with more than mild aortic regurgitation, because the degree of regurgitation will be increased by counterpulsation from the device. Aortic pathology such as dissection or a significant aneurysm would preclude the insertion of an IABP because of the risk of furthering aortic disease. In addition, severe peripheral vascular disease (or small vasculature) will limit its use in view of the development of ipsilateral limb ischemia.

A chest X-ray should be performed daily to confirm proper position. Distal pulses must be regularly checked following placement to screen for limb ischemia. The pressure waveform should be reviewed to ensure proper device function and timing (see **Figure 17.2**).

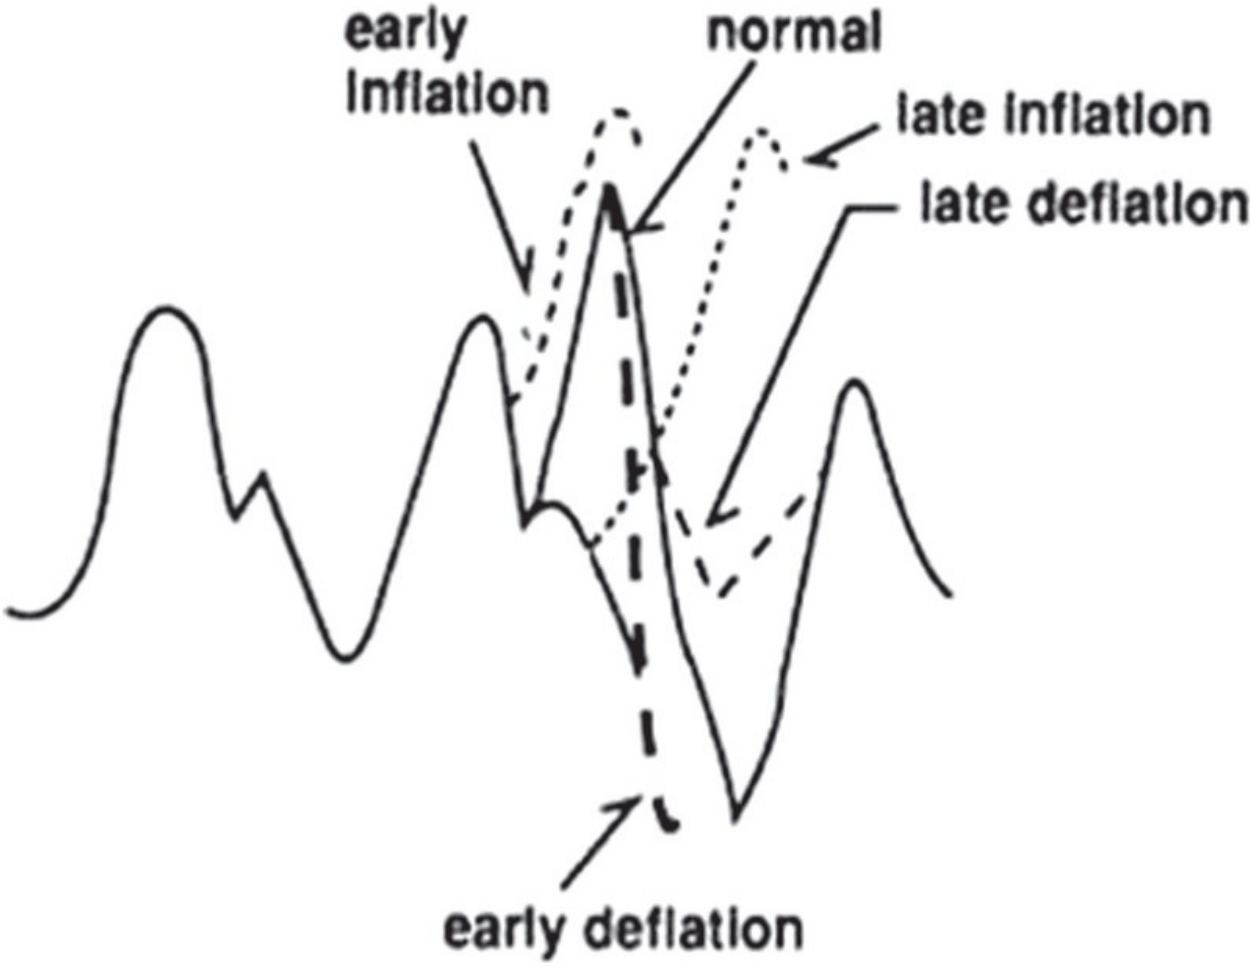

FIGURE 17.2 IABP tracing displaying normal and improper timings of balloon inflation. In a normal waveform, balloon inflation occurs at or slightly above the dicrotic notch, which represents the onset of diastole after aortic valve closure. Deflation occurs during isovolumetric contraction, just before the aortic valve opens. Early inflation, balloon inflation before aortic valve closure, can result in premature aortic valve closure and a reduced cardiac output. Late inflation, where the inflation point follows the dicrotic notch, leads to a reduction in coronary perfusion pressure. Early deflation will prevent the intended decrease in assisted systolic pressure and the resulting afterload reduction from occurring. Late deflation, occurring following aortic valve opening, will increase afterload and myocardial oxygen demand. IABP, intra-aortic balloon pump.

The use of anticoagulation with IABP support can be weighed in the context of patient-specific factors or based on institutional guidelines. Studies evaluating the routine use of anticoagulation have not demonstrated a reduced risk of thrombus formation, thromboembolism, or limb ischemia. Only an increased risk of bleeding has been found.[4]

COMPLICATIONS

The most common complications of IABP use are vascular in nature. These include limb ischemia and hemorrhage from the access site. A rare but serious complication resulting from the IABP is compromised perfusion in the aorta, leading to visceral (including renal) and spinal cord ischemia. These can be mitigated by proper placement, as discussed above.

INDICATIONS

The 2013 ACC/AHA guidelines for the management of ST-elevation myocardial infarction (STEMI) state, as a class IIa (level of evidence B) recommendation, that “the use of an IABP can be useful for patients with cardiogenic shock after STEMI who do not quickly stabilize with pharmacological therapy.”[5] In addition, they highlight its use as a temporizing measure in mechanical complications of shock such as papillary muscle rupture with resulting mitral regurgitation and ventricular septal rupture.

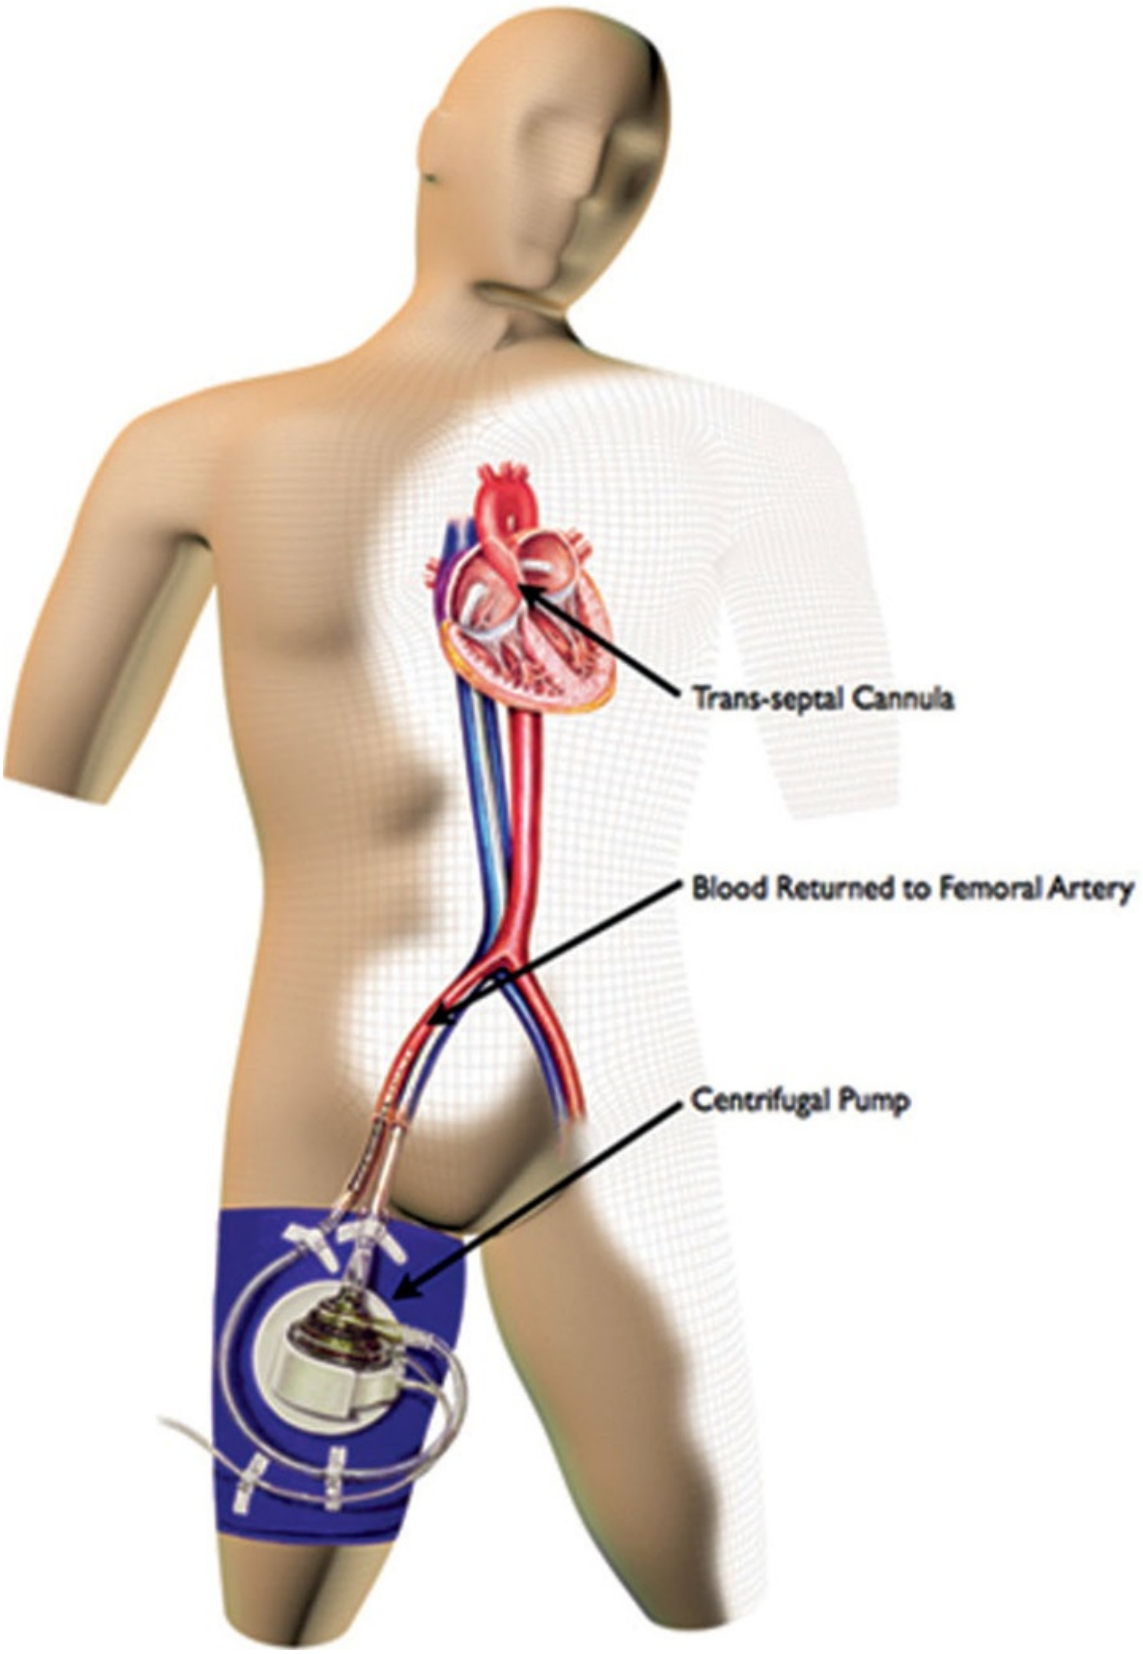
TANDEMHEART

The TandemHeart (Cardiac Assist, Inc, Pittsburgh, PA) percutaneous assist device is a left atrial to femoral artery bypass continuous flow centrifugal pump system designed to provide complete hemodynamic support. It has been studied

in a randomized fashion for patients presenting with cardiogenic shock caused by ischemic[6] and nonischemic disease.[7] When compared to the IABP it has demonstrated superior hemodynamic effects and, among other parameters, results in larger increases in CO and MAP and a greater reduction in pulmonary capillary wedge pressure (PCWP). It was also evaluated in patients with severe refractory cardiogenic shock, a scenario in which its use would likely be of the greatest benefit, and it was shown to dramatically improve hemodynamic and clinical parameters.[8] No mortality benefit has been demonstrated, but the trials were not adequately powered to evaluate this outcome.

CLINICAL USE

An atrial drainage cannula (21F) is placed in the left atrium by means of a transeptal puncture, and oxygenated blood is drawn from there and returned via a centrifugal pump to an arterial cannula (most often 17 French) in the femoral artery (see **Figure 17.3**). Aortoiliac and femoral angiography is recommended before insertion to assess vessel size, as a 12F bilateral femoral artery access system is available to accommodate smaller vasculature. It is powered by an electromagnetic motor that drives a plastic impeller at a speed of 3000 to 7500 rpm and is capable of delivering flows up to 4.0 L/min. During use, anticoagulation is administered continuously to achieve a target partial thromboplastin time of 65–80 seconds or an activated clotting time (ACT) between 180 and 220 seconds.



Trans-septal Cannula
Blood Returned to Femoral Artery
Centrifugal Pump

FIGURE 17.3 The TandemHeart percutaneous assist device. A drainage cannula is placed in the left atrium by means of a transseptal puncture, and oxygenated blood is drawn from there and returned via the centrifugal pump to a cannula in the femoral artery.

Despite the impressive hemodynamic benefits observed with the use of TandemHeart, its implementation is ultimately limited by the complexities of device insertion, which can be particularly challenging in emergency situations.

COMPLICATIONS

The most common complications of TandemHeart use are device-related limb ischemia and bleeding. These occur as a result of vascular access site trauma and the development of a coagulopathy. In trials, a high rate of blood transfusions was noted.

INDICATIONS

The 2013 ACC/AHA STEMI guidelines state, as a class IIa (level of evidence C) recommendation, that "LV assist devices for circulatory support may be considered in patients with refractory cardiogenic shock."[5]

The 2013 International Society for Heart and Lung Transplantation (ISHLT) guidelines for MCS state, as a class I (level of evidence C) recommendation, that the use of temporary mechanical support should be strongly considered in patients with multiorgan failure, sepsis, or on mechanical ventilation to allow successful optimization of clinical status and neurologic assessment before placement of a long-term MCSD.[9]

A 2015 clinical expert statement, endorsed by multiple organizations, concludes that patients with acute decompensated heart failure may benefit from early use of percutaneous MCS when they continue to deteriorate despite initial interventions.[10]

IMPELLA

The Impella (Abiomed, Inc, Danvers, MA) families of devices are axial flow pumps that work on the principle of the Archimedes screw. These devices deliver blood from the inlet area, which sits in the LV, through the impeller to the outlet opening in the ascending aorta (**Figure 17.4**). The left-sided Impella

device comes in three different sizes that differ on the basis of the degree of support it can deliver. The Impella 2.5 can provide up to 2.5 L/min, the Impella CP can deliver up to 4 L/min, and the Impella 5.0 up to 5 L/min. The family of devices has been shown to improve the hemodynamics of cardiogenic shock by unloading the LV, which results in an increased MAP, reduced myocardial oxygen demand, and a reduced PCWP. The Impella 2.5 is the only device of the group to be studied in a randomized fashion and has been shown to provide greater hemodynamic support compared to the IABP in patients with cardiogenic shock complicating AMI.[11] The Impella 5.0 was evaluated for use in postcardiotomy cardiogenic shock and was found to yield favorable outcomes.[12]

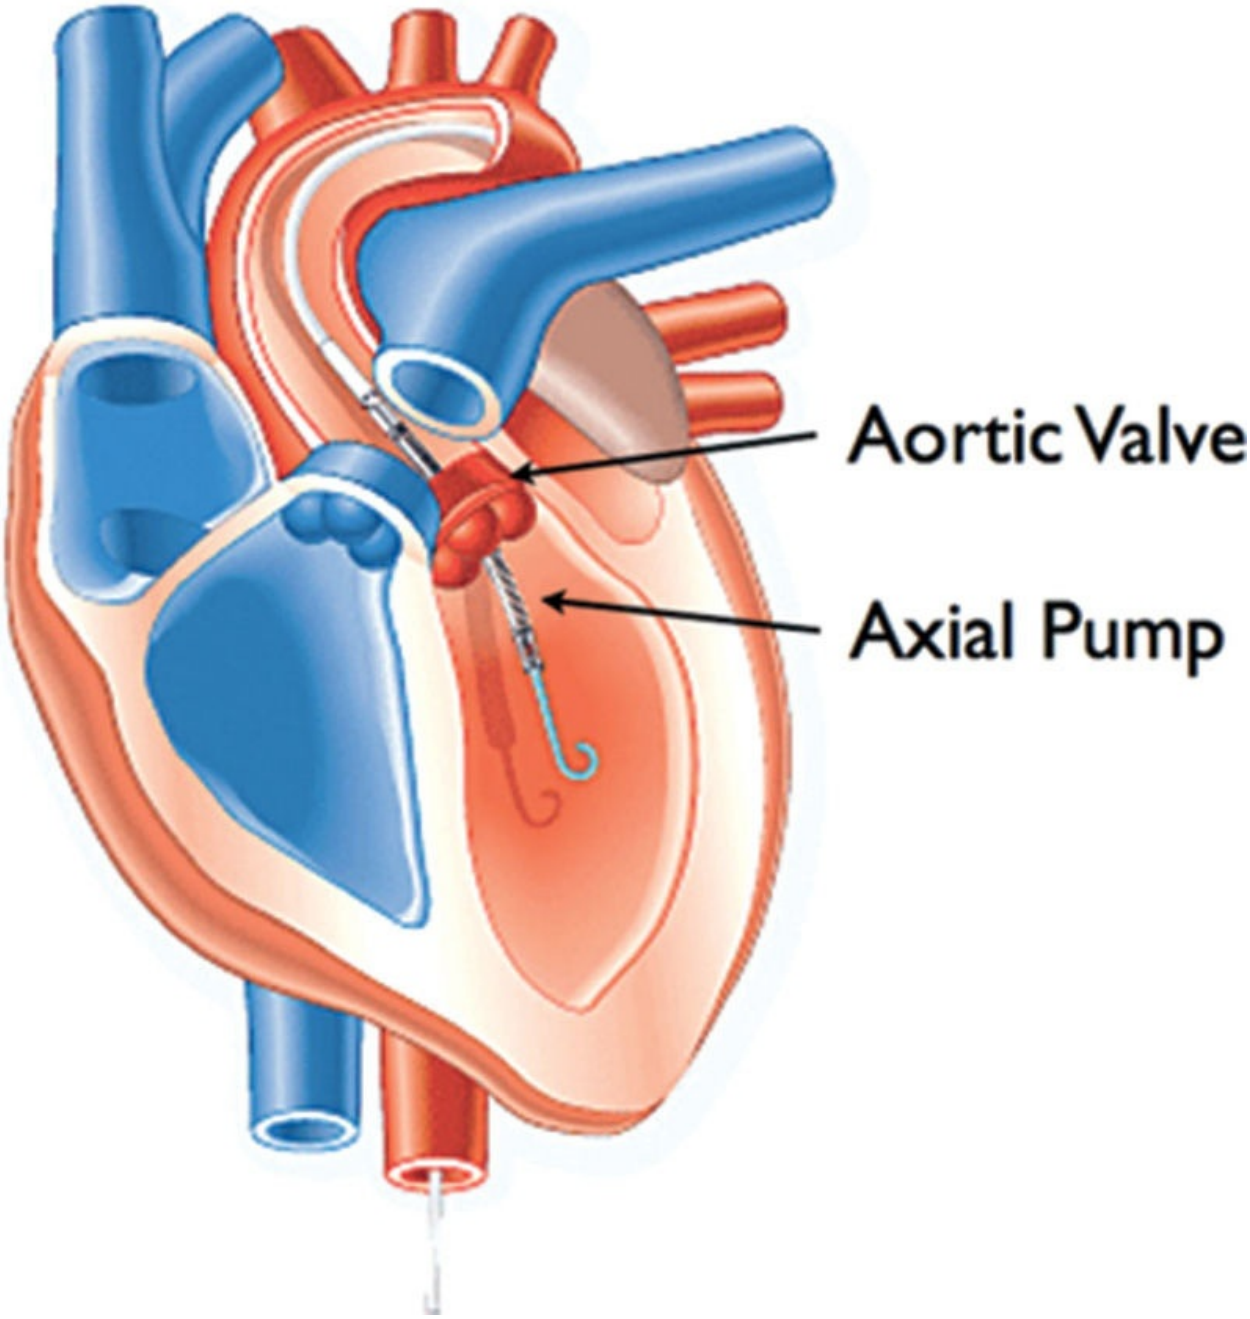


FIGURE 17.4 The Impella axial flow pump. The Impella is advanced retrograde across the aortic valve until the catheter with a pigtail tip sits in the LV. Blood is delivered from the inlet area through the impeller to the outlet area in the ascending aorta. LV, left ventricle.

CLINICAL USE

The Impella is inserted via arterial access and is advanced retrograde across the aortic valve until the catheter with a pigtail tip, which helps avoid myocardial injury and ensures a stable position, sits in the LV. The Impella 2.5 and Impella

CP can be inserted through a 14Fr introducer sheath using a percutaneous approach via the femoral artery. The Impella 5.0 uses a larger introducer sheath (23Fr) that requires a surgical cutdown for insertion and is often placed in the axillary artery. The Impella devices are typically placed under fluoroscopic guidance in the catheterization laboratory. To optimize device flow and avoid complications, proper positioning of the Impella tip in the LV is of utmost importance. Echocardiography can be used at the patient's bedside to confirm proper positioning of the device in the LV cavity. The degree of support is managed by graduation of pump speed.

The Impella requires sufficient LV preload for proper function, and its use is therefore contraindicated with significant right heart failure. Given the need for the system to cross the aortic valve, a mechanical prosthesis or severe AS precludes its use. It should be avoided when more than mild aortic insufficiency is present because a significant amount of blood that is pumped in the ascending aorta can flow back into the LV and reduce systemic perfusion. As with other devices that require arterial access, severe peripheral vascular disease limits its use. In addition, use of the Impella is contraindicated in the presence of an LV thrombus or a ventricular septal defect.

COMPLICATIONS

Major bleeding at the vascular access site is the most common complication of Impella use. Hemolysis is frequently seen owing to the high rotational speed of the impeller. If the catheter is advanced too far into the LV apex, there is a risk of ventricular arrhythmias and perforation, which may result in pericardial tamponade.[13] Limb ischemia remains a concern given the large arterial sheath required for placement.

INDICATIONS

In general, the recommendations from major society guidelines discuss all temporary mechanical support devices under the same heading. Therefore, the recommendations for Impella use in cardiogenic shock are identical to those listed for the TandemHeart.

The Impella 2.5 has received a separate indication from the FDA for use during high-risk percutaneous coronary interventions (PCI) performed in elective or urgent hemodynamically stable patients with severe coronary artery disease and depressed left ventricular ejection fraction, when a heart team,

including a cardiac surgeon, has determined high-risk PCI is the appropriate therapeutic option.

RIGHT VENTRICULAR SUPPORT

Right ventricular failure (RVF) can occur in multiple settings. It can be particularly devastating during the use of left-sided MCS devices because they rely on sufficient LV preload for proper function. The right ventricle (RV) can be placed under exceptional stress during MCS use for several reasons, including the rise in RV preload with normalization of CO, the alteration of normal RV geometry caused by septal shift resulting from LV unloading and an increase in pulmonary vascular resistance, which can typically be seen with critically ill patients and in the postoperative period. The RV often recovers over a short period of time, and patients can typically be stabilized with volume optimization along with the use of inotropes and pulmonary vasodilators. Right-sided MCS devices have been developed for use in RVF refractory to medical therapy. The Impella RP system works on the same principles previously described for the Impella family of pumps and can provide flow greater than 4 L/min at an impeller speed of 33,000 rpm. The device delivers blood from the inlet area, which sits in the inferior vena cava, through the cannula to the outlet opening in the pulmonary artery (PA). Its use was evaluated in a prospective trial comprising patients with RVF complicating left ventricular assist device (LVAD) implant and myocardial infarction or postcardiotomy.[14] Following initiation of support, there was a significant increase in cardiac index (CI) and a reduction in central venous pressure (CVP).

The TandemHeart system, described earlier, has been successfully converted to a right-sided support device. The inflow cannula draws blood from the right atrium (RA), and it is returned to the PA. Analysis of a registry of patients who received the device for management of RV failure found that its use led to an improvement in MAP, CVP, PA systolic pressure, and CI.[15]

CLINICAL USE

The Impella RP is inserted into the femoral vein via a 23Fr sheath and advance to the right heart with its tip passing through the RA, tricuspid valve, and pulmonic valve. During pump operation, an ACT of 160 to 180 is recommended.

Its use is contraindicated with right-sided mechanical valves, severe valvular stenosis or regurgitation of the tricuspid or pulmonary valve, and mural thrombus in the RA or vena cava.

The TandemHeart system can be placed percutaneously or surgically. Percutaneous implantation requires two areas of venous cannulation, and this can be accomplished via bifemoral or right internal jugular approaches using 21Fr cannulas. Surgical implantation is performed by direct cannulation of the RA and PA or by peripheral cannulation of the femoral vein and direct cannulation of the PA.

COMPLICATIONS

The most frequent complication with both devices is major bleeding. As described with the Impella systems above, hemolysis is seen with Impella RP use.

INDICATIONS

There are no societal recommendations for use of temporary right-sided mechanical support devices. The Impella RP is FDA approved for use in patients who develop acute right heart failure or decompensation following LVAD implantation, myocardial infarction, heart transplantation, or open-heart surgery.

EXTRACORPOREAL MEMBRANE OXYGENATION

Extracorporeal membrane oxygenation (ECMO) differs from the temporary devices already discussed in that it is able to provide full support in cases of severe biventricular failure. There are two forms of extracorporeal support, veno-venous (VV) and venoarterial (VA). The VV system provides only oxygenation. However, VA ECMO can provide complete cardiopulmonary support. The system consists of a continuous flow centrifugal pump and a membrane oxygenator (**Figure 17.5**). Blood is aspirated from the RA into the venous inflow cannula and, via the pump, is circulated through the membrane oxygenator. Oxygenated blood is then directed into the arterial circulation via the outflow cannula. ECMO can provide substantial hemodynamic support, with flows up to 6 L per minute, and increased LV afterload, which can have negative consequences discussed later. ECMO has been applied clinically in many forms

of circulatory failure, including cardiogenic shock from various etiologies and cardiac arrest, but no randomized controlled trials have been performed to study its use. For the most part, the data supporting its implementation come from prospective and retrospective single center experiences or pooled analysis of this data. In these, it has been suggested that ECMO use improves 30-day survival and neurologic outcomes in the cardiac arrest population but resulted in similar outcomes when compared to other forms of mechanical support, aside from IABP, in the cardiogenic shock patients.[16] When considering these data, one must recognize the nonrandomized nature of these studies and the potential large influence that confounders have on these results.

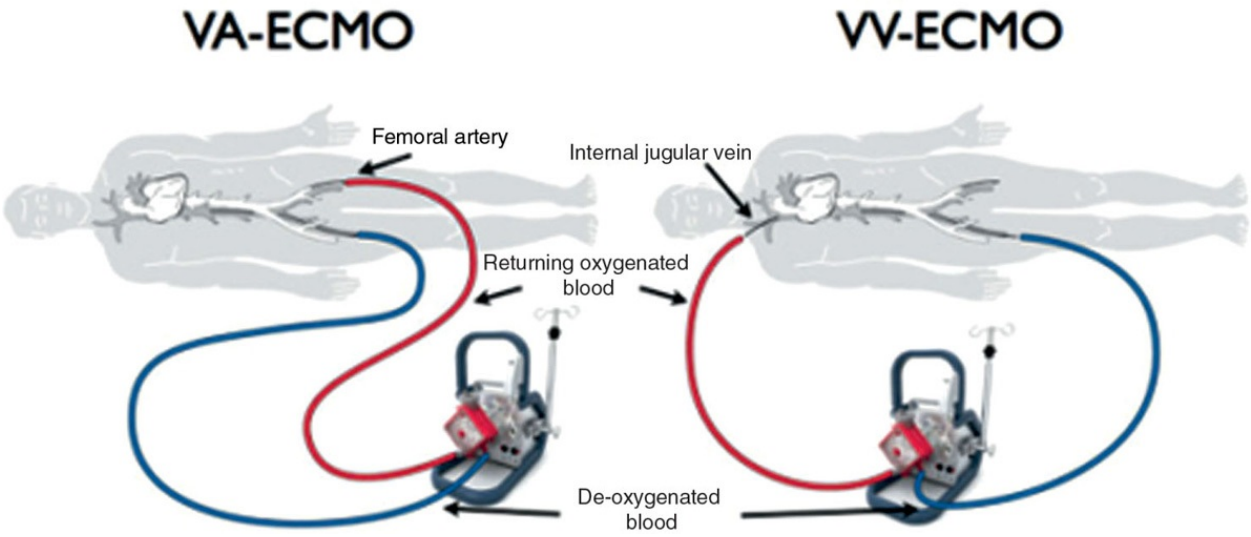

FIGURE 17.5 Diagrammatic representation of peripheral veno-venous (VV-ECMO) and peripheral veno-arterial (VA-ECMO) extracorporeal membrane oxygenation. With VA-ECMO, venous blood is circulated through the membrane oxygenator, and oxygenated blood is directed into the arterial circulation. With VV-ECMO, venous blood flows through the membrane oxygenator, and oxygenated blood is returned to the venous circulation. (From Cove ME, MacLaren G. Clinical review: MCS for cardiogenic shock complicating acute myocardial infarction. *Crit Care*. 2010;14:235.)

CLINICAL USE

The appeal of the ECMO system is the ability to provide complete cardiopulmonary support with rapid insertion peripherally at the bedside. A venous inflow cannula (ranging from 15 to 29 Fr) is inserted into the femoral vein and advanced to the RA; this is usually performed under transesophageal echocardiography guidance. The arterial outflow cannula (ranging from 15 to 23Fr) is typically placed in the femoral artery, but other arterial sites of

cannulation have been used. Adjusting the rotational speed of the device controls flow, and it should be placed at the lowest speed necessary to provide adequate perfusion. As flow is increased, the afterload rises as well. This results in a reduction in the heart's ability to unload and increases myocardial oxygen demand. In turn, there is an increase in the LVEDP/PCWP that can lead to the development of pulmonary congestion. In addition, it is thought that the unfavorable LV loading conditions created by ECMO use may adversely affect myocardial recovery. Several strategies can be employed to decompress or "vent" the LV when deemed necessary. These include inotropic support, IABP placement, Impella use, atrial septostomy, or direct LA or LV cannulation. When femoral cannulation is employed, arterial blood gases and pulse oximetry should be checked in the right arm, the farthest area from the cannulation site, to confirm uniform oxygenation throughout the arterial system. This is necessary because the ECMO device will preferentially perfuse the lower extremities with its fully saturated blood, whereas blood ejected from the heart will selectively perfuse the brain, coronaries, and upper extremities. This phenomenon can be exacerbated by improvement in native CO and IABP use.

Anticoagulation is necessary to prevent thrombus formation in the system, particularly in the membrane oxygenator, and ACTs are typically maintained between 180 and 250 seconds.

One disadvantage to ECMO use is that a cardiac perfusionist, whose availability is limited at many centers, is required for management of the system. The perfusionist plays an integral role in the ECMO circuit setup, priming, and optimization of settings during use.

COMPLICATIONS

The most frequent complication during ECMO use is hemorrhage that can occur at the sites of cannulation or other. Neurologic complications such as seizures, cerebral infarction, and hemorrhage have been reported. Cardiac thrombus formation, especially when CO remains low, is seen. Renal failure has been observed with a notable oliguric phase following implant. As with the other devices placed peripherally, limb ischemia is of concern, and in order to decrease the occurrence an additional cannula can be placed to perfuse the distal extremity. Given the multiple entry sites and large-size catheters, close monitoring for infectious complications is required.

INDICATIONS

ECMO carries a society recommendation similar to the other forms of percutaneous MCS, but strong consideration should be given to ECMO use when there is significant impairment in respiratory gas exchange.[10]

DURABLE MCS

Implantable MCS devices have become integral to the management of patients with end-stage heart failure. They have been shown to improve both survival and quality of life when compared to traditional care in this group of patients.[17] The newer-generation continuous flow pumps have proven to be more durable and carry a superior adverse event profile than the original pulsatile devices.[18] The two main indications for implantation are bridge to transplantation (BTT) and destination therapy (DT). The hope that these devices would routinely offer a path to recovery has been unrealized because this occurs in few cases.[19] BTT refers to implanting an LVAD to maintain hemodynamic support in those patients who are listed for cardiac transplantation. Given the prolonged wait times for donor organs, bridging is necessary, because many patients would not survive to the time of transplantation. Devices are placed as DT with the intent of providing prolonged support in patients who are ineligible for cardiac transplantation.

Implantation of durable mechanical support devices in patients with cardiogenic shock and multiorgan failure has traditionally been avoided in view of the concern that these critically ill patients would not tolerate the rigors of surgery and extended cardiopulmonary bypass. Registry data have indeed shown that early and midterm survival for patients implanted at INTERMACS profile 1, defined as critical cardiogenic shock, is significantly worse than for less sick patients, but despite the advanced disease state, 1-year survival is reported to be 76%.[20] Some centers have adopted strategies of inserting implantable LVADs as the primary therapy for refractory cardiogenic shock rather than attempts at hemodynamic stabilization with short-term mechanical devices.[21] This approach restores consistent CO to a greater degree and avoids the exposure to the multiple complications associated with the short-term devices.

CLINICAL USE

The two most commonly used commercially available LVADs are the Heartmate

II (St. Jude Medical, St. Paul, MN) and the HVAD (Medtronic Inc., Minneapolis, MN). Both pumps consist of a blood inlet, termed the inflow cannula, traditionally placed in the left ventricular apex, and an outlet, termed the outflow cannula, typically placed in the ascending aorta, separated by a single rotating element that imparts energy on the blood to increase flow and pressure. There is a percutaneous driveline connected to the LVAD pump that is tunneled outside the body and linked to a controller that is powered by connecting battery packs (**Figure 17.6**). The primary differences between the two devices lie in the mechanics of the rotating element and implant location. The Heartmate II is an axial flow pump whose impeller with its housing is positioned below the left rectus abdominis muscle or in the peritoneal cavity. The HeartWare HVAD is a centrifugal flow device with the impeller and its housing in the pericardial space (**Figure 17.7**). Of note, the Heartmate 3 (St. Jude Medical, Inc., St. Paul, MN), a centrifugal flow intrapericardial pump, is currently being studied in a clinical trial. Because of the continuous LV unloading and flow generated by these devices, patients most often lack a palplable pulse. Measurement of systemic pressure requires the use of a doppler device and manual blood pressure cuff, and in critically ill patients, the use of an arterial line is prudent. Patients are chronically maintained on warfarin with a goal international normalized ratio in the range of 2 to 3 and antiplatelet therapy to prevent device thrombosis.

COMPLICATIONS

Several serious complications, including stroke, bleeding, and pump thrombosis, have been noted to occur both in the initial trials and in registry data.[20] Readmissions are common, and some adverse events require management in the CCU.

Bleeding requiring transfusion of packed red blood cells, most often from a gastrointestinal source, occurs at high rates. Formation of arteriovenous malformations and acquired von Willenbrand syndrome are thought to be responsible for these events. These typically resolve with brief periods off anticoagulation or with endoscopic treatment but can continue to occur at high rates in certain individuals.

Pump thrombosis can present with a wide range of clinical manifestations, depending on the extent of the clot. In its most benign form, only elevated markers of hemolysis with little change in device function or patient symptoms are found. On the other end of the spectrum, severe hemolysis with pump failure and resulting heart failure can occur. Features suggestive of thrombosis include signs of hemolysis such as red or reddish-brown urine, elevated serum lactate dehydrogenase, decreased serum haptoglobin, and increased plasma-free hemoglobin. The change in pump performance most suggestive of thrombosis is the development of a marked or gradual increase in pump power. Given the decline in output through the pump, increased pump speed may be required to maintain adequate flow. Pump thrombosis can initially be managed with intensification of anticoagulation, but pump exchange may be indicated depending on the severity and clinical scenario.

Right heart failure can be an early or late complication of LVAD support. For proper LVAD function, the RV must supply adequate preload across the pulmonary circuit. RV failure can manifest as low flow through the device, volume overload and end-organ dysfunction. It is thought that LVAD support can further weaken an already compromised RV by increasing systemic venous return and inducing geometric changes that can increase tricuspid regurgitation or reduce the septal contribution to RV stroke volume. In the perioperative period post-LVAD implant, management of right heart failure will include high doses of intotropic support or, in refractory cases, implantation of a temporary

right ventricular assist device.

Ventricular arrhythmias, typically sustained ventricular tachycardia (VT), have been observed to occur at high rates post-LVAD implant, even in patients who had not experienced these previously.[22] These can occur in the immediate postoperative period, when electrolyte imbalances and the use of arrythmogenic inotropes contribute to their cause, or later in the course. An echocardiogram should be performed to evaluate whether endocardial irritation in the setting of excessive ventricular unloading resulting in direct contact of the LVAD outflow cannula and endocardium, termed a "suction event," is the culprit. Initially, sustained VT is typically well tolerated, as the device will continue to provide support. When the event is protracted, right heart failure can develop, and the accompanying clinical manifestations previously discussed can follow. The management of VT in an LVAD patient is similar to that employed in the typical patient. First, reversal of inciting factors and correction of electrolyte imbalances should be tried. This may include cessation of proarrythmic medications or a speed reduction to prevent approximation of the outflow cannula and endocardium. Following this, treatment with antiarrhythmics, antitachycardia pacing or defibrillation should be implemented. Only rarely, in cases repeatedly refractory to the above treatments, is ablation considered.

INDICATIONS

The 2013 ISHLT guidelines[9] for MCS state, as a class IIa (level of evidence C) recommendation, that long-term MCS for patients who are in acute cardiogenic shock should be reserved for the following:

1. Patients whose ventricular function is deemed unrecoverable or unlikely to recover without long-term device support.
2. Patients who are deemed too ill to maintain normal hemodynamics and vital organ function with temporary MCS devices (MCSDs), or who cannot be weaned from temporary MCSDs or inotropic support.
3. Patients with the capacity for meaningful recovery of end-organ function and quality of life.
4. Patients without irreversible end-organ damage.

The Centers for Medicare and Medicaid Services (CMS) has laid down the following criteria for LVAD implantation as DT:

1. New York Heart Association class IV patients with end-stage heart failure that are not candidates for transplantation.
2. Patients who have failed to respond to optimal medical management for at least 45 of the last 60 days or have been balloon pump dependent for 7 days or IV inotrope dependent for 14 days.
3. Patients who have a left ventricular ejection fraction < 25% and have demonstrated functional limitation with a peak oxygen consumption of ≤14 mL/kg/min unless balloon pump or inotrope dependent or physically unable to perform the test.

CONCLUSION

Cardiogenic shock remains a devastating condition with high rates of morbidity and mortality. Over the past several decades, we have seen the development of MCS devices that are able to offer excellent hemodynamic support. The choice of device can be tailored to patient characteristics, degree of desired support, and institutional resources. **Figure 17.8** outlines an algorithm for deciding on the proper implementation of these therapies. Their use has become widespread, and the costs associated with them continue to rise. This is all occurring without concrete evidence of improvement in mortality with the use of these devices. Whether the benefit of reversing the hemodynamics of cardiogenic shock has not translated into improved long-term outcomes because of the high rate of complications associated with these devices or as a result of delayed initiation, to a time when multiorgan dysfunction has already developed, needs further evaluation in well-designed clinical trials. In addition, before instituting support it must be confirmed that there is a reasonable chance that a pathway to a meaningful recovery will be established.

Patient and Family Information for: MECHANICAL CIRCULATORY SUPPORT

The heart is responsible for providing the force to deliver oxygenated blood to the body's organs and tissues. The heart has a right and left side that serve different functions but work in tandem to maintain the circulation of blood. The right side of the heart sends blood through the lungs, where it picks up oxygen. The oxygenated blood then passes to the left side, where it is pumped to the rest of the body. When the heart suffers a serious injury, an insufficient amount of blood is delivered to the organs to meet their demands, and organ dysfunction follows. This clinical situation is termed cardiogenic shock. The heart can be weakened to this extent either by a new cardiac event, such as a heart attack, by progression of existing heart disease, or by an insult to an already impaired heart. Signs of cardiogenic shock include fatigue, altered mental state, cool extremities, low blood pressure, kidney failure, and liver failure. Initial management is focused on treatment of reversible causes, such as opening up blocked arteries, and attempting to augment heart function with intravenous medications. At times, these maneuvers are not sufficient to restore adequate circulation. It is in these situations that the use of mechanical circulatory support (MCS) is considered. MCS refers to a variety of devices that aim to improve or replace the heart's pumping function. They are placed in order to allow the heart to recover adequate function or until a more definitive treatment is implemented. These devices differ in several ways, including the way they function, the level of support provided, the manner in which they are placed, and the associated complications.

The *IABP* is typically used and is the best studied device in patients with cardiogenic shock resulting from a heart attack. The device imparts its impact by

timed inflation and deflation of a balloon that sits at its tip. It supports the failing heart by decreasing the pressure that the heart has to pump against and increasing blood flow to the coronary arteries. It is usually placed in the arteries of the lower extremities and advanced up the aorta to its proper position. The most common complications of IABP use are related to the artery in which it is placed. Complications include disruption of blood flow to the lower extremities and bleeding from the site of access.

The *TandemHeart* assist device is a continuous flow pump designed to provide a high level of support. A catheter is placed in the veins of the lower extremities and advanced to the heart, where its tip crosses from the right to the left side. Blood is drained from the left side of the heart and directed, using the force of the pump, to a catheter in the arteries of the lower extremities where it enters circulation. The most common complications of TandemHeart use are related to the blood vessels in which the catheters are placed. Complications include disruption of blood flow to the lower extremities and bleeding from the site of access. It is not uncommon to require a blood transfusion as a result of significant bleeding.

The *Impella* system is available in three distinct sizes that differ in the amount of support they can provide. They all function on the same principle. The system is inserted into the peripheral arteries, and its tip is advanced into the LV of the heart. Using the force of the pump, blood is pulled through the opening at the tip seated in the LV and pushed to the aorta. Complications include disruption of blood flow to the lower extremities and bleeding from the site of access. In addition, it is common to induce breakdown of blood cells given the force placed on them when passing through the pump.

ECMO is the only device system able to provide full cardiac support and oxygenate blood. A catheter is placed in the veins of the lower extremities and advanced to the right side of the heart. Blood is drained from the right side and directed, using the force of the pump, to a device that provides oxygen to the blood. The oxygenated blood is then passed to a catheter in the arteries, typically in the lower extremities, where it enters circulation. Complications include disruption of blood flow to the lower extremities and bleeding from the site of access. As a result of the disruption to normal blood flow, clot formation in the heart can occur. In addition, neurologic events such as seizures and strokes have been documented during use.

Placement of a long-term support device, called a *LVAD*, can be considered in cases where there is little hope of restoring adequate heart function in a

relatively short period of time. These pumps restore blood circulation in a reliable manner and are quite durable. They must be implanted surgically in the operating room with use of the heart–lung machine. Blood enters the system through a tube in the LV and flows through the pump. From the pump, it is passed through tubing and exits the system in the aorta, where it circulates to the rest of the body. LVADs can remain in place for months to years. They remain in use until the heart recovers its native function or until a heart transplant is available or permanently remain for those patients not eligible for heart transplantation. They have been proven to both improve survival and quality of life in patients with advanced heart failure. The impressive benefits of the device do not come without cost. There are several complications associated with LVAD support. These include bleeding, infection, stroke, device malfunction requiring exchange and ventricular arrhythmias.

The condition of cardiogenic shock, resulting from severely impaired cardiac function, carries a high risk of morbidity and mortality. This has led to the development of novel devices with the hope of improving outcomes. These mechanical devices have repeatedly been proven to enhance blood circulation dramatically, but studies have yet to demonstrate an overall improvement in survival. It is important to understand that it is not appropriate to employ MCS in all cases. Use of these devices comes with a high rate of complications, many of them serious, which can place further stress on an already critically ill patient. In addition, the health care costs associated with their use are significant. The physicians must have a high index of suspicion that the patient can recover from their critically ill state and enjoy a meaningful quality of life in the future. To reach this end, these devices can serve as a bridge to recovery of native heart function, to placement of a long-term mechanical device, or to cardiac transplantation.

Selection and Care of the Heart Transplant Patient

INTRODUCTION

Despite making great advances in the medical treatment of heart failure over the last several decades, heart transplantation remains the definitive therapy for end-stage heart failure by extending survival and improving quality of life.[1, 2] Although the number of heart transplantations performed annually in the United States has remained static over the last decade, both short- and long-term survival rates have increased significantly.[3]

This chapter will discuss patient selection for transplantation as well as postoperative and follow-up care. It will focus on the first 6 months after transplantation, making references to later time points.

PATIENT SELECTION

Heart transplantation is indicated for the treatment of Stage D heart failure according to the American Heart Association/American College of Cardiology comprehensive heart failure guidelines. Transplantation may also be considered for the treatment of refractory arrhythmias; hypertrophic cardiomyopathy; severe

angina, valvular heart disease, or congenital heart disease not amendable to surgical repair; and, less frequently, selected cardiac neoplasms. A second transplant may be considered for patients with a history of heart transplant who develop allograft failure from vasculopathy, rejection, or other causes.

The specific criteria employed by transplant centers to decide patient eligibility may vary somewhat. The International Society for Heart and Lung Transplantation (ISHLT) has published consensus guidelines regarding patient selection.[4] Among the many criteria used, perhaps none is as variable as age. The ISHLT recommends that patients should be less than or equal to 70 years of age. Some centers draw the line at 65 years, whereas others have no absolute age criteria. Notably, in 2006, of the 2192 transplants performed in the United States, 243 (11%) occurred in patients over 65. Given that the majority of heart failure cases occur in patients older than 65, there is an implicit need for either transplantation or other destination therapies for patients in their seventh and eighth decades of life.

All patients should be without neoplasm. Select patients with recently treated localized cancers with a low chance of recurrence may be eligible if they are free of metastatic disease. Cancer screening includes colonoscopy in all patients over 50 years, a prostate-specific antigen in men, and mammography and a PAP smear in women. Cardiac transplantation has been successfully performed to treat cardiac neoplasms such as large atrial myxomas, and cardiac sarcomas without evidence of metastatic disease. Primary amyloidosis is an emerging indication for transplantation. Transplantation using extended-donor criteria followed by chemotherapy alone or in conjunction with bone marrow transplantation has been shown to extend survival in these patients.[5]

Although once excluded from consideration, diabetic patients can now be listed for transplant provided they have little or no evidence of end organ disease such as retinopathy, nephropathy or peripheral vascular disease. Patients with other debilitating chronic illnesses that may impact survival and those who lack the ability to provide self-care are generally excluded. Examples include dementia or hemiplegia after stroke. Patients with severe peripheral or cerebral vascular disease are excluded, as are those patients with significant restrictive or obstructive pulmonary disease (FEV***1*** <1 L).

Evaluation of liver and kidney function should be done at baseline and repeated at regular intervals. Patients with chronic kidney disease with a creatinine clearance of less than 34 mL/minface a high risk for developing chronic renal failure and should be considered for combined heart–kidney

transplantation. Patients with significant liver dysfunction are at risk for perioperative bleeding, vasoplegia, and organ failure. A transjugular liver biopsy may be required in those patients with significant liver dysfunction in order to exclude cirrhosis. This also permits measurement of hepatocaval and hepatic vein pressures to clarify the etiology and severity of the disease. Patients with significant irreversible disease, defined by bilirubin >2.5 or alanine transaminase/aspartate transaminase >3x normal, may be declined listing or, at select centers, considered for heart–liver transplant. Patients with reversible hepatic dysfunction with "nutmeg liver" from outflow obstruction may still be considered eligible for transplant because central venous pressure should fall with transplantation of a new cardiac allograft.

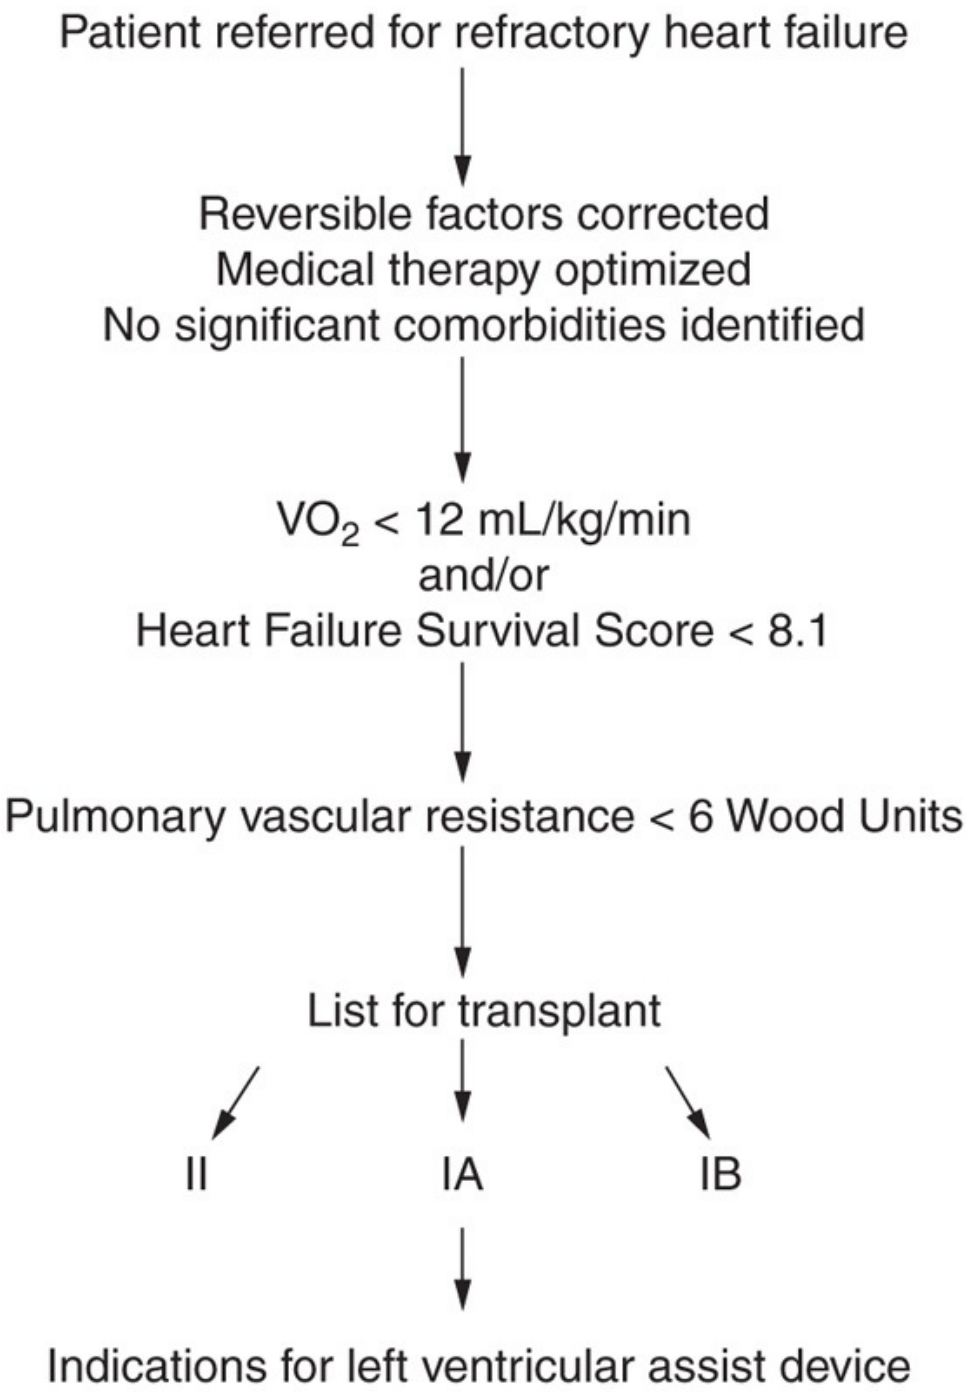
Screening for chronic viral infection should be performed before listing. Testing for herpes simplex virus (HSV), Epstein Barr virus (EBV), cytomegalovirus (CMV), hepatitis A, B, and C as well as HIV is recommended. Prophylaxis against reactivation of CMV and HSV is determined on the basis of the results of serologic testing. Controversy remains as to whether patients infected with hepatitis B and C should be transplanted in view of the risk of increased viral replication in the setting of immunosuppression. Infected patients with HIV have recently been considered eligible at some centers using extended-donor criteria. Eligible patients must have an undetectable viral load and a reconstituted immune system with normal CD4 count.[6, 7] Titers for *Trypanosoma cruzi* (Chagas) should be tested in all patients with nonischemic cardiomyopathy who are native or resided in South or Central America. Screening for strongyloides is recommended for those patients who lived or visited an endemic area such as Puerto Rico or the Dominican Republic.

Selection of heart transplant recipients should be reserved for those patients with a significant cardiovascular limitation resulting in reduced 1-year survival. Identifying such patients can be challenging, particularly in ambulatory patients. Cardiopulmonary exercise testing to measure peak oxygen consumption (VO_2 max) is a proven risk stratifying method and should be performed in all ambulatory patients.[8] A peak oxygen consumption of less than 12 mL/min/kg, or less than 14 mL/kg/min if intolerant of a beta-blocker, is considered the threshold for listing because it is predictive of reduced 1-year survival. Other noninvasive predictive models include the heart failure survival score, which incorporates peak oxygen consumption, or the Seattle Heart Failure model.[9, 10]

Patients with pulmonary hypertension are at increased risk for right heart failure following transplant because the unconditioned donor right ventricle (RV)

may struggle and fail in the face of increased afterload. Generally speaking, a pulmonary vascular resistance (PVR) of greater than 6 Wood Units or greater than 3 Wood Units following vasodilator testing with nitroprusside is considered a contraindication to transplantation. Long-term treatment with an inodilator, such as milrinone, or a ventricular assist device may help reduce PVR to safely allow transplantation. When PVR remains fixed, heart–lung transplantation may be considered. A summary of our transplant listing algorithm can be found in **Figure 18.1**.

Proposed Listing Algorithm



Hemodynamic instability despite high-dose inotropic therapy +/– intra-aortic balloon pump

Predictably prolonged waiting time in a tenuous 1A

FIGURE 18.1 The approach to evaluating patients for heart transplantation begins with referral to an advanced heart failure program. Reversible factors are corrected and medications are optimized. Persistently symptomatic patients will be risk stratified with a cardiopulmonary stress test and multivariable risk scores. Those with predicted high 1-year mortality will be formally evaluated, a process that includes right heart catheterization to screen for fixed pulmonary hypertension. Acceptable candidates will be listed for transplant and further stratified as 1A if they require intensive care hospitalization, 1B if they require continuous inotrope infusion, or II if they are otherwise stable.

The presence of alloantibodies increases the risk of experiencing either acute or chronic rejection. All potential recipients are screened against a panel of reactive antibodies (PRA). It is our practice to perform a donor-specific prospective crossmatch for all recipients with a PRA greater than 10% to reduce the chance of developing acute or hyperacute rejection. This step reduces the risk of allograft loss, but, because of the mechanics of performing the test, effectively reduces the donor pool. Further steps to minimize the risk of humoral sensitization include limiting blood product transfusion while awaiting transplantation. Patients who are more likely to have elevated levels of alloantibodies include postpartum women and prior recipients of organ transplants. A program of desensitization can be performed in patients whose PRA remains elevated. Both plasmapheresis and infusions of immunomodulatory drugs, such as intravenous gamma globulin (IVIG) and rituximab, have been employed with varying degrees of success.[11]

Obese patients experience a greater number of complications following cardiac surgery, including prolonged ventilatory times, renal failure, and wound infection.[12] The presence of obesity in heart transplant recipients is associated with poorer survival compared with nonobese patients. A body mass index (BMI) greater than 35 is considered a relative contraindication to transplantation at our center, and all patients are encouraged to reduce their BMI to less than 30 to improve their odds of long-term survival.

Other contraindications to heart transplantation include any psychological or social barrier that would preclude one’s ability to reliably comply with medical therapy and follow-up examinations. Active drug, alcohol, or tobacco use excludes consideration for transplantation. Nicotine blood levels, as well as blood alcohol levels and urine toxicology screens, can be used to test for compliance. Decisions about the severity of a patient’s substance dependency are generally made as part of a general evaluation of all patients by a psychiatrist. Social support is critical for the patient posttransplantation given the physical and psychosocial stressors encountered.

It is recommended that patients on the waiting list be formally reevaluated every 6 months to ensure that they still fulfill the necessary listing criteria. Occasionally, a patient's clinical condition will improve as a result of medical or device therapy. Those patients with significant improvement in cardiac function and symptoms should be considered for removal from the waiting list.

DONOR SELECTION

Following the establishment of brain death, organs are offered for transplantation by local organ donor networks following the rules established by the United Network for Organ Sharing. Because the specific criteria used to accept donor organs remain variable between transplant centers, a recent consensus statement provided recommendations to improve the evaluation and successful utilization of potential cardiac donors.[13] In general, donors should be younger than 50 years old, but older donors may be considered for extended criteria recipients. Donors with significant chest wall trauma are excluded from transplantation, although short periods of cardiopulmonary resuscitation or isolated rib fractures are acceptable. To ensure that the heart is of a sufficient size to match the recipient's needs, a donor's weight should not be less than 80% of that of the recipient, and the donor should be no more than 6 inches smaller than the recipient. Some believe that a male donor whose height exceeds 66 inches is sufficient for all recipients regardless of their height. Donors should be free of malignancy and should have negative blood and sputum cultures to reduce the risk of bacterial transmission. Donors with HIV or active hepatitis B infection are excluded from consideration. Although in the past donors with serologic evidence of hepatitis C infection have been used in some centers, a recent study called this practice into question. Gasink et al investigated the impact of transplanted hearts from hepatitis C seropositive patients into seronegative recipients.[14] One-, five- and ten-year mortality rates were significantly higher in those patients who received organs from seropositive donors. Donors who are seronegative for hepatitis B surface antigen but seropositive for the core antibody may be acceptable donors. When these hearts are used, recipients should receive prophylactic treatment with lamivudine and hepatitis B immune globulin to further reduce the risk of viral transmission. All patients should be offered hepatitis B vaccination while awaiting transplantation.[15] Patients infected with HIV or HTLV (Human T-lymphotropic Virus) are not acceptable donors.

To assess the heart's suitability for donation, one typically performs an electrocardiogram (ECG), echocardiogram, and, on occasion, coronary angiography. Cardiac enzymes may be minimally elevated in the setting of brain death because of the occurrence of myocardial contraction band necrosis. Markedly elevated levels of the MB fraction of creatine phosphokinase or troponin-I are more consistent with myocardial injury or infarction.

Echocardiography is particularly useful for evaluating cardiac structure and function. Left ventricular hypertrophy with a septal or posterior wall thickness greater than 13 mm is frequently a contraindication to donation because of the difficulty in preserving such a thickened myocardium. A significantly reduced ejection fraction or regional wall motion abnormalities suggestive of infarction will similarly exclude donation, as will severe regurgitant or stenotic valvular lesions.

Coronary angiography is recommended for male donors over 45 and females over 55 as well as younger patients with significant atherosclerotic risk factors. The use of computed tomography (CT) angiography in lieu of percutaneous angiography may be considered in those centers unable to provide coronary angiography. The presence of coronary disease can also be assessed by palpation of the coronary arteries at the time of harvesting. Inspection should include evaluation of significant valvular disease and the presence of congenital lesions or a large patent foramen ovale (PFO). Such PFOs are generally sutured closed at the time of transplantation to prevent paradoxical embolization. A summary of absolute and relative contraindications to donation can be found in **Table 18.1**.

TABLE 18.1 Absolute and Relative Contraindications to Donor Heart Selection

ABSOLUTE CONTRAINDICATIONS
Organ transport time > 4 h
Confirmed myocardial infarction with systolic dysfunction
LVEF < 30%
Severe valvular disease not amenable to repair
Active infection with transmissible pathogens including, but not limited to, HIV hepatitis B (HBSAg +) or C virus, or highly resistant bacteria
Bacterial endocarditis
A history of major extracranial or metastatic malignancy
Age > 65 years
Significant penetrating cardiac trauma
RELATIVE CONTRAINDICATIONS
Donor–recipient height mismatch > 6 inches
Age 50–65 years
Male donors > 45 years and female donors > 50 years with cardiovascular risk factors and an inability to perform coronary angiography

Previous high-risk behavior including intravenous drug use or risky sexual activity
Donor instability manifested by hypoxia, severe acidosis with pH < 7.2, hypotension requiring high-dose vasoconstrictors
Organ transport time 3–4 hours

LVEF, left ventricular ejection fraction.

PATIENT MANAGEMENT

The patient with a newly transplanted heart faces a number of physiologic challenges. Without having time to recover from cold ischemia and facing reperfusion injury, the denervated heart is expected to function fully and provide an adequate cardiac output as soon as possible after being weaned from cardiopulmonary bypass. The loss of sympathetic innervation makes the allograft dependent on circulating catecholamines in order to sustain cardiac output. Infusions of positive inotropic medicines, such as dobutamine or milrinone, are always given in sufficient quantity to assist the heart in providing an adequate cardiac output. This obligatorily requires continuous patient monitoring with arterial lines and a pulmonary artery catheter in an intensive care unit. Vasoconstrictors such as arginine vasopressin (AVP) and norepinephrine may be temporarily employed to counter the vasoplegia that often occurs after cardiopulmonary bypass in advanced heart failure patients. Because of their deleterious effects on the microcirculation, vasoconstrictors should be weaned and discontinued at the earliest possible time. Weaning of positive inotropic medicines generally begins 48 hours after transplantation after allowing the sinus node to recover from cold ischemia, and for the RV to accommodate itself to the increased afterload in those patients with preexisting pulmonary hypertension. Transfer out of the intensive care unit to a floor with continuous telemetry monitoring commonly occurs before weaning is completed.

Vasodilatory hypotension is commonly encountered postoperatively. The mechanism for this may be related to the pretransplant use of vasodilatory drugs, such as angiotensin converting enzyme inhibitors, and inodilators such as milrinone. Other suspected factors include a systemic inflammatory response to prolonged cardiopulmonary bypass and a reported depletion of AVP that occurs as consequence of long-standing advanced heart failure. Although vasoconstrictors such as norepinephrine have generally been used to treat vasodilatory hypotension, synthetic AVP may be more effective in this patient

population because it does not constrict pulmonary arteries or compromise renal function.

Renal dysfunction is a common posttransplant occurrence and contributes to both a prolonged hospital stay and increased risk of mortality. Postoperative renal failure is usually a consequence of ischemic injury that results from diminished renal perfusion during cardiopulmonary bypass, perioperative hypotension, and perhaps from embolization from an atherosclerotic aorta. Its presence not only contributes to the volume-overloaded state, but may also delay the initiation of immunosuppressive therapy, particularly the use of calcineurin inhibitors. Temporarily withholding the calcineurin inhibitor may allow time for renal function to improve.[16] When patients with reduced urine output are unable to match their obligatory inputs, such as blood products and intravenous medications, diuretics may be used. Frequently, oliguric renal failure will require mechanical renal replacement therapy. When clearance is not required, aquapheresis (Aquadex FlexFlow System, Sunshine Heart Inc., Eden Prairie, MN) may be employed. Slow, low efficiency dialysis or continuous veno-venous hemofiltration (CVVH) allows for removal of large volumes of fluid, provides clearance, and may facilitate renal recovery. Rarely, patients will develop fulminant renal failure postoperatively. These patients are typically patients with preexisting chronic kidney disease. Such patients may be managed with dialysis, but in consideration of poor long-term outcomes, renal transplantation is preferred.[17, 18]

Right heart failure is common in the posttransplant patient. Reasons for its occurrence include ischemia–reperfusion injury, preexisting pulmonary hypertension, and volume overload from infusion of intravenous fluids. Multiple blood product infusions, including packed red blood cells and fresh frozen plasma, may further volume load an already distended RV. In the face of this additional preload, ventricular function may deteriorate. A rising central venous pressure (CVP) in the setting of systemic hypotension will compromise myocardial perfusion and lead to ventricular ischemia with contractile dysfunction. Release of cytokines such as thromboxane from transfused platelets may further increase pulmonary arteriolar pressure and place additional afterload on a straining RV. Furthermore, transplantation of a smaller donor heart into a larger recipient predisposes to RV dysfunction more than to left ventricle (LV) dysfunction. RV failure should be suspected when CVP rises and cardiac output falls. Transthoracic echocardiography may not offer adequate RV visualization in postoperative patients because of an inability to obtain sufficient

echocardiographic windows or position the patient properly; thus, transesophageal echocardiography is preferred in endotracheally intubated patients.

Treatment is directed at improving the loading conditions for the RV while providing adequate inotropic support to maintain circulation. Aggressive diuresis to achieve a CVP of 12 to 15 mm Hg will lower RV preload and may help to reduce tricuspid regurgitation. When patients are diuretic resistant or in overt renal failure, or simply need large volumes of fluid removed quickly, aquapheresis or CVVH is indicated. Inhaled nitric oxide will reduce RV afterload by dilating pulmonary arteries. Nitric oxide also improves oxygenation and V/Q matching. When patients require positive inotropic support for a prolonged period of time, milrinone is preferred over dobutamine, because of its superior ability to dilate the pulmonary vasculature. Mechanical support, using a right ventricular assist device, may be necessary for some patients as a means of providing longer-term support. The ventricular assist device can be slowly weaned over a period of days or weeks as right heart function improves.

Bradyarrhythmias are frequently encountered, but their incidence has decreased with the use of bicaval anastamoses, which tend to spare the sinus node. Given that resting heart rate of a denervated heart is between 90 and 120 beats per minute (bpm), rates lower than this may be a result of sinus node dysfunction, ischemia, or preoperative use of amiodarone. Both isoproterenol and aminophylline were widely used in the past to elevate resting heart rate, but nowadays electronic pacing through temporary wires is preferred. Temporary pacing wires should remain in place long enough to ensure that sinus node function has adequately recovered. Temporary pacing can be considered for patients whose heart rates are below 90 bpm, especially if the patient has evidence of low cardiac output. Permanent pacemakers are reserved for patients with persistent sinus or atrioventricular nodal dysfunction.

Although infrequently encountered, tachyarrhythmias are usually a sign of an injured allograft. Atrial fibrillation is commonly seen in cardiac surgery, but less so following heart transplantation. This is believed to be a result of the left atrial anastamosis, which effectively isolates the pulmonary veins and prevents atrial fibrillation. When present, atrial arrhythmias are a sign of either ischemic injury or early rejection. Ventricular arrhythmias are also rare, but are generally not a sign of rejection but of myocardial ischemia or infarction. Congenital arrhythmias in the donor heart, such as Wolf Parkinson White syndrome, are occasionally seen and can be treated with catheter ablation.

ACUTE ALLOGRAFT DYSFUNCTION

Acute allograft dysfunction remains one of the most common causes of early posttransplant death. It occurs in up to 5% of transplants and has multiple etiologies. These include ischemia–reperfusion injury, poor preservation, and unrecognized or underappreciated predonation dysfunction. Both prolonged ischemia and the use of high-dose catecholamine infusions predispose to allograft dysfunction, perhaps by depleting myocardial energy stores. Hyperacute rejection, which occurs because of the presence of preformed antibodies to human leukocyte antigens, is now rarely seen because of the routine use of PRA screening. The struggling allograft can usually be adequately supported with infusions of epinephrine, dobutamine, or milrinone. More severe degrees of dysfunction require mechanical support with the use of intra-aortic balloon counterpulsation, or the placement of ventricular assist devices to rest the allograft and provide adequate organ perfusion. Patients who can be weaned successfully from the device have a survival rate similar to that of the general transplant population. Although urgent repeat transplantation is an option for these patients, the presence of multiorgan dysfunction often limits their candidacy. Causes of death in the posttransplant period are listed in **Table 18.2**.

TABLE 18.2 Causes of Death in the Posttransplant Period

Cardiac allograft vasculopathy	54 (1.7%)
Acute rejection	208 (6.5%)
Lymphoma	2 (0.1%)
Malignancy, other	2 (0.1%)
CMV	4 (0.1%)
Infection, non-CMV	414 (12.9%)
Primary graft failure	831 (26.0%)
Graft failure	445 (13.9%)
Technical	237 (7.4%)
Other	213 (6.7%)
Multiple organ failure	431 (13.5%)

Renal failure	18 (0.6%)
Pulmonary	134 (4.2%)
Cerebrovascular	205 (6.4%)

CMV, cytomegalovirus.

IMMUNOSUPPRESSION

Prior to the routine use of cyclosporine (CyA) in the early 1980s, heart transplantation survival was so poor that many physicians called for a moratorium on the procedure. Although advances in immunosuppression have improved outcomes dramatically, allograft rejection still accounts for 6.5% of early deaths following transplantation. Typical maintenance immunosuppression in the current era consists of a calcineurin inhibitor in combination with an antimetabolite and corticosteroids.

The use of induction immunosuppression, although once routine, has lately been called into question. It was thought that by passivating the immune system through the use of either monoclonal or polyclonal antibodies, induction therapy allowed time for the allograft to recover function without facing the threat of rejection. This period of induction also allowed for postoperative recovery of renal function prior to the initiation of a calcineurin inhibitor with its attendant risk of nephrotoxicity. In retrospect, this approach was limited by the fact that induction therapy induced T-cell anergy, but not clonal depletion. In effect, moderate-to-severe rejection was not prevented, but only delayed by 6 to 12 months. Nonetheless, upward of half of all transplant centers continue to use induction immunosuppression, although use of OKT3 and polyclonal antibodies, such as thymoglobulin, has declined, whereas use of selective interleukin-2 (IL-2) receptor antibodies has increased. The IL-2 receptor blocker basiliximab has been shown to reduce both the severity and the frequency of cardiac rejection as well as increase the time to a first rejection episode. Its use is not associated with the cytokine release syndrome or the significant side effects associated with OKT3.[19]

Cell cycle antagonists, either aziothioprine or mycophenelate mofetil (MMF), are started intraoperatively or on postoperative day one. Both drugs work by inhibiting the de novo pathway of purine synthesis, a step crucial to cellular proliferation. Because leukocytes and lymphocytes lack the salvage pathway,

these drugs particularly inhibit their proliferation. Azathioprine produces a greater degree of bone marrow suppression than does MMF. It is given as a single dose of 1.5 to 5 mg/kg adjusted for white blood cell and liver function. Azathioprine is metabolized by thiopurine methyltransferase (TPMT) in vivo. Small proportions of patients have very low levels of TPMT (roughly 0.3% of the general population) and are at greater risk of experiencing myelosuppresion.

Following the results of a large multicenter randomized clinical trial showing its benefits over azathioprine, MMF has become the preferred antiproliferative agent at most transplant centers.[20] Patients receiving MMF experienced fewer episodes of hemodynamically significant rejection and enjoyed a higher survival rate at the first year of follow-up, as well as a trend toward a lesser incidence of severe rejection. Opportunistic infections were seen more commonly in patients receiving MMF, but most of these resulted from either HSV or herpes zoster and were not life threatening. MMF is given as a fixed dose of 1500 mg twice daily for patients with preserved renal function. Lower doses of 500 to 1000 mg bid are used for patients with estimated creatinine clearance of less than 50 mL/kg/min. The dose of MMF may need to be reduced in the setting of gastrointestinal upset or leucopenia. Blood levels of mycophenolate and its metabolite can be measured, but are not available at all centers.

Inhibition of the calcineurin pathway is the cornerstone of solid organ transplantation. The introduction of the first calcineurin inhibitor, CyA, in 1983 revolutionized solid organ transplantation, essentially doubling the 1 and 5-year survival rates. They work by inhibiting calcineurin, a calcium calmodulin–dependent phosphatase that activates transcription factors responsible for transcription of IL-2. Calcineurin inhibition prevents both IL-2 transcription and T-lymphocyte activation.

CyA is a cyclic decapeptide that is derived from the fungus *Trichoderma polysporin*. Its major immunosuppressive effect is to inhibit the production of IL-2 and other cytokines by activated lymphocytes. CyA binds to cyclophilin in the cytoplasm of T-lymphocytes, and this complex then binds to and inhibits calcineurin, ultimately preventing transcription of IL-2. CyA affects T-helper and cytotoxic T-cells but has little or no effect on suppressor T-cells. The drug is metabolized by cytochrome P450 3A4, located in the liver and along the gastrointestinal tract. Approximately 5% to 10% of the parent compound is excreted unchanged in the urine. CyA has a half-life of 19 hours. Different formulations of CyA are supplied for both intravenous and oral administration. When given intravenously, CyA is mixed in a 1:1 concentration in either normal

saline or 5% dextrose and infused continuously. CyA (Sandimmune, Novartis, East Hanover, NJ) for oral use is provided in liquid (100 mg/mL) and capsule form and is administered 2 or 3 times daily. Neoral (Novartis, East Hanover, NJ) is a microemulsion formulation of CyA that has improved absorption and bioavailability and is given in two daily doses. CyA can be given as a continuous infusion immediately after transplant or delayed for 24 to 48 hours until it can be given enterally. A typical continuous infusion begins at 0.5 to 1.0 mg/h and is adjusted accordingly. When converting to oral CyA, approximately 3 times the total daily intravenous dose is given. In the early posttransplant period, CyA is administered to achieve a trough whole blood level of 300 to 350 ng/mL. Target levels decrease with time as rejection risk begins to wane. Typical target levels are 250 to 350 in the first 6 months, 150 to 250 in months 6 to 12, and 100 to 150 long-term. Side effects include nephrotoxicity, hypertension, hypertrichosis, gingival hyperplasia, tremor, and seizures. Serum levels of CyA are affected by many medications. Those that elevate levels are drugs that inhibit its metabolism through the cytochrome P450 system, such as erythromycin, fluconazole, and amiodarone and the antihypertensive diltiazem.

Tacrolimus (Prograf, also known as FK-506) is a macrolide antibiotic derived from the bacteria Streptomyces tsukubaensis. It has now become the preferred drug at many transplant centers. The major advantage of tacrolimus over CyA is the lesser degree of hypertension and hyperlipidemia. Some prescribers prefer its use in women for cosmetic reasons, because it produces less hirsutism and gingival hyperplasia than CyA. After binding with FKBP-12 (also referred to as the FK506 binding protein), tacrolimus inhibits calcineurin. Although its mechanism of activation is similar to that of CyA, it is much more potent but appears to produce less nephrotoxicity. Other side effects include seizures, insomnia, tremor, and hypertension. Tacrolimus is also associated with an increased risk of hyperglycemia, although whether the long-term incidence of diabetes is increased remains controversial. Tacrolimus can be administered either orally or intravenously. When given intravenously, an initial dose of 0.01 to 0.05 mg/kg/d is infused continuously and adjusted to achieve a level of around 12 to 15 ng/mL. When given enterally, a 1 mg dose test of tacrolimus is given to all patients because clearance of the drug may vary significantly between patients. Typical trough target levels are 10 to 15 ng/mL in the first 2 months, 8 to 12 ng/mL for the next 3 to 6 months, and 5 to 10 ng/mL thereafter.

Rapamycin (Rapamune) and everolimus (Zortress, Certican) are reserved for patients with transplant vasculopathy. When initiating these proliferation signal

inhibitors, one should discontinue antiproliferative drugs such as MMF or azathioprine. Doses of tacrolimus should be reduced to achieve trough levels of approximately 4 to 6 ng/mL. An initial rapamycin dose of 6 mg is given 6 hours after tacrolimus and is followed by a daily dose of 2 mg. This daily dose should be adjusted to achieve rapamycin levels of approximately 10 ng/mL in the first year of transplant and between 5 and 10 ng/mL thereafter.

Corticosteroids are the third class of medications used for maintenance immunosuppression. Intravenous methylprednisolone is given preoperatively and switched to prednisone once the patient can tolerate oral agents. Prednisone dosing is tapered down during the first several months of transplant. Corticosteroids have numerous troublesome side effects: they worsen glycemic control, increase serum lipids, and stimulate appetite, leading to obesity. They have profound effects on bone absorption, producing osteoporosis and a susceptibility to fracture. Avascular necrosis of the hips and shoulders from steroid use necessitates joint replacement surgery in some patients. Other debilitating side effects include cataract formation, colonic perforation, and, especially with higher doses, mood disorders such as psychosis. Motivated to limit these toxicities, many centers attempt to wean patients entirely off corticosteroids after 6 to 12 months.[21] The optimal timing of complete steroid withdrawal has yet to be determined, and the majority of patients remain on steroids indefinitely.

REJECTION SURVEILLANCE

Endomyocardial biopsy remains the gold standard for the diagnosis rejection. Biopsies are taken from the RV via the transvenous approach **(Figure 18.2)**. At the time of each biopsy, four to five samples are taken and graded using the 2004 revised ISHLT system. Both the revised and standard system, published in 1990, are summarized in **Table 18.3**. Biopsies are performed at a frequency that matches the time-dependent risk of rejection. A typical schedule would require biopsies on a weekly basis for the first month, then on a biweekly basis for the second and third months, and on a monthly basis for the fourth through sixth months, with the frequency diminishing thereafter. Routine performance of endomyocardial biopsy after the fifth transplant year is no longer required. Biopsies should be performed anytime rejection is suspected.

TABLE 18.3 **Standardized ISHLT Cardiac Biopsy Grading Scales**

(2005 Revised Version in Comparison with 1990 Version)			
1990 SCALE		**2005 SCALE**	
Grade	***Description***	***Grade***	***Description***
0	No rejection	0	No rejection
1A	Focal perivascular or interstitial infiltrate without necrosis	1R	Interstitial and/or perivascular infiltrate with up to 1 focus of myocyte damage
1B	Diffuse but sparse infiltrate without necrosis	2R	Two or more foci of infiltrate with associated myocyte damage
2	One focus only with aggressive infiltration and/or focal myocyte damage	3R	Diffuse infiltrate with multifocal myocyte damage, edema, hemorrhage, vasculitis
3A	Multifocal aggressive infiltrates and/or myocyte damage		
3B	Diffuse inflammatory process with necrosis		
4	Diffuse aggressive polymorphous infiltrate, with or without edema, hemorrhage or vasculitis; with necrosis		

ISHLT, The International Society for Heart and Lung Transplantation.

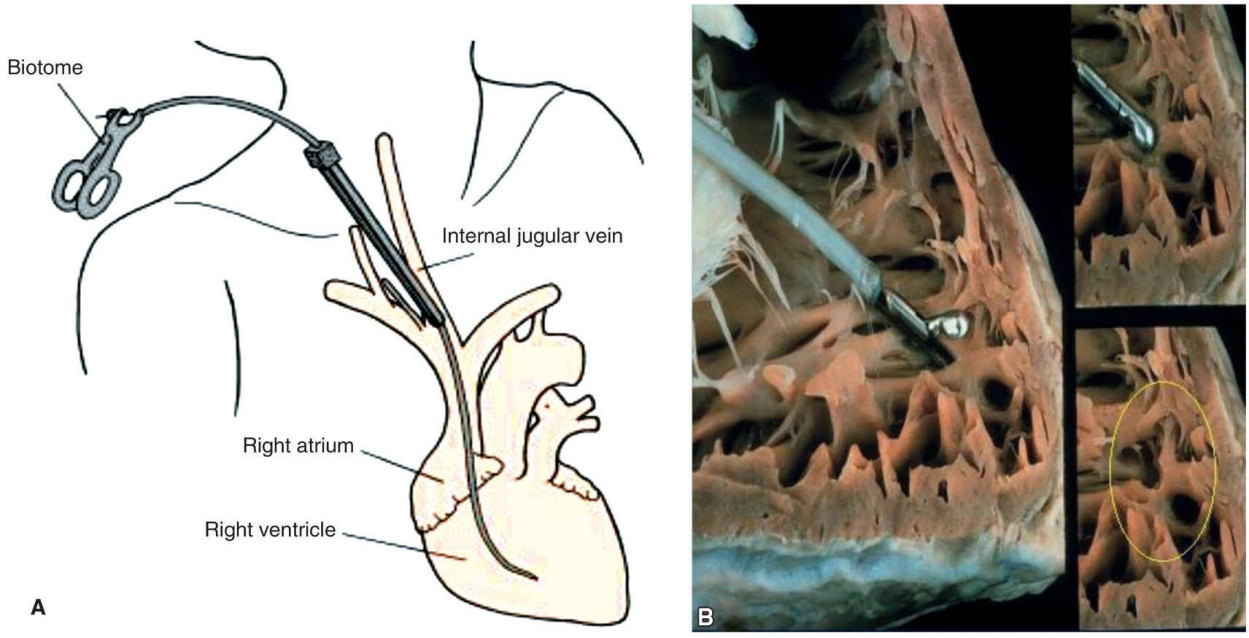

FIGURE 18.2 Endomyocardial biopsy is performed under fluoroscopic guidance. A bioptome is advanced through the jugular vein and directed across the tricuspid valve into the right ventricle and positioned against the interventricular septum (A). After the bioptome is closed and withdrawn, a small defect remains within the myocardium (B). During a typical biopsy session, four to six pieces of myocardium will be sampled and sent to pathology for review.

Symptoms of rejection are often absent, but can be insidious when present. They may include malaise or generalized fatigue, symptoms of heart failure (shortness of breath, peripheral edema), and palpitations. Arrhythmias, such as atrial fibrillation, may be present. Biopsy should be promptly arranged for in any

patient in whom rejection is suspected. Assessment of ventricular dysfunction should be performed using either echocardiography or magnetic resonance imaging. Depending on the degree of suspicion for rejection, empiric therapy may need to be given while awaiting endomyocardial biopsy results. A typical biopsy schedule is shown in **Table 18.4**.

TABLE 18.4 Typical Endomyocardial Biopsy Schedule for Rejection Surveillance

TIME POSTTRANSPLANT	FREQUENCY
1 month	Weekly
2 months	Biweekly
3–6 months	Monthly
7–12 months	Every 2 months
12–18 months	Every 3 months
>18 months	Every 6–12 months

Recent work suggests that detection of cellular rejection may be possible using less invasive methods. The Cargo Study evaluated the gene expression profile of peripheral blood mononuclear cells obtained from patients a minimum of one year after transplantation. Using this profile, a scoring system was created that could exclude the presence of ≥ ISHLT 2R (previously 3A) rejection with a negative predictive value of 99.6%. The system is currently approved for clinical use, and studies are ongoing to predict whether the test is useful in patients during the first year posttransplant.[22]

TREATMENT OF CELLULAR REJECTION

Strategies for the treatment of rejection differ significantly from center to center. Factors influencing one's decision to treat include grade of rejection, impact on cardiac function (as determined by echocardiogram and/or right heart catheterization), and time from transplantation. At our center, patients are treated as follows: Grade 0 and Grade 1R (previous grades 1A, 1B, and 2) biopsies do not require treatment in the absence of symptoms or abnormal hemodynamics. Care is taken to ensure that doses and levels of immunosuppressive medications are at their therapeutic targets. Patients with symptomatic rejection are treated with corticosteroids. Grade 2R (previous grade 3A) rejection may be treated with a short pulse of oral steroids, for example, prednisone 50 mg bid, if occurring more than 3 months posttransplant. Patients with grade 2R rejection that are

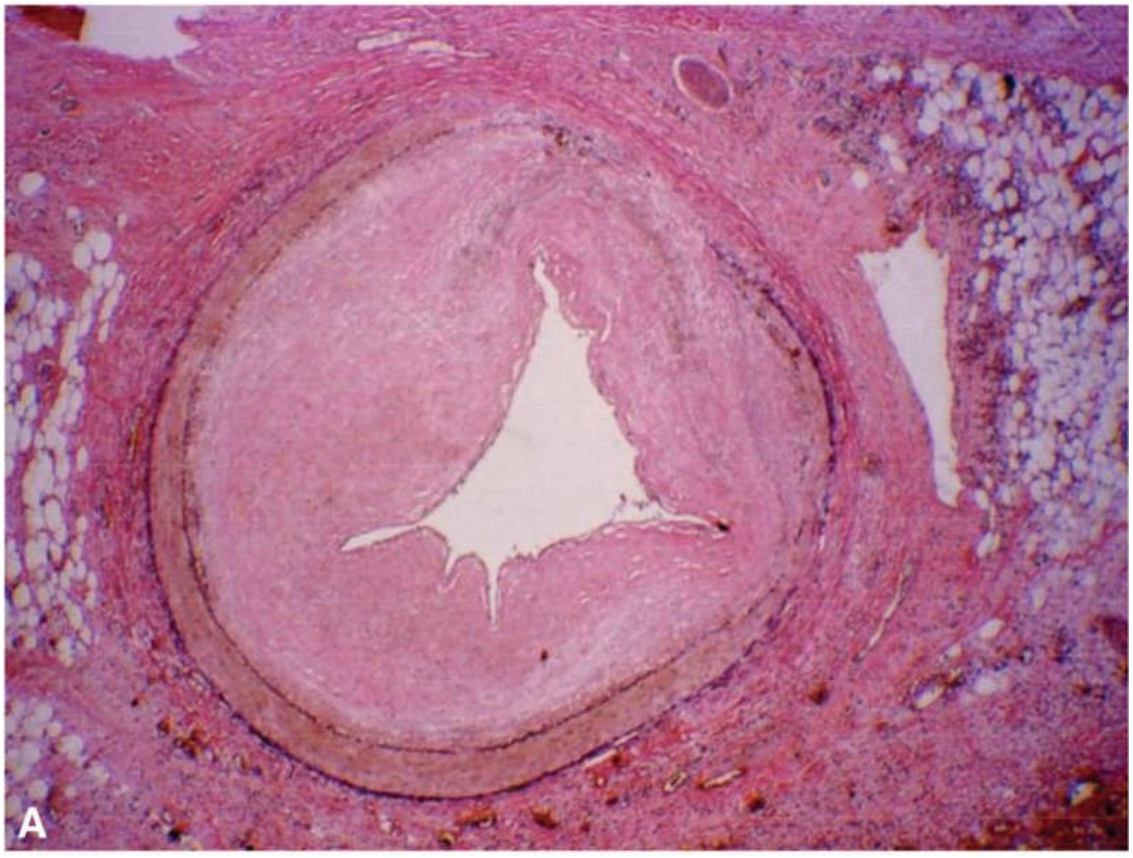
symptomatic or have hemodynamic consequences of rejection, as well as those patients less than 3 months posttransplant, are treated with intravenous methylprednisolone (1000 mg/d for 3 days) followed by a prednisone taper. Repeat biopsy is typically performed in 2 weeks. Hemodynamically severe rejection occurs in fewer than 5% of patients, but requires inpatient admission and treatment with cytolytic therapy consisting of thymoglobulin. Inpatient admission and hemodynamic monitoring are essential because patients are at risk of rapidly progressing cardiac failure and circulatory collapse.

HUMORAL REJECTION

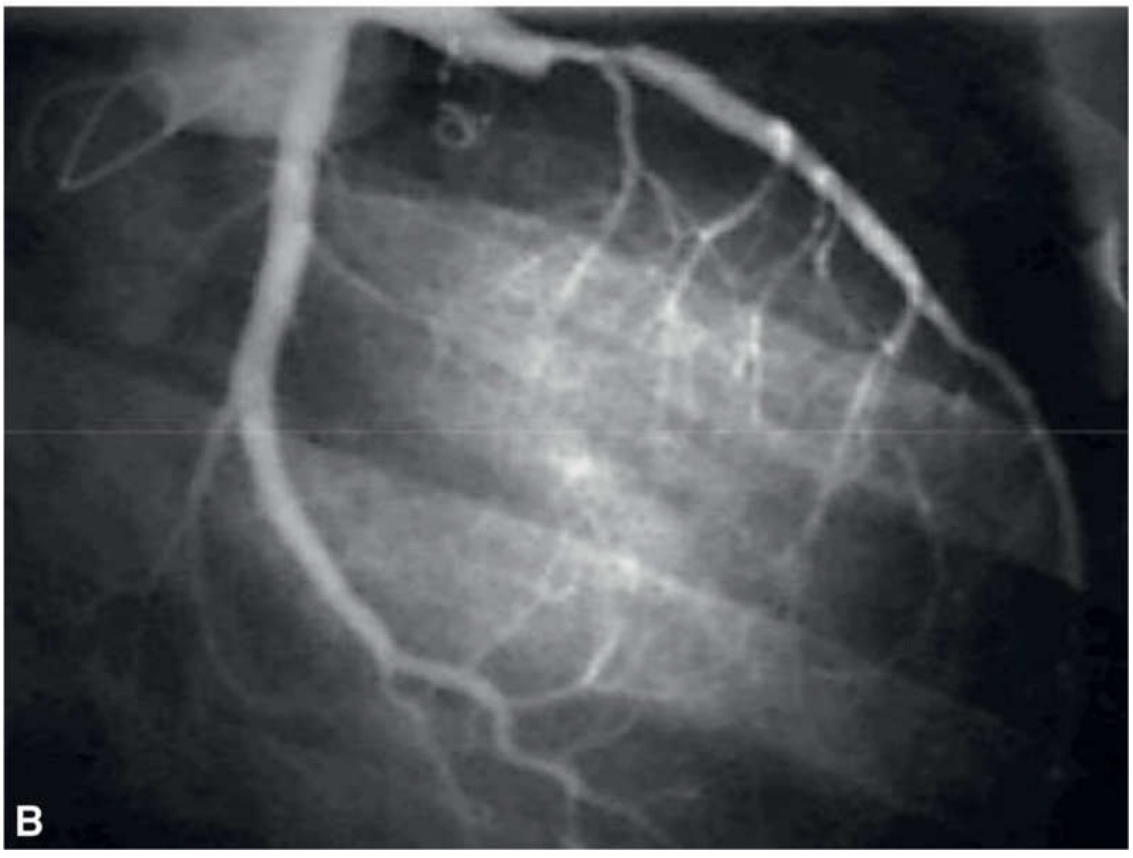
Humoral rejection is a B-cell mediated process in which alloantibodies attach to major histocompatibility complex class I or II antigens usually in a perivascular pattern. It can present in a variety of ways, from an insidious process to fulminant hyperacute rejection. Its diagnosis is confirmed with either immunofluorescence or immunoperoxidase staining for the complement degradation products C4D or C3D. When the latter is used, a positive stain must be present in the setting of symptoms or other signs of rejection such as abnormal hemodynamics or left ventricular dysfunction to complete the diagnosis. Risk factors for its development include having an elevated pretransplant PRA, the development of specific antidonor antibodies, or the preoperative use of a left ventricular assist device. Treatment of humoral rejection is targeted at three distinct processes: clearance or neutralization of circulating antibodies, eradication of plasma cells, and prevention of sensitized B-cells transforming into plasma cells. Plasmapheresis with plasma exchange can quickly remove circulating alloantibodies and allow graft function to recover.[23] Up to 40% of circulating immunoglobulin G may not be cleared by plasmapheresis, but may be neutralized by administering IVIG. We typically prefer a sucrose-free preparation in order to avoid nephrotoxicity. Intravenous cyclophosphamide (0.5 to 1.0 g/m^2) may be given following plasmapheresis to eliminate alloantibody-producing plasma cells. More recently, the anti-CD20 monoclonal antibody rituximab (Genentech, San Francisco, CA), a chimeric humanized antibody directed against the pan–B-cell surface molecule CD20, has been used as the third component of therapy. It targets sensitized B-cells and interferes with their ability to transform into antibody-producing plasma cells. Ultimately, rituximab may provide long-term benefit by eliminating “memory” B cells and preventing the adverse late sequelae of humoral rejection.

CARDIAC ALLOGRAFT VASCULOPATHY

Cardiac allograft vasculopathy (CAV) is a diffuse arteriosclerosis that remains one of the most common long-term complications of cardiac transplantation. CAV resembles the arteriopathy of restenosis following balloon angioplasty **(Figure 18.3)**. Both processes represent an abnormal response to vessel injury. In the case of CAV, both immunologic and nonimmunologic arterial injury contributes to its development. The arteriopathy comprises both intimal proliferation and negative remodeling of the external elastic lamina. Because it produces concentric rather than eccentric luminal stenoses, the presence of CAV is often underestimated, but its prevalence may be as high as 55% by the third posttransplant year.[24] The presence of CAV limits the long-term success of cardiac transplantation. In a multicenter study of 2609 heart transplantation recipients, 42% had angiographic evidence of graft vasculopathy by 5 years following transplantation.[25] Up to 7% of transplant recipients will die or require repeat transplantation because of CAV.



A



B

FIGURE 18.3 Cardiac allograft vasculopathy (CAV) is a proliferative disorder that typically arises in the branches and distal vessels in response to both immunologic and nonimmunologic forms of injury. A cross section of an artery affected by CAV shows near obliteration of the lumen (A). Coronary angiography remains the most common modality to diagnose CAV. Typical pruning of the branch and distal vessels (B).

The development of CAV is an insidious process. Because the transplanted heart is denervated, patients will rarely, if ever, present with angina. Instead, they may experience atypical exertional symptoms, such as malaise or generalized discomfort, or, when allograft dysfunction is pronounced, symptoms of heart failure. Frequently, CAV remains asymptomatic, and therefore yearly screening is encouraged. Coronary angiography is the accepted method of assessing CAV. For those patients whose baseline angiogram is free of disease, angiography can be performed on an alternate year basis. In the intervening years, noninvasive imaging with either positron emission tomography or dobutamine echocardiography is acceptable. For those patients in whom CAV is detected, yearly angiography should be performed to track its progression. More recently, CT angiography has been employed for routine detection of CAV, avoiding the need for invasive angiography.[26]

Effective prevention of CAV includes the use of aspirin and HMG-CoA reductase inhibitors (statins). Pravachol is preferred because it is not metabolized by CYP 3A4, but other statins are equally effective in preventing CAV. Unfortunately, treatment options remain limited. Target of rapamycin inhibitors, such as sirolimus and evorolimus, have been shown to slow, and in some cases prevent, the progression of vasculopathy.[27] Revascularization with either coronary stenting or bypass surgery is frequently not an option because secondary and tertiary branches of the coronary arteries are often involved, reducing “downstream” blood flow. Intracoronary stenting may be an option for treating focal symptomatic lesions. Rates of restenosis are higher for CAV than for typical atherosclerotic lesions. The use of drug-eluting stents produces lower restenosis rates as compared to bare metal stents, but both have rates that are higher than those seen in nontransplant patients. For severe disease, retransplantation remains the only definitive treatment option.

ANTIMICROBIAL PROPHYLAXIS AND TREATMENT

Transplanted patients are at risk for infection from both common and opportunistic pathogens. Typical signs of infection may be less prominent in the setting of immune suppression, and fever may be suppressed by the use of

corticosteroids. The prevalence of infection in the early transplant period is 47% for bacterial infections, followed by viral (42%), fungal (8%), and protozoal (4%) infections.[28]

The risk of bacterial infection is particularly high during the immediate postoperative period and slowly abates over a 6-month period. Antibiotic prophylaxis to prevent surgical wound infection using an agent against gram-positive cocci (ie, cefazolin or vancomycin) is routinely used in all patients. Contact isolation with the use of gowns and gloves is recommended to prevent nosocomial infection. Respiratory isolation is not required for patients, but hand washing before and after patient contact is encouraged, as is the early removal of support lines and tubes. Visitors are certainly allowed, but they should also perform hand washing. Patients should not be exposed to fresh cut flowers and should handle fruit and vegetables only after they have been thoroughly cleaned or peeled. The use of a surgical mask may help prevent airborne transmission when venturing out of the hospital room.

The risk of fungal infection is greatest during the period of maximal immune suppression and tails off by the sixth postoperative month. The most commonly encountered infection is candidiasis, particularly oral thrush. It is easily prevented with nystatin swish and swallow or mycelex troches. Deep tissue infections require more aggressive treatment with systemic antimicrobial drugs such as fluconazole. Pneumocystis carinii is an opportunistic fungal pathogen that classically presents as an interstitial pneumonia producing cough and hypoxemia, particularly with exertion. Prophylaxis with trimethaprim/sulfamethoxazole is given throughout the first year to prevent fulminant infection. Dapsone or atovaqoune can be used as a substitute in the sulfa allergic patient. Other fungal pathogens like aspergillus or cryptococcus can produce life-threatening infections. Therapy for these more severe infections requires aggressive care with intravenous azole therapy or amphotericin.

The risk of protozoal infection peaks at month 3 and dissipates over the first year. All transplant donors and recipients should be tested for exposure to toxoplasmosis gondii. Seronegative recipients from a positive donor should receive pyrimethamine prophylaxis or high-dose trimethoprim/sulfamethoxazole for 6 weeks. Folinic acid is given concomitantly to prevent pyrimethamine hepatotoxicity. As more patients from endemic areas receive transplants, it is incumbent on the transplant team to consider reactivation of a broad spectrum of pathogens. These include strongyloides hyperinfection in those patients who lived for a time in Puerto Rico or the Dominican Republic. Reactivation of

Trypanosoma cruzi may be encountered in patients from South or Central America where Chagas cardiomyopathy is the leading cause of heart failure. Screening for both these pathogens should take place before listing for transplant.

Risk of viral infection, particularly from HSV, CMV, and varicella zoster virus, increases over the first 6 weeks after transplant, but falls by the sixth month coincident with the reduced dose of immunosuppressive therapy. Chronic infection may persist, particularly from viruses such as CMV, HBV, and EBV, and the latter may contribute to the risk of malignancy, particularly posttransplant lymphoproliferative disorder.[4]

Infection with CMV is of particular concern because it can occur from either latent viral reactivation or direct donor transmission. Seronegative patients who receive a heart from a seropositive donor have a 50% risk of developing infection. Symptoms of CMV can vary considerably, including flulike symptoms or a gastrointestinal syndrome with profuse watery diarrhea and elevation of liver transaminases. Leucopenia may be present as a consequence of bone marrow suppression. Other manifestations of CMV include pneumonitis, pancreatitis, retinitis, and encephalitis. Polymerase chain reaction is the most sensitive diagnostic test for the detection of viremeia, but the diagnosis can also be made from identification of virus from tissue biopsy (usually stomach or colon) or from the serum buffy coat.

ADJUVANT THERAPY FOR THE TRANSPLANT PATIENT

Routine treatment of the posttransplant patient with HMG-CoA reductase inhibitors (statins) decreases the incidence of CAV and increases long-term survival. In a landmark 1995 trial, cardiac transplant patients randomized to pravastatin had less rejection and CAV, and improved survival compared to controls.[29] These results were recently reconfirmed in a “real world” analysis of over 1000 transplant patients.[30] It is unclear whether the results are secondary to the anti-inflammatory effects of statins or to their lipid-lowering properties. Aspirin is routinely given to all heart transplant patients. Although data supporting antiplatelet therapy are not as robust as those for the statins, transplant patients are thought to be more likely to have activated platelets. Aspirin prophylaxis may consequently decrease the risk of myocardial infarction.[31, 32]

Concomitant use of corticosteroids and calcineurin inhibitors places the

transplant patient at increased risk for developing osteoporosis. To lower this risk, patients receiving chronic corticosteroid therapy should take a calcium and vitamin D supplement. Patients with dexa scan evidence of either osteopenia or osteoporosis, and any patient considered at increased risk for fracture, are encouraged to take one of the bisphosphanates, such as alendronate or risedronate. Calcitonin may be considered an alternative to the bisphosphonates.[33]

HOSPITAL DISCHARGE

Discharge planning should begin shortly after the patient leaves the intensive care unit. Physical therapy should be initiated as soon as the patient is medically clear to participate. Nutritionists should be consulted to provide education to patients about heart-healthy diets as well as drug–food interactions. Medical regimens are reviewed with the patient and family members. Before being cleared for discharge, patients must be hemodynamically stable without any need for vasoactive medicines, must have an endomyocardial biopsy free of rejection, and must have a therapeutic tacrolimus or CyA drug level. It is our general practice to ensure that patients can successfully recite the names of their immunosuppressive drugs before allowing home discharge. Follow-up appointments in the transplant clinic are generally performed within 1 week of discharge. Patients are instructed to stay near the transplant center for several months should the need for urgent hospitalization arise.

The goal of cardiac transplantation is to both extend life and restore productivity. Unfortunately, less than 30% of transplant recipients return to full-time employment. Although this is partially attributable to the advancing age of the transplant population, other obstacles exist. Patients may be severely deconditioned from their previous heart failure condition, and may require intensive physical therapy to regain full function. Chronic corticosteroid therapy, which produces proximal muscle weakness and central obesity, may contribute to this deconditioning. It is possible that a strategy that employs earlier implantation of bridging left ventricular assist devices will allow sufficient reconditioning prior to transplant to allow for quicker postoperative recovery. The denervated heart also limits full cardiovascular performance, because it produces a slightly diminished maximal cardiac output. This is particularly evident in size-mismatched recipients. Despite these limitations, the majority of heart transplant recipients enjoy a physically active lifestyle and an improvement in quality of life, especially when compared to their pretransplant state.

Patient and Family Information for: Selection and Care of the Heart Transplant Patient

Patients with advanced heart failure (also referred to as Stage D or end-stage heart failure) experience symptoms of fatigue and shortness of breath in spite of optimal medical therapy. Once heart failure has progressed to this point, few treatment options remain. Heart transplantation has been performed since the 1960s. Over the years, refinements in both surgical technique and medical management have significantly improved patient survival and quality of life. In the early days of transplantation, most patients lived only a few months, whereas now heart transplant patients can expect to live many years with a good quality of life. About 90% of heart transplant recipients survive the first year. More than half of all recipients live for more than 10 years, and some live for more than 20 years with the same transplanted heart. The major downside to heart transplantation is that there simply are not enough donor hearts to go around. Currently in the United States, there are close to 200,000 patients living with advanced heart failure, but only 2000 heart transplants will be performed annually. This means that there is a constant need to increase awareness of organ donation to increase the pool of available organs.

Patients who are referred to an advanced heart failure program for consideration of heart transplantation must first undergo a standard evaluation. This evaluation is designed to answer two questions: first, is the patient sick enough to require transplant, and, second, are there any reasons why this patient should not receive a heart transplant. The typical evaluation includes consultations with a cardiologist, surgeon, and transplant coordinator. Additional visits with social work and psychiatry are necessary to screen for potential psychological, financial, or social barriers to living with a transplant. Typical

tests include a CT scan, ultrasound, and age-appropriate cancer screening. One invasive test, a right heart catheterization, will measure the pressures inside the heart and lungs to ensure that it is safe to perform the operation.

The decision to place a patient on the heart transplant waiting list is made by a committee of transplant professionals, the same individuals who met the patient during the evaluation process. Waiting times vary from state to state and are determined by a patient's body size, blood type, and heart failure severity. Those patients who require admission to an intensive care unit or who have a failing ventricular assist device are moved to the top of the list because they face the highest risk of dying in the near future.

The transplant operation takes about 6 to 8 hours to perform. Most patients will remain in the intensive care unit for at least 4 or 5 days and in the hospital for about 10 to 14 days. During this time, the transplanted heart will be supported by a number of intravenous medications and occasionally a temporary pacemaker to ensure that it beats fast enough. This is also the time when patients start to receive medications that suppress the immune system and prevent the heart from being rejected by the body. Even though it sounds severe, heart transplant rejection is rarely severe and can almost always be treated simply by increasing the dose of immune suppressive medications.

Before leaving the hospital, all patients must have a heart biopsy to check for rejection. This procedure takes less than half an hour to perform. A physician will place a tube in the jugular vein and pass a bioptome (a small scissor-like instrument) through it to sample a few pieces of heart tissue. These samples will be looked at by a pathologist to make sure there is no sign of rejection. This procedure is repeated throughout the first year at regular intervals to make sure the heart is not being rejected and to safely allow reductions in immune suppressive medications.

Most patients feel very well living with a transplant. Although some have run marathons and climbed mountains, most heart transplant recipients simply live life without experiencing fatigue and shortness of breath as they did when they had heart failure. To make sure that the transplanted heart continues to function well, patients will have to return for check-ups several times each year. Everyone will have an echocardiogram performed annually to make sure that the heart is still beating well. Patients will also have an annual angiogram to make sure that the transplanted arteries remain free of blockages that could weaken the heart over time. All patients who take immune suppressive medications are more vulnerable to infections. In addition to taking antibiotics to prevent infection,

transplant recipients should use common sense and avoid close contact with family or friends who are sick.

There are a number of long-term complications that can limit the success of heart transplantation. Some of the immune suppressive medicines can weaken the kidneys. About 5% of heart transplant recipients will have advanced kidney disease requiring dialysis or a kidney transplant. Although the immune suppressive drugs do not cause cancer, they do place transplant patients at higher risk for developing cancers. These include a rare form of lymphoma, which affects the immune system. Skin cancer is the most common form of cancer and should be prevented by wearing a hat, long-sleeved shirts, and sunscreen when outdoors.

Medications Used in the Management of Heart Failure

The past 30 years have provided remarkable advances in the pharmacotherapeutic management of patients with acute and chronic heart failure (HF). Major improvements in both survival and symptom management now provide practitioners with the ability to provide therapy that is well tolerated, decreases recurrent hospitalizations, and improves quality of life. As the incidence of HF continues to increase with the advancing age of the population, and there is improved post-infarction survival, maximizing the use of currently available agents, development of new class of drugs, and the continued development of implantable devices for treatment of mechanical and electrical complications of HF should further our ability to improve patient care.

In this chapter, we explore the various agents currently available for the management of HF.

INOTROPES

Intravenous inotropes dobutamine and milrinone are useful in patients with severe systolic dysfunction with relative hypotension and evidence of inadequate end-organ perfusion, who are not responsive to, or are intolerant of, vasodilators

and diuretics. Inotropic agents relieve acute HF symptoms and may preserve end-organ function, but have not been demonstrated to improve survival. On the contrary, several studies have demonstrated increased adverse outcomes, including increased mortality with chronic intravenous inotropic therapy.

DOBUTAMINE

Dobutamine, a synthetic catecholamine, is primarily a β adrenergic stimulant with minimal α_1 cardiac sympathetic activity. Its β_1 sympathetic activity accounts for its inotropic activity through β-receptor–mediated activation of intracellular cyclic-adenosine monophosphate (c-AMP). The resulting sarcoplasmic reticulum calcium release mediates myocardial contractility. Similar β_1 activity at the sinoatrial (SA) node accounts for its modest chronotropic activity. Patients taking β-blockers on admission may have an attenuated initial response to dobutamine, until the β-blocker has been metabolized or renally eliminated.[1] However, cardiac output response to increasing doses of dobutamine has been observed in patients on chronic carvedilol.[2] The dose-dependent β_2 effect produces mild peripheral arteriolar dilation. As with most intravenous sympathetic stimulants, dobutamine has a rapid onset of action (1 to 2 minutes) and has a peak effect within 10 minutes. The drug is rapidly methylated providing for a short duration of action ($t_{1/2}$—2 minutes), ideal for a drug requiring titration based on hemodynamic effects.

The hemodynamic effects of dobutamine in patients with HF include increased cardiac output, arteriolar dilation, reduction of pulmonary artery occlusion pressure (PAOP or wedge pressure), and small but variable change in blood pressure (**Table 19.1**). In responsive patients, the hemodynamic benefits of the drug increase end-organ perfusion, manifest by improving renal function and urine output, decreased pulmonary vascular congestion, and improved skin perfusion and mentation.

TABLE 19.1 Hemodynamic Effects of Intravenous Agents Used in the Treatment of Acute Decompensated Heart Failure

DRUG	DOSE	HR	MAP	PAOP	CO	SVR
Dobutamine	2.5–15 μg/kg/min	0/+	0	−	+	−
Milrinone	0.375–0.75 μg/kg/min	0/+	0/−	−	+	−

Dopamine	0.5–3 μg/kg/min	0	0	0	0/+	−
Dopamine	3–10 μg/kg/min	+	+	0	+	0
Dopamine	>10 μg/kg/min	+	+	+	+	+
Nesiritide	Bolus: 2 μg/kg Infusion: 0.01 μg/kg/min	0	0/−	−	+	−
Nitroglycerin	5–200 μg/min	0/+	0/−	−	0/+	0/−
Nitroprusside	0.25–3.0 μg/kg/min	0/+	0/−	−	+	−

CO, cardiac output; HR, heart rate; MAP, mean arterial pressure; PAOP, pulmonary artery occlusive pressure; SVR, systemic vascular resistance.
Adapted from DiPiro JT, Talbert RL, Yee GC, et al. *Pharmacotherapy: A Pathophysiologic Approach*. 7th ed. New York, NY: McGraw Hill; 1999.

The adverse effects that should be monitored in patients with HF include dose-related tachycardia – most concerning in ischemic cardiomyopathy – as well as atrial arrhythmias (like atrial fibrillation) and ventricular arrhythmias (like ventricular tachycardia).

Dobutamine dosing begins at 2.5 to 5 μg/kg/min and is progressively increased on the basis of clinical and hemodynamic response. Because it is not a vasoconstrictor (pressor), dobutamine does not need to be administered through a central line. Dosing may be increased to 15 μg/kg/min, although maximum hemodynamic benefit may be achieved at lower doses, and ventricular ectopy risk increases as the dose is increased. Once hemodynamic stability has been accomplished, dobutamine infusions should be gradually tapered off. Although intermittent ambulatory dobutamine infusions have been used for quality-of-life enhancement in patients who are not candidates for transplantation or pump implantation, or as a pharmacologic bridge to cardiac transplantation, the practice has generally been replaced by implantation of ventricular assist devices.[3] In addition, randomized trials have demonstrated increased mortality with the use of ambulatory dobutamine infusions.[4]

MILRINONE

Milrinone is a selective inhibitor of phosphodiesterase III, an enzyme responsible for the intracellular breakdown of c-AMP. c-AMP accumulation increases intracellular calcium and thereby facilitates myocardial contractility. Although milrinone’s hemodynamic effects are similar to those of dobutamine,

milrinone produces more arterial and venous dilation, earning it the label "inodilator" (**Table 19.1**). Theoretical advantages of milrinone as compared to dobutamine include greater afterload reduction, augmenting the cardiac output produced by its inotropic effect, and its post-receptor mechanism of action, a potential benefit in patients receiving β-blockers for chronic HF. Hemodynamic improvement is usually observed within 15 minutes of initiation of therapy. The drug is renally eliminated with an elimination half-life of approximately 3 hours in patients with HF, and the maintenance infusion should be adjusted on the basis of creatinine clearance.

Although the package insert recommends a 50 μg/kg loading dose, many practitioners refrain from administering the loading dose to reduce the risk of hypotension. Typical maintenance doses of milrinone range from 0.375 to 0.75 μg/kg/min (**Table 19.2**). At maintenance doses above 0.5 μg/kg/min, once hemodynamic and clinical stability has been achieved, the infusion should be gradually tapered off. However, because the drug has a longer elimination half-life than does dobutamine, lower milrinone maintenance doses may be reduced more rapidly than dobutamine doses, provided hemodynamic stability has been achieved. In addition to hypotension, the most common side effects are tachyarrhythmias. Milrinone may produce less tachycardia than does dobutamine, but it also has the potential to produce both atrial and ventricular arrhythmias.

TABLE 19.2 Renal Dosing of Milrinone

CREATININE CLEARANCE (mL/min/1.73 m^2)	MILRINONE INFUSION RATE (μg/kg/min)
5	0.20
10	0.23
20	0.28
30	0.33
40	0.38
50	0.43

Despite the potential adverse long-term impact on morbidity and mortality related to intravenous inotropic therapy, patients with acute decompensated HF

benefit from the short-term hemodynamic improvement associated with the administration of these agents, pending the resolution of the underlying events that precipitated their hemodynamic deterioration.

DOPAMINE

Dopamine possesses dose-dependent hemodynamic effects, stimulating D_1 dopamine receptors, α_1-, β_1-, and β_2-receptors. Other than the diuretic effect of low-dose (renal dose) dopamine to enhance volume loss in patients with diuretic-resistant HF, dopamine use is typically reserved for use in patients with marked hypotension including those with cardiogenic shock. Inotropic doses in the 2 to 5 μg/kg/min range promote increase in cardiac output; however, intermediate- and high-dose dopamine increase systemic vascular resistance, increasing afterload and PAOP, and impeding cardiac output (**Table 19.1**). In the setting of cardiogenic shock, dopamine may be required to maintain mean arterial pressure and coronary perfusion pressure until the underlying etiology can be treated or resolved.

DIGOXIN

Digoxin is a moderately potent inotrope with additional neurohormonal modulating effects producing increased parasympathetic nervous system activity and decreased central sympathetic nervous system drive. Its inotropic effect is related to inhibition of sarcolemmal sodium-potassium-ATP-ase, resulting in increased myocardial cell calcium, the final common pathway for all currently available inotropic agents. The benefit of digoxin in HF was debated for most of its first 200-year history. The drug has little use in the treatment of acute HF in patients with sinus rhythm. Perhaps the least controversial use of the drug in patients with HF is to assist (in combination with β-blockers or amiodarone) in the management of rate control in patients with atrial fibrillation. The Digoxin Investigation Group (DIG) clarified the role of digoxin in the management of patients with HF with normal sinus rhythm.[5] This study demonstrated that digoxin, in addition to background angiotensin-converting enzyme inhibitor (ACEI) and diuretic therapy, improved exercise tolerance, and reduced HF-related hospitalizations, but did not improve survival. Therefore, digoxin therapy for HF may be considered in patients with atrial fibrillation or in patients in sinus rhythm on target doses (if tolerated) of angiotensin-converting enzyme inhibitor/angiotensin receptor blocker (ACEI/ARB) and β-blockers who exhibit

continued exercise intolerance or recurrent HF-related hospitalizations.

Digoxin is primarily renally eliminated with a serum elimination half-life of 1.6 days in patients with normal renal function. Recent trials have demonstrated that the efficacy of digoxin in HF can be achieved with doses that produce serum concentrations of 0.5 to 1.0 ng/mL, lower than those previously defined as "therapeutic."[6] Higher serum concentrations provide no added benefit and increase the risk of digoxin toxicity.

Digoxin Toxicity

Digitalis intoxication is a clinical diagnosis based on the presence of signs and/or symptoms including anorexia, nausea, and vomiting, and atrial or ventricular arrhythmias. Given the establishment of lower effective serum concentration, the incidence of digoxin toxicity has likely diminished. It is important to understand that the diagnosis of digoxin toxicity is never based solely on the digoxin concentration. Elevated serum digoxin concentrations are only one etiology of drug toxicity, usually related to maintenance doses inappropriate for the level of renal function. Most patients with normal renal function require 0.125 mg digoxin daily. Patients with renal insufficiency typically require 0.125 mg every other day or less. Many other factors that do not produce elevated serum digoxin concentrations are capable of causing digoxin toxicity including diuretic-induced hypokalemia or hypomagnesemia, hypoxemia, acidosis, hyperthyroidism, and others. Concurrent amiodarone therapy may double the serum digoxin concentration, and typical digoxin dosing in these patients should be reduced by 50% of the usual dose, considering renal function.

DIURETICS

Classical descriptions of acute decompensated HF characterize patients as volume overloaded, but well perfused ("wet and warm") or hypoperfused and not volume overloaded ("cool and dry"). However, the majority of hospitalized patients will require acute diuretic therapy to relieve signs and symptoms associated with their acute presentation. Much of the efficacy data associated with diuretic therapy for acute HF has been derived from experience before the era of randomized controlled trials. Despite their effectiveness for symptom relief, diuretics have not been demonstrated to improve survival in HF. Because of their potency, and rapid onset of action, loop diuretics (furosemide, torsemide,

and bumetanide) are considered the mainstay of treatment (**Table 19.3**). These agents inhibit sodium and chloride reabsorption in the ascending limb of the loop of Henle. Their effect of reducing venous tone and therefore pulmonary capillary wedge pressure often begins to improve pulmonary symptoms before a significant increase in urinary output. It is important to recognize that patients with chronic HF may have increased pulmonary capillary pressures and progressive dyspnea in the absence of significant pulmonary crackles on physical examination. Conversely, patients with new-onset HF are more likely to demonstrate pulmonary vascular congestion (crackles) on examination.

TABLE 19.3 Diuretics Used in the Treatment of Heart Failure

DRUG	INITIAL DAILY DOSE(S)	MAXIMUM TOTAL DAILY DOSE	DURATION OF ACTION
Loop diuretics			
Bumetanide	0.5–1.0 mg once or twice	10 mg	4–6 h
Furosemide	20–40 mg once or twice	600 mg	6–8 h
Torsemide	10–20 mg once	200 mg	12–16 h
Potassium sparing diuretics			
Eplerenone	25 mg once	50 mg once	24 h
Spironolactone	12.5–25 mg once	50 mg	2–3 d
Triamterene	50–75 mg	200 mg	7–9 h
Sequential nephron blockade			
Metolazone	2.5–10 mg once plus loop diuretic		
Chlorothiazide (IV)	500–1000 mg once plus loop diuretic		

Dosing of loop diuretics is empiric. In general, a 40-mg oral dose is equivalent to a 20-mg intravenous dose. In volume-overloaded patients with normal renal function, an initial intravenous dose should be 1 to 2 times the chronic oral dose. Response to an individual intravenous dose can be assessed in several hours.

Patient response is based on relief of pulmonary vascular congestion, daily weight, hepatic congestion, and peripheral edema. Because loop diuretics require a threshold serum concentration to affect their natriuretic response, patients with chronic HF, and those with moderate-to-severe renal insufficiency will usually require higher initial doses than patients with normal renal function or new-onset HF (diuretic-naive patients). Alternative furosemide dosing strategies comparing bolus dosing to continuous infusions have been evaluated in a number of small uncontrolled trials. Earlier studies, in addition to a review of eight randomized trials, suggest that continuous intravenous infusions of furosemide ranging from 10 to 40 mg/h, depending on renal function, produce a greater diuretic effect than similar total doses administered by intermittent bolus dosing, with fewer adverse effects.[7] The DOSE (Diuretic Optimization Strategies Evaluation) trial, a randomized, open-label comparison between twice-daily bolus furosemide versus continuous infusion demonstrated no differences in outcomes in hospitalized, volume-overloaded patients with HF.[8] There was a trend toward less hypokalemia and hypotension in the continuous infusion group. Although no definitive data currently resolve the dosing route of administration controversy, it does not appear that continuous infusion offers a significant advantage over traditional bolus dosing of furosemide.

Monitoring of adverse effects of diuresis such as abnormal electrolytes, orthostatic hypotension, prerenal azotemia or increasing serum creatinine, is essential. Less commonly, patients with a history of chronic gout may experience an acute gout exacerbation. Excessive diuresis can enhance undesired neurohormonal activation, increasing the risk of excessive hypotensive effects from ACEI and β-blockers.

Diuretic resistance is not uncommon in patients with an acute exacerbation of chronic HF. A number of factors predispose to lack of diuretic response including worsening renal function, agents such as nonsteroidal anti-inflammatory drugs (NSAIDs) that antagonize the effects of diuretics, or renal hypoperfusion secondary to HF or overly aggressive diuresis or vasodilators. A number of strategies to produce effective diuresis in nonresponsive patients have been employed. First, if appropriate diuretic response is not achieved within 4 hours, the intravenous dose can be successively doubled until an intravenous dose of 120 mg is reached. Higher single doses are unlikely to enhance diuresis and are more likely to risk ototoxicity. Despite the lack of controlled data, anecdotal reports of successful diuresis with continuous furosemide infusions in diuretic-resistant patients may promote successful diuresis. Oral metolazone,

unlike other oral thiazide diuretics, can be effective in patients with renal insufficiency. An oral dose of 5 to 10 mg should be administered before intravenous furosemide—30 to 60 minutes is the accepted time frame, although pharmokinetically the distal tubule blockade requires at least several hours. Other distal convoluted tubule diuretics include oral hydrochlorothiazide, chlorthalidone, or intravenous chlorothiazide. However, metolazone, perhaps related to its efficacy in patients with renal insufficiency and its longer elimination half-life, seems to be preferred by most clinicians.

Diuretics that act more distally, such as spironolactone or amiloride, are less likely to overcome diuretic resistance, but may have a role in limiting hypokalemia and hypomagnesemia provoked by loop diuretics. These acute electrolyte disturbances in patients with HF increase the risk of hemodynamically compromising, or potentially life-threatening arrhythmias. Intravenous low-dose dopamine stimulates renal dopamine receptors and has been demonstrated to increase urine output; however, no controlled studies in patients with diuretic-resistant HF have been undertaken. Interpatient variability in response to the β_1 adrenergic inotropic effects of dopamine may play a role in its ability to increase urinary output in HF. The UNLOAD (***UN***load the ***L***eft ventricle in patients with ***AD***vanced heart failure) trial demonstrated that ultrafiltration produced greater weight and fluid loss, as well as fewer HF-related hospitalizations than intravenous diuretics in patients hospitalized for HF.[9] The CARRESS-HF (***CA***rdiorenal ***RES***cue ***S***tudy in Acute Decompensated ***H***eart ***F***ailure) trial was undertaken to demonstrate the efficacy of ultrafiltration in patients with HF having persistent congestion and worsening renal function. Unfortunately, the ultrafiltration had no benefit over stepped pharmacological therapy (diuretics).[10] In fact, ultrafiltration was associated with more adverse events—worsening renal failure, bleeding, and catheter-related events. Therefore, ultrafiltration is reserved for patients with refractory congestion who have failed to respond to diuretic-based strategies.[11]

ALDOSTERONE ANTAGONISTS

The adverse effects of aldosterone in HF are related to its sodium- and water-retaining potential initiated by activation of the rennin–angiotensin–aldosterone system (RAAS), and from decreased hepatic aldosterone clearance. As important is the impact of aldosterone on myocardial and vascular remodeling that

produces increased collagen deposition and fibrosis. These effects produce ventricular systolic and diastolic dysfunction and contribute to the progressive nature of chronic HF. Although both ACEIs and ARBs lower aldosterone production in the short term, long-term suppression may not be maintained. Aldosterone antagonists spironolactone and eplerenone have both been demonstrated to improve symptoms, reduce HF-related hospitalizations, and improve survival in selected patients. The ***R***andomized ***AL***dactone ***E***valuation ***S***tudy (RALES) trial evaluated the effect of spironolactone (maximum dose 25 mg daily) in patients with New York Heart Association (NYHA) class IV symptoms, or class III symptoms in recently hospitalized patients.[12] The EPHESUS (***E***pleronone ***P***ost-Acute Myocardial Infarction ***H***eart ***F***ailure ***E***fficacy and ***SU***rvival ***S***tudy) trial studied eplerenone (maximum dose 50 mg daily) in patients with HF or diabetes and left ventricular ejection fraction (LVEF) <40% within 14 days of myocardial infarction (MI). Both drugs demonstrated an improvement in survival and reduction in HF-related hospitalization.[13] The EMPHASIS (***E***plerenone in ***M***ild ***P***atients ***H***ospitalization ***A***nd ***S***urv***I***val ***S***tudy) trial expanded the use of aldosterone antagonists by evaluating the effect of eplerenone in patients with NYHA II symptoms and LVEF ≤35%, again resulting in reduction of mortality and hospitalizations.[14]

The benefits associated with the use of aldosterone antagonists must be carefully weighed against the potential for life-threatening hyperkalemia. Given that ACEI therapy has become a mainstay in the treatment of HF, and because some degree of renal insufficiency is common as the severity of HF increases, it is imperative that patients be chosen carefully, and that appropriate monitoring of serum potassium concentrations takes place. The major trials excluded patients with serum creatinine >2.5 mg/dL; however, serum creatinine is a poor predictor of creatinine clearance, especially in elderly patients. Aldosterone antagonists should not be administered to patients with creatinine clearances below 30 mL/min, and the dose should be reduced at creatinine clearances less than 50 mL/min. More frequent use of aldosterone antagonists in the general HF population, as opposed to patients enrolled in clinical trials, subsequent to the publication of the two major trials, has resulted in an incidence of hyperkalemia up to 24%.[15] Serum potassium concentrations should be monitored within 3 days of drug initiation and again at 1 week. Serum potassium concentrations greater than 5.5 mEq/L should promote discontinuation of the drug. The lack of routine monitoring has been well documented in the ambulatory care setting.[16]

Spironolactone may cause painful gynecomastia in approximately 10% of

patients, according to the RALES study, and probably increased rates in higher doses. This is attributed to the anti-androgenic and indirect estrogenic effect of spironolactone. Eplerenone is much more selective than spironolactone in aldosterone receptor blockade and does not exert anti-androgenic and estrogenic effects. However, it is less potent than its corresponding dose of spironolactone. Eplerenone is also more expensive than spironolactone, and is therefore usually administrated when patients complain of spironolactone-related side effects.

VASODILATORS

Nitroglycerin, nitroprusside, and nesiritide are all effective in improving hemodynamic and symptoms of pulmonary vascular congestions in patients who are not hypotensive. These agents are indicated in patients with ongoing pulmonary vascular congestion not responsive to diuretic therapy and standard oral therapy. Additional indications for intravenous vasodilator therapy include patients with HF and ongoing ischemia, hypertension, or significant mitral regurgitation.

NITROGLYCERIN

Nitroglycerin is primarily a venodilator with dose-dependent arteriolar dilating properties. At higher doses, nitroglycerin is a potent coronary vasodilator, making it an ideal agent for patients with ischemic cardiomyopathy. Nitrate-induced preload reduction results in reduced PAOP, myocardial oxygen demand, and improvement in dyspnea. Because of its short onset and duration of action, the infusion rate can be quickly adjusted, allowing easy titration toward maximal beneficial hemodynamic effects, and rapid correction of adverse effects. The risk of hypotension with nitroglycerin as with the other intravenous vasodilators is critically dependent on intravascular volume. Hemodynamic monitoring may be useful to assess the beneficial effects, and limit the risk of hemodynamic adverse effects with both nitroglycerin and nitroprusside, as well as with intravenous inotropes. Tolerance to the hemodynamic effects of nitroglycerin can be seen in 12 to 72 hours in patients on continuous nitroglycerin infusions.[17]

NITROPRUSSIDE

Nitroprusside is a more balanced arteriolar and venous dilator than nitroglycerin.

As a more potent arteriolar dilator, it has greater effect in increasing cardiac output in patients with elevated systemic vascular resistance, while retaining the preload lowering benefit of reducing PAOP and pulmonary congestion. Although nitroprusside has been associated with coronary steal in patients with obstructive coronary disease, in patients with HF the reduction in both preload and afterload generally decreases myocardial oxygen demand.[18] Obviously a significant reduction in aortic diastolic pressure has the potential to decrease coronary perfusion pressure and increase ischemia. As with nitroglycerin, nitroprusside is short acting, providing for easy titration. The most common side effect is hypotension. Two biochemical toxicities have potentially led to the underutilization of nitroprusside in acute decompensated HF—cyanide and thiocyanate toxicity. Malnourished patients or patients with liver disease are more prone to cyanide intoxication because of their inability to combine cyanide produced in the serum from nitroprusside with the hepatically produced sulfhydryl group to form thiocyanate. The accumulated cyanide produces elevated lactate levels and metabolic acidosis. Patients with decrease renal function are unable to eliminate the thiocyanate metabolite and develop neurotoxicity including headache, altered mental status, and seizures. Because thiocyanate has an elimination half-life of 4 days in patients with normal renal function, infusions of less than 3 μg/kg/min administered for less than 3 days in patients with a serum creatinine less than 3.0 mg/dL are unlikely to result in toxicity. Serum thiocyanate concentrations can be measured in the hospital laboratory.

NESIRITIDE

Nesiritide is an intravenous form of recombinant human brain natriuretic peptide (BNP). It produces a dose-dependent reduction in venous and arterial pressures, natriuresis, and diuresis. Its most consistent effect is decreased dyspnea and POAP, much like nitroglycerin. Questions remain as to the impact of nesiritide on hospitalization rates and mortality, especially in the face of its relatively high cost compared to nitroglycerin. In addition, in a review of a series of publications, nesiritide significantly increased the risk of worsening renal function.[19] The ASCEND-HF (Acute Study of Clinical Effectiveness of Nesiritide in Decompensated Heart Failure) trial enrolled 7141 patients hospitalized with acute HF randomly assigned to nesiritide or placebo. Nesiritide did not impact mortality or rehospitalization, and was not associated with

worsening renal function, but it was associated with an increase in rates of hypotension.[20]

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS/ANGIOTENSIN RECEPTOR BLOCKING AGENTS

ACEIs have been demonstrated to improve survival in NYHA Class II to IV patients with systolic dysfunction, and improve symptoms in many patients (**Table 19.4**). Their pharmacologic effects, inhibiting the conversion of angiotensin I to angiotensin II, result in a decreased production of angiotensin II and aldosterone. Limiting aldosterone production decreases the progression of left ventricular dysfunction and reduces ventricular remodeling, myocardial fibrosis, cardiac hypertrophy, and dilatation. The chronic hemodynamic effects of ACEIs to reduce afterload (angiotensin is a potent vasoconstrictor), and, to a lesser extent, preload, improves exercise tolerance and quality of life. In addition to improving survival, ACEIs decrease the rate of HF-related hospitalizations, and limit the need for increasing diuretic doses. For post-MI patients, ACEIs reduce the risk of developing HF, recurrent MI, and HF-related hospitalizations. Angiotensin-converting enzyme is also responsible for the degradation of bradykinin. The cough and rare cases of angioedema observed in patients treated with ACEI are attributed to this elevation of bradykinin. Therefore, substitution of an ACEI with a direct ARB can bypass this effect without raising bradykinin levels. Owing to the significant cumulative data demonstrating the benefit for ACEI in the treatment of chronic HF, these drugs, as opposed to ARBs, are recommended as first-line therapy for chronic HF. ARBs, which probably possess similar symptom and survival benefit, should be reserved for the 10% to 15% of patients who develop ACEI-induced cough.

TABLE 19.4 Oral Agents FDA Approved for Treatment of Chronic Heart Failure

DRUG	INITIAL DOSE	TARGET DOSE	ELIMINATION
ACE inhibitors			
Captopril	6.25 mg tid	50 mg tid	Renal

Enalapril	2.5–5 mg bid	10 mg bid	Renal
Lisinopril	2.5–5 mg daily	20–40 mg daily	Renal
Quinapril	10 mg bid	20–40 mg bid	Renal
ARB			
Candesartan	4 mg daily	32 mg daily	Renal
Valsartan	40 mg bid	160 mg bid	Liver/some renal
ARNI

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; ARNI, angiotensin receptor–neprilysin inhibitor; FDA, U.S. Food and Drug Administration.

ACEI therapy for ischemic or nonischemic cardiomyopathy should be initiated at low doses, but may be titrated to maximum doses within a few days to weeks, provided blood pressure and renal function remain stable. It is important to note that patients with more severe HF may have relatively low blood pressures (systolic pressures in the 100 mm Hg range), and as long as symptomatic hypotension is not present, ACEI therapy should be maintained. Dose reduction or transient withholding of ACEI administration should not be based only on the systolic blood pressure reading, but on the presence of symptomatic hypotension. In addition, new-onset hypotension or an increase in serum creatinine, in the setting of ACEI therapy, warrants an evaluation for cause, especially overly aggressive diuretic therapy, or hyponatremia in the

setting of NYHA Class IV HF. Although survival enhancement can be achieved with low doses of ACEIs (lisinopril 5 mg or its equivalent), maximum symptom improvement and limitation of HF-related hospitalizations are best achieved with higher doses (20 to 40 mg lisinopril).

For patients with acute decompensations of chronic HF, ACEIs or ARBs have minimal acute hemodynamic benefit, but should remain part of the therapeutic regimen as long as they are hemodynamically tolerated.

The two most likely adverse effects associated with ACEI/ARB administration in hospitalized patients are hypotension and worsening renal function. The risks of both of these outcomes are enhanced by overly aggressive diuresis. Small (10%) increases in serum creatinine are commonly associated with initiating ACEI/ARB therapy in patients with HF, and should not provoke dosage reduction or drug withdrawal. Progressive increases in serum creatinine, however, are a typical manifestation of decreased renal blood flow, commonly the result of aggressive diuretic therapy, or worsening HF. Reducing the rate of diuresis, rather than holding the dose of ACEI/ARB, will usually allow renal function and/or blood pressure to return to its baseline level. It is not usually necessary to temporarily withhold administration of the ACEI/ARB, unless the rise in serum creatinine continues. Drug-induced hypotension, even in the face of total body volume overload, will usually require holding the diuretic until intravascular volume equilibrates.

A second common cause of worsening renal function associated with the administration of ACEIs/ARBs is the concomitant use of other nephrotoxic agents, most notably, intravenous contrast administered for coronary artery imaging. Because of the risk of nephrotoxicity associated with iodinated contrast, especially in the diabetic patient, withholding ACEIs/ARBs for patients with suspected dye-induced nephrotoxicity is appropriate until renal function returns to baseline. Although volume repletion is an effective method of reducing the risk of dye-induced nephrotoxicity, this may be more difficult in patients with HF than in patients with coronary artery disease without HF.[21] The presence of preexisting renal disease in patients with HF should not be considered a contraindication to ACEI/ARB therapy in chronic HF. Several trials in various patient populations including post-MI patients with decreased left ventricular function have demonstrated that ACEIs are more effective in the subset of patients with mild-to-moderate renal insufficiency than in patients with normal renal function.[22] Judicious routine monitoring of renal function is required in patients hospitalized for HF, irrespective of the addition of

ACEIs/ARBs. Prevention of hyperkalemia is especially important in patients with HF with chronic kidney disease receiving ACEI/ARB therapy.

ANGIOTENSIN RECEPTOR–NEPRILYSIN INHIBITORS

A new class of drugs was recently developed, combining inhibition of the RAAS via an ARB with a molecule that inhibits the endogenous peptidase neprilysin—an enzyme responsible for the degradation of natriuretic peptides, bradykinin and adrenomedullin (counterregulatory substances released in HF, among other conditions). By inhibiting neprilysin, these counterregulatory substances are upregulated allowing for natriuresis, diuresis, vasodilation, and anti-fibrotic/antiremodeling effects. As with ACEIs, angiotensin receptor–neprilysin inhibitors reduce the degradation of bradykinin (**Table 19.4**). This is why the neprilysin inhibitor molecule was combined with an ARB and not an ACEI. This decision stemmed from the results of a study combining neprilysin inhibition and ACE inhibition in one molecule—omapatrilat, a "super ACE inhibitor." Trials with this molecule had a disturbing rate of angioedema, probably due to the double inhibition of bradykinin degradation causing marked bradykinin elevation.[23] Therefore, a molecule combining valsartan (ARB) and sacubitril (neprilysin inhibitor) was constructed and initially termed LCZ696. After preclinical testing, a large-scale trial (PARADIGM-HF, ***P***rospective Comparison of ***AR***NI with ***A***CEI to ***D***etermine ***I***mpact on ***G***lobal ***M***ortality and ***M***orbidity in ***H***eart ***F***ailure, trial) enrolling patients with HF having reduced LVEF (<40% and then 35% during the trial) and NYHA Class II to IV symptoms was initiated. This trial compared enalapril 10 mg bid versus LCZ696 (Sacubitril/Valsartan) in a randomized double-blind design after two single-blind run-in periods (where patients were tested with enalapril and then with LCZ696 individually).[24] The PARADIGM-HF trial demonstrated superiority of LCZ696, later named Entresto, over enalapril. This was reflected in reduced cardiovascular mortality, as well as in hospitalizations. The main side effects are similar to ACEI/ARB—hypotension and angioedema. Following this trial, HF guidelines began to endorse Entresto instead of ACEI/ARB if a patient is still symptomatic despite optimal medical therapy.[25]

β-BLOCKERS

β-Blockers were originally considered contraindicated in patients with HF because of their negative inotropic effects (**Table 19.4**). Once the paradigm for the pathogenesis of HF shifted away from primary myocardial dysfunction to a syndrome resulting from the action of "compensatory" mechanisms related to the sympathetic nervous system and the renin–angiotensin–aldosterone axis, it became clear that agents that antagonize these mechanisms might be beneficial. Several large randomized trials in the 1990s demonstrated that β-blockers improve survival in patients with NYHA Class II to IV HF.[26–28] In addition, they decrease the risk of overt HF in patients with asymptomatic left ventricular dysfunction. The progression and degree of chronic HF severity are associated with the serum concentration of norepinephrine. Patients with the highest norepinephrine concentrations have the poorest prognosis. Hemodynamically, norepinephrine-induced tachycardia and inotropic effects increase myocardial oxygen demand. In addition, the peripheral vasoconstriction increases left ventricular afterload, further increasing oxygen demand and decreasing cardiac output. Chronically, sympathetic stimulation produces myocardial cell loss through apoptosis and cell necrosis, as well as downregulation of myocardial β_1 receptors and loss of sensitivity to sympathetic stimulants. As had been previously discovered with the use of ACEIs to interfere with the adverse effects of the RAAS on progressive ventricular dysfunction, survival, and symptoms, blocking the detrimental effects of catecholamines on the failing ventricle with β-blockers resulted in improved left ventricular function, attenuating ventricular remodeling, decreasing the risk of life-threatening arrhythmias, and decreasing myocardial oxygen demand.

A number of issues are relevant to the use of β-blockers in the patient hospitalized for HF. These include timing of drug therapy initiation, methods for increasing doses toward chronic target dosing, strategies for dosing in patients on chronic β-blockers who are admitted for acute HF decompensation, and choosing between various β-blockers approved for use in chronic HF.

β-Blocker therapy should be initiated in patients with new-onset HF only after volume status has been optimized. Patients who remain volume overloaded are more likely to develop increasing HF symptoms, whereas patients who are intravascularly volume depleted are more like to become hypotensive. Several studies have addressed the order in which ACEI/ARB or β-blockers should be administered, because initiation of both agents is recommended within 24 hours of the onset of MI.[29] These studies, however, have been performed in patients with mild-to-moderate chronic HF, not patients hospitalized with new-onset or

acutely decompensated HF. Although both β-blockers and ACEIs are effective for myocardial remodeling post MI, current guidelines recommend initiation of ACEI within 24 hours of the MI, and delaying the introduction of β-blockade until the signs and symptoms of HF have been resolved. It is not necessary to achieve the "target dose" of ACEI/ARB before initiating starting doses of the β-blocker.

Unlike the initial dosing strategy with ACEIs/ARBs, β-blockers should be titrated toward their target doses more gradually, with a minimum of 2-week intervals between dosage increases. It is well documented that many patients with chronic HF do not receive doses consistent with target doses determined by large controlled trials. As with ACEIs/ARBs, small doses of β-blockers do positively impact survival; however, greater reduction in HF hospitalizations and improvement in LVEF are achieved with dosing strategies intended to achieve target doses. It is common for ambulatory care providers to maintain patients on the low-dose β-blockers that were initiated during an acute hospitalization, presumptively based on concerns for worsening HF as the dose is increased, or assuming that the patient has achieved the ultimate level of symptom control. Clearly, monitoring for adverse effects such as worsening HF, symptomatic bradycardia, or hypotension are a requisite part of chronic monitoring during titration toward target doses of β-blocker therapy. Especially for patients with new-onset HF, however, maintaining a starting dose, without an attempt to titrate to target doses, diminishes the potential benefit that the combination of ACEI/ARB and β-blockers can achieve for prevention of disease progression.

Recent data have addressed the question of withdrawing β-blockers in patients on chronic therapy who present with an acute decompensation of HF. Until recently, the approaches have generally been either to temporarily discontinue the β-blocker or to decrease the chronic dose to some degree. The appropriate strategy clearly depends on the level of severity of the acute decompensation. Patients who present with severe hemodynamic decompensation (hypotensive, or approaching cardiogenic shock), or those with severe pulmonary vascular congestion are obvious candidates for transient withdrawal of β-blockers. Data prospectively analyzed from the OPTIMIZE-HF (Organized *P*rogram to Initiate Lifesaving Treatment in Hospitalized Patients with Heart Failure) demonstrated that patients who were withdrawn from β-blocker therapy had a higher risk for mortality, compared with those continued on β-blockers.[30] Patients who were eligible for β-blocker therapy, but did not receive them, had similar risk for mortality as those who had therapy withdrawn. During the 60- to 90-day follow-

up period, 94% of patients remained on β-blockers after discharge. Only 57% of patients who had their β-blocker withdrawn received β-blocker treatment during the 60- to 90-day follow-up period. Of the patients maintained on therapy during hospitalization, only 12% had their maintenance dose reduced during follow-up. The remaining 88% were maintained on their preadmission dose, or had their dose increased (12%). It appears therefore from limited registry data that patients with chronic HF admitted to the hospital on β-blocker therapy should not have this therapy withdrawn unless they are hemodynamically compromised. An additional risk associated with β-blocker withdrawal is failure to reinstate the drug after hospital discharge.

Two β-blockers are currently approved in the United States for the treatment of HF—metoprolol controlled release/extended release (CR/XL) and carvedilol. Bisoprolol has also been demonstrated to reduce the incidence of sudden death and of HF-related death, but is not approved by the U.S. Food and Drug Administration for this indication in the United States. Metoprolol is a cardioselective β-blocker, whereas carvedilol is a nonselective β-blocker with α-adrenergic blocking activity. Both agents have demonstrated similar reductions in morbidity and mortality in large randomized controlled studies of patients with HF. Subtle pharmacodynamic features may influence the decision to use one drug or the other. The cardioselectivity of metoprolol may be beneficial in patients with reversible airway disease such as asthma; however, cardioselectivity diminishes with increasing dosage. The recommended target dose of metoprolol of 200 mg daily likely provides little cardioselectivity. The α-blocking property of carvedilol has a theoretical advantage in patients with a history of cocaine abuse in whom pure β-blocker pharmacology leaves unopposed coronary artery α-receptors susceptible to the vasospastic potential of cocaine. Both metoprolol XL and carvedilol are available as once-daily dosing formulations to enhance patient compliance.

The most common adverse effects of β-blockers in patients with HF include worsening of HF symptoms, especially in volume-overloaded patients or in those whose dose titration has occurred too rapidly, symptomatic bradycardia, or hypotension.

IVABRADINE

Ivabradine is a drug that inhibits the If Current (If—“I funny”—because this

sodium channel current is triggered by hyperpolarization, as opposed to other sodium channels) in the SA node. If is the “pacemaker current” responsible for spontaneous depolarization of the SA nodal tissue. The rationale behind the development of this agent was to produce further lowering of the heart rate, in addition to β-blockers. Ivabradine does not have negative inotropic effects, so patients with β-blocker intolerance can receive a lower dose of β-blocker with ivabradine or ivabradine alone as a heart-rate–lowering agent. The SHIFT (***S***ystolic ***H***eart ***F***ailure Treatment with the **I**f Inhibitor Ivabradine ***T***rial) enrolled patients with HF having LVEF ≤35%, with NYHA class II to IV symptoms, and on optimal medical therapy with a heart rate >70. In this trial, ivabradine reduced the combined end point of hospitalizations and cardiovascular mortality.[31] Therefore, ivabradine (marketed as Corlanor) can be added on to optimal β-blocker therapy, along with ACEI/ARB and spironolactone in patients with LVEF ≤35% and are still symptomatic. Side effects include bradycardia and luminous phenomena—phosphenes, brightness in the visual fields. The visual changes are presumed to be the result of ivabradine inhibiting similar retinal channels.

HYDRALAZINE-ISOSORBIDE DINITRATE

The combination of the direct arteriolar dilator, hydralazine, and isosorbidedinitrate (ISDN), a long-acting nitrate venodilator was the first vasodilator regimen to demonstrate improved survival in chronic HF (V-HeFT, Vasodilator Heart Failure Trial).[32] Within a few years, ACEIs had been shown to enhance survival to a greater degree than did the original vasodilator combination, and had become the standard of care for chronic HF. A post hoc analysis of the original hydralazine-nitrate trial suggested that the combination was particularly effective in African-Americans. The A-HeFT (African-American Heart Failure Trial) compared a fixed combination of hydralazine and ISDN (maximum dose hydralazine 75 mg plus ISDN 40 mg 3 times a day) versus placebo in self-identified African-American patients on background ACEI, β-blocker, and a diuretic with or without digoxin and spironolactone.[33] The hydralazine-ISDN group had a significant reduction in mortality, in HF-related hospitalizations, and in an improvement in quality of life.

Oral vasodilator therapy with ACEIs and the combination of hydralazine have primarily been studied in patients with chronic HF. However, in patients

hospitalized with acute HF for whom ACEIs may be transiently withheld because of acute elevations of serum creatinine, hydralazine-isosorbide has been substituted for its beneficial hemodynamic effect.[34] Once stable renal function has been reestablished, ACEIs are the preferred choice for chronic management. In addition to its use in African-American patients, chronic hydralazine-isosorbide therapy may be appropriate for patients who do not tolerate either ACEIs or ARBs because of renal insufficiency or hyperkalemia.

The frequency of side effects such as headache and gastrointestinal complaints from the hydralazine-isosorbide combination in large trials is significant, and in both vasodilator HF trials many patients did not tolerate target doses of these drugs. In addition, the necessity of 3 times daily dosing increases the risk of noncompliance.

Patient and Family Information for: MEDICATIONS USED IN THE MANAGEMENT OF HEART FAILURE

DRUGS FOR PATIENTS HOSPITALIZED WITH HEART FAILURE

Patients with HF symptoms often need hospitalization when their symptoms become severe. Several drugs are useful to relieve the symptoms of HF and to return them to the quality of life they experienced before the need for hospitalization. For most patients, relieving symptoms related to shortness of breath and swelling of their extremities are important goals. For patients who are more severely ill, improving their heart function will provide better blood flow to their organs and muscles. There are three drug categories that are frequently used for patients hospitalized for HF: drugs that relieve swelling and shortness of breath—diuretics such as furosemide (Lasix), drugs that improve heart pumping function (dobutamine or milrinone), and drugs that relax blood vessels and make it easier for the heart to pump blood into the blood vessels (nitroglycerin or nitroprusside).

Diuretic drugs decrease the amount of volume that is in the bloodstream by increasing the amount of salt and water that is removed by the kidneys. Patients with HF are often short of breath because the amount of fluid in the lungs makes it difficult for them to breathe. In addition, many patients have fluid accumulation in their ankles, legs, and even in their abdomen. The primary goal in patients hospitalized for HF is to eliminate fluid from the lungs, followed by a reduction of fluid in other parts of the body. It is important for these patients to

know their “dry weight,” the target weight they should maintain as outpatients. Appropriate use of diuretic drugs in the hospital should bring patients close to their dry weight. It is equally important for patients with HF to weigh themselves daily at home, because this is a practical method to determine fluid accumulation. Weight gain of more than 2 to 3 pounds within a few days is an indication that their HF may not be well controlled. Dietary salt intake has the greatest potential to promote fluid accumulation. Patients should be aware of the salt (sodium) content of the foods they eat, especially prepared foods such as canned vegetables and soups, prepared meats, and snack foods such as pretzels, potato chips, and similar items. They should also avoid adding salt to their meals at the table. Excessive salt intake can easily overcome the effects of diuretic drugs, and result in fluid accumulation. Some physicians have successfully educated patient to increase the dose of their diuretic drugs (furosemide or Lasix) when their weight increases by several pounds. If weight gain continues, or patients become increasingly short of breath with exertion, or when lying down at night, they should contact their physician. The side effects of diuretics that are closely monitored are decreases in blood pressure, kidney function, and other body salts such as potassium and magnesium. A careful balance is maintained between too much volume in the circulation, producing symptoms of shortness of breath and swelling, and too little volume, resulting in diminished kidney function or low blood pressure.

In addition to diuretics such as furosemide, which are used in the hospital, and chronically to manage fluid balance, two other diuretic drugs may be used in selected patients with HF with moderate-to-severe forms of HF. Spironolactone (Aldactone) and eplerenone (Inspra) are diuretic drugs that work by a mechanism different from that of furosemide, and, unlike other diuretic agents, have been shown to improve survival in selected patients with HF. Although they add to the ability of diuretic drugs to maintain appropriate fluid balance, their major impact is to add to the survival benefit of drugs like ACEIs and β-blockers (see subsequent text). The most important side effect of these added diuretics is their ability to increase the level of potassium in the blood. Because ACE inhibitors or ARBs also have the ability to cause the kidneys to hold on to potassium, serum potassium level should be closely monitored, especially in patients whose kidney function is impaired.

Intravenous drugs that increase the force of contraction in patients with HF are sometimes required in hospitalized patients when more conservative therapy has failed to improve symptoms and blood flow. Dobutamine and milrinone are both

drugs that increase the force with which the heart contracts, and therefore increase the amount of blood to the kidneys, muscles, and other vital organs. These drugs are intended for short-term use—several days—and are effective in improving blood flow, stabilizing blood pressure, and improving symptoms. Because these drugs have a short duration of action, doses can be easily adjusted to the heart pressures that are being closely monitored in severely ill patients. Most patients with HF have poorly contracting ventricles (lower heart chambers). Although it seems logical that drugs which improve the force of contraction of the heart should improve survival, the effect of these drugs is to improve symptoms and restore normal pressures in the circulation, rather than to benefit survival. The major side effect of dobutamine and milrinone include increased heart rate and heart rhythm disturbances. These potential side effects are closely monitored in patients in intensive care units. In rare cases, dobutamine may be used as an intermittent outpatient infusion to relieve symptoms in patients with severe HF who are not candidates for heart transplants or implantable heart pumps.

The only oral drug used in HF to increase the force of contraction is digoxin. The drug, used for more than 200 years in the treatment of HF, is much less powerful than agents such as dobutamine or milrinone. There are two circumstances in which digoxin may be used in HF. In hospitalized patients whose HF is complicated by the cardiac rhythm disturbance, atrial fibrillation, a rhythm disturbance of the upper chambers of the heart, digoxin may be used with other drugs to reduce pulse rate. In patients with chronic HF, digoxin may be added to other chronic HF medications to improve symptoms of exercise intolerance and to decrease the rate of hospitalizations for HF symptoms. Digoxin must be administered at lower dose or less frequently (every other day) to patients whose HF is complicated by reduced kidney function. Loss of appetite, nausea, and changes in heart rhythm are side effects that should be monitored in patients receiving digoxin therapy.

Nitroglycerin and nitroprusside are intravenous drugs that dilate arteries and/or veins and may also be used in patients with severe HF. By relaxing arteries, more blood can be ejected from the heart, increasing blood flow to vital organs. Because these drugs have the potential to lower blood pressure in patients whose heart function is already compromised, they must be administered under close supervision, making sure that blood flow is improved while blood pressure is maintained. Fortunately, both nitroprusside and nitroglycerin are very short-acting drugs, whose doses can be quickly altered if

necessary. Because nitroprusside has some side effects that occur more commonly in patients whose kidneys are not functioning normally, some physicians prefer nitroglycerin in such patients. Because nitroprusside is better able to dilate arteries than nitroglycerin, it may be preferred in patients with normal kidney function. Nitroglycerin dilates veins, to a greater extent than arteries, and is especially useful in patients with significant shortness of breath due to fluid accumulation in the lungs, and in patients with coronary artery disease, who may be experiencing chest pain associated with their HF symptoms.

DRUGS FOR CHRONIC HEART FAILURE

Most drugs used for the treatment of chronic HF will be continued when patients are hospitalized. At times during a patient's hospitalization, especially if the blood pressure decreases, or the kidney function worsens, these drugs may be withheld for short periods of time. However, once the patient's symptoms and vital organ function (especially kidneys) have improved, these agents will be restarted before discharge from the hospital.

ACEIs (lisinopril and others) are drugs that relax (dilate) blood vessels, making it easier for the heart to eject blood into the circulation. They thereby decrease the amount of work that the heart has to perform to provide adequate blood flow to vital organs and muscles. Most importantly, these drugs reduce the rate of deterioration of heart function responsible for the progression of HF, and prolong survival. Patients with HF and their caretakers should understand that although most patients experience some symptom improvement, continued compliance with the medication is critical, even in those whose symptoms do not improve, or improve only slightly, because the drugs prolong life. About 10% of patients experience a dry cough with ACEI therapy. The cough may occur at any time during therapy, and the patient's caretaker may notice the symptoms before the patient. Should the cough become bothersome, replacing the ACEI with an ARB will provide the same benefit without the associated cough. Many HF experts, however, prefer ACEIs as first-line therapy for HF. Rarely, patients may experience swelling of the lips, tongue, or throat from ACEIs. This reaction is a medical emergency and the patient should be taken to an emergency department for treatment to make sure that the airway is not blocked.

ARBs provide similar benefit for patients with HF, but are generally reserved

for patients who do not tolerate ACEIs. The incidence of swelling of the lips and throat is lower than with ACEIs, but there are rare cases of such swelling in patients receiving ARBs who had previous reactions with ACEIs. Patients receiving ACEIs of ARBs will require monitoring of blood pressure, kidney function, and potassium levels in the blood.

Similar to ACEIs, β-blocker drugs are an important part of the treatment of chronic HF. β-Blockers work in HF by preventing chemicals produced by the nervous system from interacting with heart muscle. This interaction is partially responsible for the chronic decrease in pump function with progression of symptoms experienced by patients with HF. β-Blockers, like ACE inhibitors and ARBs, may also be used to treat high blood pressure, but their use in HF is not primarily directed at blood pressure. Like ACEIs, β-blockers prevent the progression of pump function loss, improve survival, and, for most patients, improve exercise tolerance and other symptoms of HF. Also similar to ACEI therapy, lack of symptom improvement should not cause patients to stop taking the drug, because it also prolongs life. For patients with new-onset HF, β-blockers will be started at a low dose, whether the patient is in the hospital or is treated as an outpatient. However, β-blocker therapy will not be started until the patient's HF symptoms, especially fluid overload, have been treated, and the patient is considered stable. The dose of β-blocker will be gradually increased toward a maximum target dose no more frequently than every 2 weeks, provided no adverse effects are noticed. The most important β-blocker side effects are excessive slowing of heart rate or reduction of blood pressure, producing symptoms of dizziness or lightheadedness. Other side effects may be observed in patients with diseases such as asthma or diabetes. Patients with asthma may experience shortness of breath or wheezing. This side effect can be minimized with certain β-blocker drugs such as metoprolol (Toprol), but may still occur and should be closely monitored. Diabetic patients, especially those receiving insulin, should closely monitor their blood sugars at home since β-blockers may either increase or decrease blood sugar. In addition, these drugs may interfere with a patient's ability to recognize the symptoms of low blood sugar. Sweating and change in mental status may still occur, but the patient may not experience tremor, rapid heart rate, or anxiety typically observed with low blood sugar in the absence of β-blockers. β-Blockers should not be discontinued abruptly without close medical supervision because of the risk of heart attack or serious heart rhythm disturbances.

The combination of hydralazine and isosorbide, when added to standard

ACEI, β-blocker, and diuretic therapy in African-American patients has been shown to improve survival, reduce hospitalizations, and improve quality of life in patients with moderate-to-severe HF. These drugs relax arteries (hydralazine) and veins (isosorbide), improving blood flow, decreasing the work of the heart, and possibly preventing changes in the structure of the heart muscle associated with HF. This drug combination is available as a single fixed combination dosage form (Bidil) or as separate drug entities, which are less costly. A significant disadvantage of the combination is the necessity of administering the drugs 3 times a day. Because most drug therapies for HF are administered once or twice a day, the addition of this combination may challenge the likelihood of successful compliance. The incidence of side effects with this combination is also higher than with most other HF regimens. Headache, dizziness, and gastrointestinal distress increase with dose and are fairly common. Dosage should be gradually increased toward the target maximum dose (hydralazine 75 mg and isosorbide 40 mg 3 times daily) or to a dose which is tolerated by the patient.

There are a number of drugs that should be avoided in patients with HF. Most of these drugs are only available by prescription, and will be known by the physician. These include some drugs used for high blood pressure, diabetes, heart rhythm disturbances, and arthritis. Patients must be aware that some over-the-counter medications have the potential to worsen the symptoms of HF. Most important among these is NSAIDs such as ibuprofen (Motrin), naproxen (Aleve, Naprosyn) and similar drugs for pain and inflammation. Acetaminophen (Tylenol) in appropriate doses is safer. NSAIDs may cause salt and water retention, leading to edema (swelling), worsening shortness of breath, and to a decrease in kidney function. In addition, many herbal products including ginseng, licorice, and St. John wart should be avoided in patients with HF. It is best to consult with the pharmacist or physician before adding any new over-the-counter medication or herbal preparation to the prescribed regimen. Patients with HF are commonly prescribed complicated drug therapy regimens, and have other medical conditions related to heart disease including diabetes, high cholesterol, high blood pressure, or others. Behaviors that improve drug therapy compliance can help reduce the need for hospitalizations. Patients should always keep a list of their current drug therapy regimen with them, especially when visiting health care providers or on admission to the hospital.

Pathway for the Management of Sleep Apnea in the Cardiac Patient

EPIDEMIOLOGY

Sleep-disordered breathing is a highly prevalent medical condition that is currently estimated to affect 5% to 10% of the general population, regardless of race and ethnicity; almost two-thirds of these are underdiagnosed.[1] More than 80% of patients with moderate-to-severe obstructive sleep apnea (OSA) have not been diagnosed by their health care providers.[2, 3] Undiagnosed sleep apnea leads to increased morbidity and mortality, particularly related to increased incidence of cardiovascular events.[4] The cost of untreated OSA is currently estimated to reach $3.4 billion.[5] It is therefore imperative that we identify patient population at high risk for sleep apnea and refer them to the appropriate therapy as early as possible.

SLEEP DISORDERS

OBSTRUCTIVE SLEEP APNEA

OSA is a highly prevalent disorder with an estimated prevalence 3% to 7% in

men and 2% to 5% in women.[6] It is characterized by repetitive episodes of airflow cessation (apnea) or reduction (hypopnea) despite persistent thoracic and abdominal respiratory effort, likely due to collapse of the pharyngeal airway that occurs during sleep.[7] This collapse generally occurs posterior to the tongue, uvula, and soft palate. These episodes result in hypoventilation as well as hypoxemia, and provoke awakenings (recurrent arousals) that restore pharyngeal dilator muscle tone and airflow. OSA is generally defined as five or more apneas and/or hypopneas per hour of sleep (Apnea-Hypopnea Index [AHI] > 5) assessed by a cardiorespiratory or full polysomnography (PSG) recording. Obstructive sleep apnea syndrome (OSAS), on the other hand, is defined as an AHI ≥ 5 accompanied by either excessive daytime sleepiness or two or more of the following symptoms such as witnessed apneas, recurrent awakenings, gasping for air, bed partners complaining of excessive snoring, waking unrefreshed, morning headache, daytime fatigue, or impaired concentration or memory.[8] Recurrent episodes throughout the night lead to frequent nocturnal awakenings, resulting in excessive daytime somnolence,[9] which is often the presenting complaint.

CENTRAL SLEEP APNEA

Central sleep apnea (CSA) is common, although less prevalent in the general population than OSA. In a population-based study that included 5804 community-dwelling adults aged 40 years and older, the overall prevalence of CSA on PSG was 0.9%.[10] Approximately half of the CSA cases were associated with Cheyne–Stokes breathing.[11] While the International Classification of Sleep Disorders identifies six different forms of CSA,[12] in general CSA is caused by a loss of ventilatory drive, either due to hyperventilation or hypoventilation leading to cessation of ventilation during sleep. Post-hypocapnia hyperventilation is the underlying pathophysiologic mechanism for central apnea associated with congestive heart failure (HF), high-altitude sickness, and primary CSA. These patients chronically hyperventilate in association with hypocapnia during wake and sleep and demonstrate increased chemoresponsiveness and sleep state instability. CSA due to hypoventilation results from the removal of the wakefulness stimulus to breathe in patients with compromised neuromuscular ventilatory control. Chronic ventilatory failure due to neuromuscular disease or chest wall disease may manifest with central apneas or hypopneas, at sleep onset or during phasic rapid eye movement (REM) sleep.

This is typically noted in patients with central nervous system disease, neuromuscular disease, or severe abnormalities in pulmonary mechanics.[13] The apnea episode is 10 seconds or longer in the absence of a respiratory drive, and five or more events occurring in 1 hour are considered abnormal. The diagnostic criteria for CSA depend on the etiology. A diagnosis of primary CSA requires four findings: five or more central apneas/hypopneas per hour of sleep on PSG in the absence of Cheyne–Stokes breathing; patient reports sleepiness, awakening with shortness of breath, witnessed apneas or insomnia; no evidence of daytime or nocturnal hypoventilation; and, finally, absence of a concurrent sleep disorder, medical or neurologic disorder, or substance use disorder than can better explain the patient's symptoms. CSA associated with Cheyne–Stokes respirations, which is typically characterized by an absence of air flow and respiratory effort followed by hyperventilation in a crescendo–decrescendo pattern and most often observed in patients with congestive HF.[14] Furthermore, obstructive and central apnea episodes can occur together in this condition.[15] Diminished upper airway muscle activation at a ventilatory nadir can result in pharyngeal collapse leading to obstruction.

The severity of sleep apnea is quantified using the AHI, which measures the number of episodes/hour. Mild sleep apnea is defined as AHI of 5 to 14 episodes/hour, moderate as 15 to 29, and severe sleep apnea as 30 or more episodes/hour.[16]

CARDIOVASCULAR CONSEQUENCES OF SLEEP APNEA

Prevalence of OSA is noted to be two to three times higher in patients with cardiovascular disease.[17] There is accumulating evidence linking atrial fibrillation,[18–20] hypertension,[21, 22] HF,[23, 24] and stroke[25] to sleep apnea. It is unclear if these conditions coexist or if a true causative relationship exists. Prior studies have shown that patients with OSA who were treated conservatively had increased mortality, with most deaths being cardiovascular in origin.[26–28]

There is a bidirectional relationship between OSA and weight gain; up to 80% of patients with sleep apnea are obese, which results in an anatomically small airway leading to recurrent pharyngeal collapse during sleep. However, OSA can also cause or worsen obesity by a number of proposed mechanisms. Frequent nocturnal arousals lead to daytime somnolence, which results in the body

craving caffeine and high-calorie sugary foods. These cravings are mediated by the hormone leptin, which is produced by adipose tissue.[29] In addition, patients with OSA have decreased REM sleep, during which the body burns the most calories. There is a significant association between insulin resistance and OSA as well as with atherosclerosis, advocating that the metabolic disturbances may well be a significant link between OSA and cardiovascular disease.[30] Moreover, reports from sleep clinics demonstrated the association between the degree of insulin resistance and severity of OSA.[31] Indeed, those patients with insulin resistance have 5-fold increase in the risk of developing diabetes mellitus, which in turn aggravates obesity.[32]

The prevalence of hypertension in sleep clinics is estimated to be 30% to 50%[33]; likewise, it is estimated that about 50% to 80% of patients with hypertension have OSA.[34, 35] Intermittent hypoxemia, sympathetic stimulation, chemoreceptor activation leading to systemic vasoconstriction, and the renin–angiotensin–aldosterone system have been linked to the development of hypertension in OSA.[36] OSA episodes produce surges in systolic and diastolic pressure that keep mean blood pressure (BP) levels elevated at night, resulting in blunted fall in nocturnal BP, or "nondipping phenomena."[37] In many patients, BP remains elevated during the daytime, when breathing is normal. Contributors to this diurnal pattern of hypertension include sympathetic nervous system overactivity and alterations in vascular function and structure caused by oxidant stress and inflammation.[35]

The prevalence of OSA in patients with HF ranges from 12% to 53%, with a higher incidence of Cheyne–Stokes respiration. Recurrent hypoxemia, sympathetic stimulation, and left ventricular (LV) wall stress due to recurrent apnea episodes, over time can lead to LV hypertrophy, dilatation, and systolic dysfunction.[38] OSA in HF has been shown to increase mortality.[39] Thus, a bidirectional relationship may exist between sleep apnea and HF, typically observed by a gradual shift from predominantly obstructive apneas at the beginning of the night to predominantly central apneas toward its end.[40] Salt and fluid retention in HF can contribute to the pathogenesis of OSA and CSA, and effects of the latter can worsen HF. This pathologic relationship may be attributed to marked neurohumoral activation, surges in BP and heart rate (HR), and a greater propensity to lethal arrhythmia induced by CSA.[41, 42]

Excessive daytime somnolence is the most common symptom of OSA. Recurrent episodes of nocturnal hypoxemia lead to recurrent arousals. This

daytime somnolence frequently results in work-related and motor vehicle accidents. Approximately 25% of patients with untreated OSA report falling asleep while driving. [43]

Cardiac arrhythmias are common in patients with sleep-disordered breathing due to alterations in sympathetic and parasympathetic activity that occurs during periods of hypoxemia.[44, 45] Bradycardia, first- to third-degree atrioventricular (AV) conduction block and sinoatrial node block during apneas have been reported in patients with OSA. Becker et al.[46] reported AV-block II–III and/or sinus arrest in 7% of an unselected group of patients with OSA and the prevalence was even higher (20%) in the subgroup with severe OSA. Transmural and intrathoracic pressure gradient changes lead to left atrial enlargement, which has also been linked to the development of atrial fibrillation.[47] The prevalence of atrial fibrillation is significantly higher in patients with OSA than that of the general population. According to the Sleep Heart Study, patients with severe OSA were four times more likely to have atrial fibrillation.[44] Untreated OSA has been shown in several studies to decrease the likelihood of successful rhythm control strategies; likewise, patients who undergo electrical cardioversion and those with untreated OSA are two times more likely to have atrial fibrillation recurrence at 1 year as compared to those who use continuous positive airway pressure (CPAP).[48] Antiarrhythmic drugs have also been shown to be less effective in patients with severe OSA.[49] Although OSA has been shown to increase the risk of atrial fibrillation recurrence after radiofrequency catheter ablation by 40%,[50] its treatment reduces the risk of atrial fibrillation recurrence after catheter ablation.[51]

The higher occurrence of life-threatening ventricular arrhythmias among patients with OSA[52] was suggested to contribute to the abnormal circadian pattern of sudden death in these patients. Gami *et al.53,54* showed a peak in sudden death from cardiac causes during sleeping hours, namely, 10 PM to 6 AM in patients with OSA in contrast to the traditional window of cardiovascular vulnerability which is 6 and 11 AM.

The Busselton Health Study[55] as well as an 18-year follow-up of the Wisconsin Sleep Cohort[56] showed that sleep apnea is an independent risk factor for all-cause mortality. OSA severity, particularly an AHI ≥ 20 as well as the degree of nocturnal hypoxemia have been shown to be directly related to the risk of sudden cardiac death.[54]

Numerous studies linked OSA to an increased risk of myocardial infarction[57,

[58] which is likely related to the intermittent hypoxemia, systemic vasoconstriction, unpredicted increase in BP, and the resultant changes in intrathoracic and intramural pressures.[59, 60] A 7-year prospective study demonstrated that untreated OSA was associated with a 5-fold increase of coronary artery disease (CAD) independent of age, sex, BP, diabetes, or smoking.[61] It has also been suggested that increased oxygen demand and reduced oxygen supply following OSA may trigger an attack of angina pectoris in patients with CAD, who already have reduced coronary flow reserve.[62]

Finally, OSA also appears to be linked to an increased risk of stroke, independent of other cardiovascular risk factors.[63] Nocturnal fluctuations in BP, nocturnal hypoxemia, reductions in cerebral blood flow, and systemic vasoconstriction appear to contribute to the development of stroke.[64] Habitual snoring and excessive daytime somnolence may also contribute to the risk of developing wake-up stroke.[65]

PATHWAY FOR THE MANAGEMENT OF SLEEP APNEA IN THE CARDIAC PATIENT

Owing to the high incidence of sleep apnea in patients with cardiovascular disease and the increased morbidity and mortality associated with these conditions, we propose a Sleep Apnea Pathway (SAP, **Figure 20.1**) to correctly identify and triage these patients to the appropriate therapy.

Pathway for Management of Sleep Apnea in Cardiology

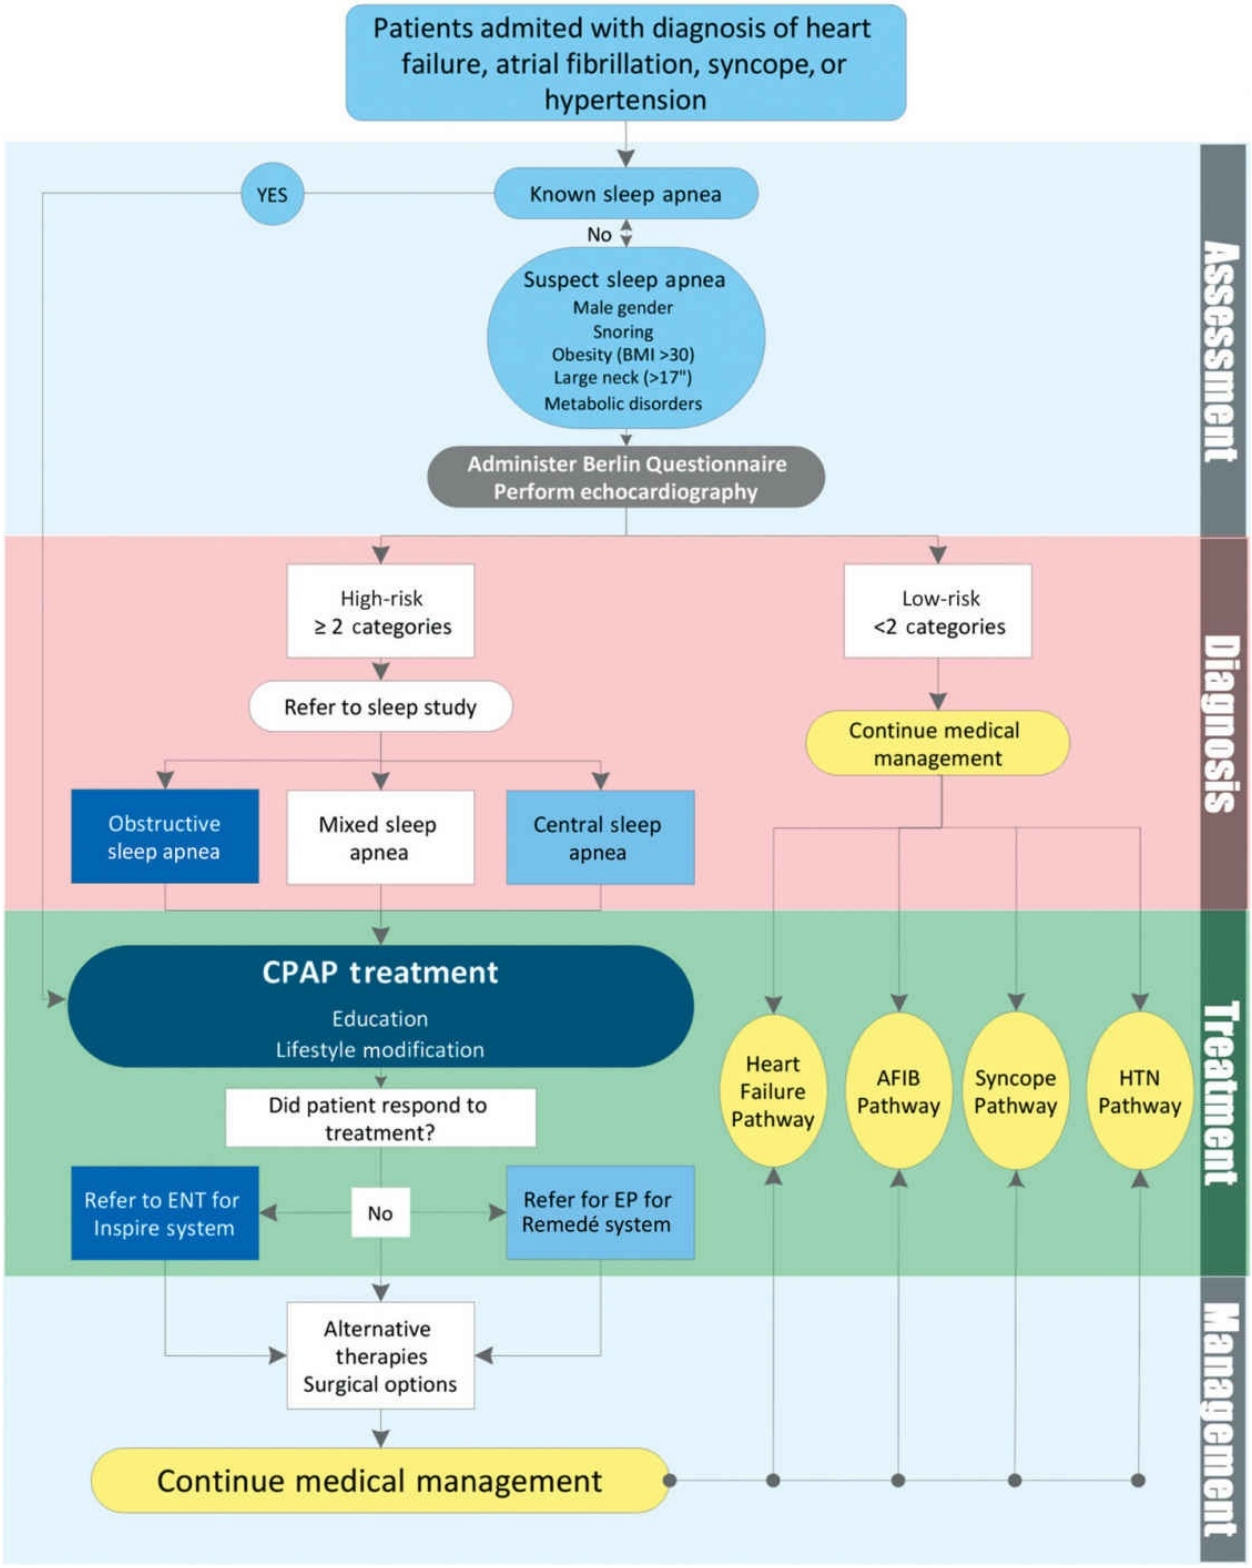

FIGURE 20.1 Pathway for the management of sleep apnea in cardiology. AFIB, atrial fibrillation; BMI, body mass index; CPAP, continuous positive airway pressure; ENT, ear-nose-throat; EP, electrophysiologist; HTN, hypertension.

STEP A: ASSESSMENT

All patients admitted with diagnosis of atrial fibrillation, syncope, hypertension, and HF should be evaluated for sleep apnea. Those patients with known sleep apnea diagnosis should be initiated on CPAP therapy according to their home setting. Those with suspected sleep apnea based on the following criteria, male gender, body mass index (BMI) > 30, snoring, neck circumference >17 inches, and metabolic disorders such as hyperlipidemia and insulin resistance will be screened by administrating the Berlin Questionnaire (BQ). We advise to perform an echocardiography as well on admission to evaluate heart function, pulmonary pressure, and any valvular disease.

STEP B: DIAGNOSIS

There are a number of tools available to screen for sleep apnea. These questionnaires are the BQ, the Epworth Sleepiness Scale (ESS), STOP, and STOP-Bang. These four questionnaires were compared in a cross-sectional study to determine effectiveness. The BQ, STOP, and STOP-Bang were shown to have the highest sensitivity, whereas the ESS was found to have higher specificity.[66] We have selected the BQ (**Figure 20.2**) as the screening tool for our SAP as it has shown better accuracy and is simpler to classify patients.[67] The BQ has also been shown to be predictive of those patients who are at higher risk for sleep apnea, limiting unnecessary PSG testing in patients who are lower risk and triaging them appropriately to medical management.[68] The BQ includes questions regarding snoring, daytime somnolence, hypertension, and BMI. The patient's family or bed partner is often used to confirm responses.[69]

Berlin Questionnaire

Sleep Evaluation in Primary Care

Please Complete the following:

height _____ age _____

weight _____ male/female _____

Category 1

1. Do you snore?

- ☐ yes
- ☐ no
- ☐ don't know

If you snore:

2. Your snoring is?

- ☐ slightly louder than breathing
- ☐ as loud as talking
- ☐ louder than talking
- ☐ very loud. Can be heard in adjacent rooms.

3. How often do you snore?

- ☐ nearly every day
- ☐ 3-4 times a week
- ☐ 1-2 times a week
- ☐ 1-2 times a month
- ☐ never or nearly never

4. Has your snoring ever bothered other people?

- ☐ yes
- ☐ no

5. Has anyone noticed that you quit breathing during your sleep?

- ☐ nearly every day
- ☐ 3-4 times a week
- ☐ 1-2 times a week
- ☐ 1-2 times a month
- ☐ never or nearly never

Category 2

6. How often do you feel tired or fatigued after your sleep?

- ☐ nearly every day
- ☐ 3-4 times a week
- ☐ 1-2 times a week
- ☐ 1-2 times a month
- ☐ never or nearly never

7. During your waketime, do you feel tired, fatigued or not up to par?

- ☐ nearly every day
- ☐ 3-4 times a week
- ☐ 1-2 times a week
- ☐ 1-2 times a month
- ☐ never or nearly never

8. Have you ever nodded off or fallen asleep while driving a vehicle?

- ☐ yes
- ☐ no

if yes, how often does it occur?

- ☐ nearly every day
- ☐ 3-4 times a week
- ☐ 1-2 times a week
- ☐ 1-2 times a month
- ☐ never or nearly never

Category 3

9. Do you have high blood pressure?

- ☐ yes
- ☐ no
- ☐ don't know

10. BMI > 30 (*See Chart*)

- ☐ yes
- ☐ no

Scoring Questions: Any answer within box outline is a positive response.

Scoring categories:

- ☐ Category 1 is positive with 2 or more positive responses to questions 1-5
- ☐ Category 2 is positive with 2 or more positive responses to questions 6-8
- ☐ Category 3 is positive with 1 positive responses to questions 9-10

Final Result: If 2 or more possible categories are positive, you have a high likelihood of sleep apnea.

Name _____

Address _____

_____

FIGURE 20.2 Berlin Questionnaire.

According to the BQ results, patients will be classified as high- and low-risk patients. High-risk patients are those who score positive in two or more categories, whereas low-risk patients only score positive in one category.

Patients who are deemed a high risk for sleep apnea achieve a score >2 on the BQ. These high-risk patients should then be referred for PSG testing. An AHI of 15 or an AHI of 5 or higher in conjunction with symptoms of daytime somnolence, unrefreshing sleep, waking up choking or gasping for breath, or bed partners confirming snoring or breathing interruptions during sleep warrants treatment. The test will classify patients as being pure OSA or CSA or a mixed picture. Regardless of the diagnosis, all patients should be considered for a treatment trial with CPAP therapy.

TREATMENT

Those patients who score <2 on the BQ are deemed low risk for sleep apnea. They should therefore be deferred to continue medical management of their comorbidities, such as atrial fibrillation,[70] hypertension,[71] syncope,[72] or HF,[73] according to our published pathways.

Although treatment with CPAP is the mainstay of treatment for sleep apnea, education and certain lifestyle modifications in concert with CPAP therapy have shown to be very effective.[74] Patient education program components are listed in **Table 20.1**. Behavioral treatment options include weight loss, exercise, positional therapy, and avoidance of alcohol and sedatives before bedtime; these have shown to decrease the upper airway muscle relaxation that occurs and can precipitate apnea episodes. Side sleeping has also been shown to decrease the upper airway collapse that occurs.[75] A study from Karolinksa Institute in Sweden showed that an average weight loss of 40 lb resulted in a 58% reduction in sleep apnea symptoms and decreased apnea episodes by 21/hour.[76]

TABLE 20.1 Components of Patient Education Programs

Findings of study, severity of disease
Pathophysiology of sleep apnea
Explanation of natural course and associated disorders
Risk factor identification, explanation of exacerbating factors, and risk factor modifications
Genetic testing when indicated
Treatment options
What to expect from treatment
Outline the patient's role in treatment, address concerns, and set goals

Consequences of untreated disease
Drowsy driving/sleepiness counseling

OSA treatment using CPAP has been shown to acutely decrease BP and nocturnal sympathetic tone. Several studies have shown that nocturnal CPAP can decrease daytime BP by approximately 2 mm Hg and seems to have the greatest effect in patients with uncontrolled hypertension and severe OSA.[77] Use of CPAP in sleep apnea has been shown to attenuate intrathoracic pressure changes and thus decrease preload, afterload, BP, and HR.[78, 79] Kaneko et al.[77] observed that 1 month after initiation of CPAP, the LV ejection fraction increased by 9% in patients with HF. Two observational studies have been performed comparing treated to untreated OSA patients; one study showed a 2-fold higher increase in mortality in the untreated group,[76] whereas the other showed a greater hospitalization-free survival in the treated group.

Treatment of CSA is more controversial; however, CPAP is still often employed to treat this condition. Multiple trials have been performed evaluating the role of CPAP in CSA. Canadian Positive Airway Pressure Trial for Patients With Congestive Heart Failure and Central Sleep Apnea (CANPAP) was a study that included 258 patients. Use of CPAP in this population reduced nocturnal desaturations and showed a modest improvement in LV ejection fraction.[81] However at 2 years, there were no significant differences in outcomes between the treated and untreated groups.

Mixed or complex sleep apnea exhibits signs of OSA; however, on initiation of CPAP therapy, central apneas persist or emerge.[80] Variable positive airway pressure (VPAP) is often used to treat mixed apnea.[82] VPAP normalizes breathing and suppresses CSA and Cheyne–Stokes respirations.

Failure of Continuous Positive Airway Pressure Therapy

If patients with OSA fail CPAP therapy, then we recommend referral to ear-nose-throat (ENT) specialists for consideration of implantation of the Inspire system (**Figure 20.3**). The Inspire system is an implantable device that senses breathing patterns and maintains airway patency during sleep by delivering stimulation to targeted airway muscles. The system consists of three implanted components including a small generator, breathing sensor lead, and stimulation lead, all controlled with the small handheld Inspire sleep remote. Patients who qualify for the Inspire system must have moderate-to-severe OSA (AHI 20 to 65, with <25% central apnea), be unable to use CPAP, and be free of complete concentric

collapse of the palate. Long-term study outcomes in patients using the Inspire system showed a 78% reduction in apnea–hypopnea events from baseline and an 80% reduction in oxygen desaturation levels.[83] In addition, patients had a clinically significant improvement in quality of life, including daytime somnolence that was measured by the ESS. Patients also showed a high adherence rate to therapy and significant improvement in important sleep-related quality-of-life outcome measures that are maintained across a 2-year follow-up period.[84, 85]

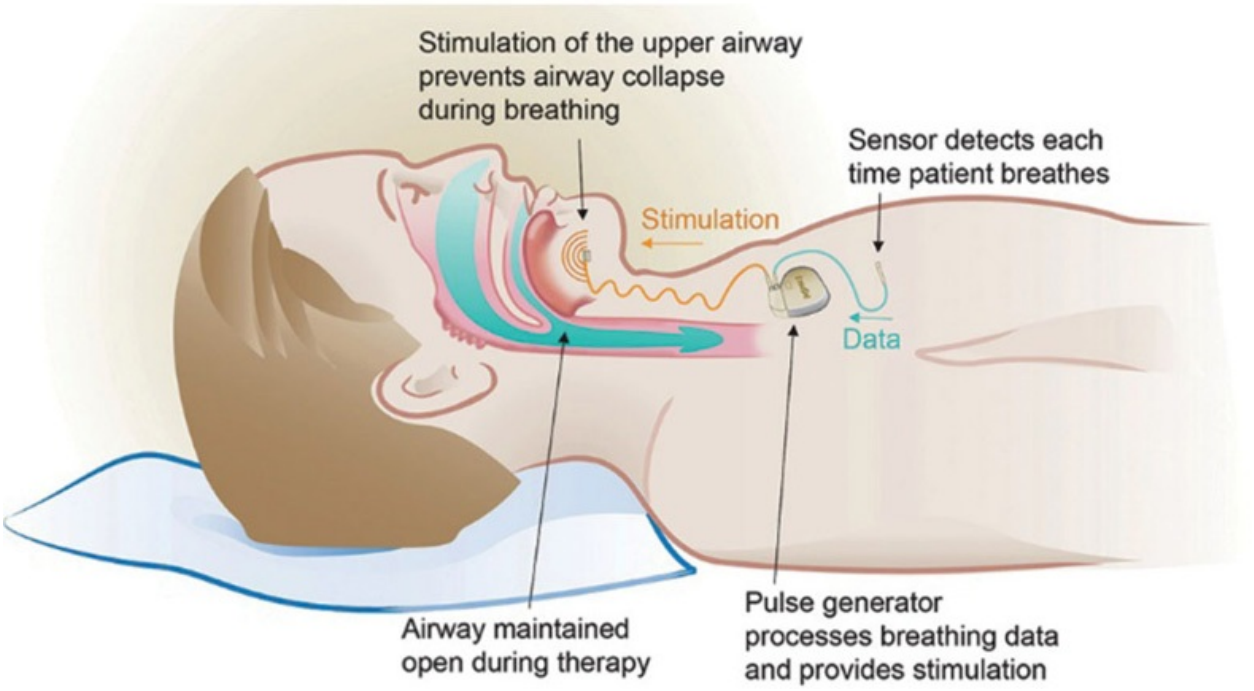

FIGURE 20.3 Inspire system.

Patients with CSA who fail CPAP therapy should be referred for consideration to the Remedé system. The system (**Figure 20.4**) is a phrenic nerve stimulator designed to restore the body's normal breathing pattern, which results in better oxygenation and less activation of the sympathetic nervous system. The settings of the device are monitored by the physician and can be changed remotely. Patients who are studied for indication of the Remedé system include those with AHI ≥ 20, Central Apnea Index (CAI) at least 50% of all apneas with at least 30 central apnea events, and Obstructive Apnea Index ≤ 20% of the total AHI. In the pilot study of the Remedé system, performed to evaluate outcomes at 3 and 6

months, CAI decreased by 84%, AHI decreased by 55%, Oxygen Desaturation Index improved by 52%, nocturnal arousals decreased by 35%, and REM by 29%.[86] Data published from the Remede–System Pivotal Trial Study Group showed that a significantly higher proportion of patients in the treatment versus control group achieved a ≥50% AHI reduction, and 91% 12-month freedom from serious adverse events related to the implant procedure, Remede–system, or delivered therapy.[87]

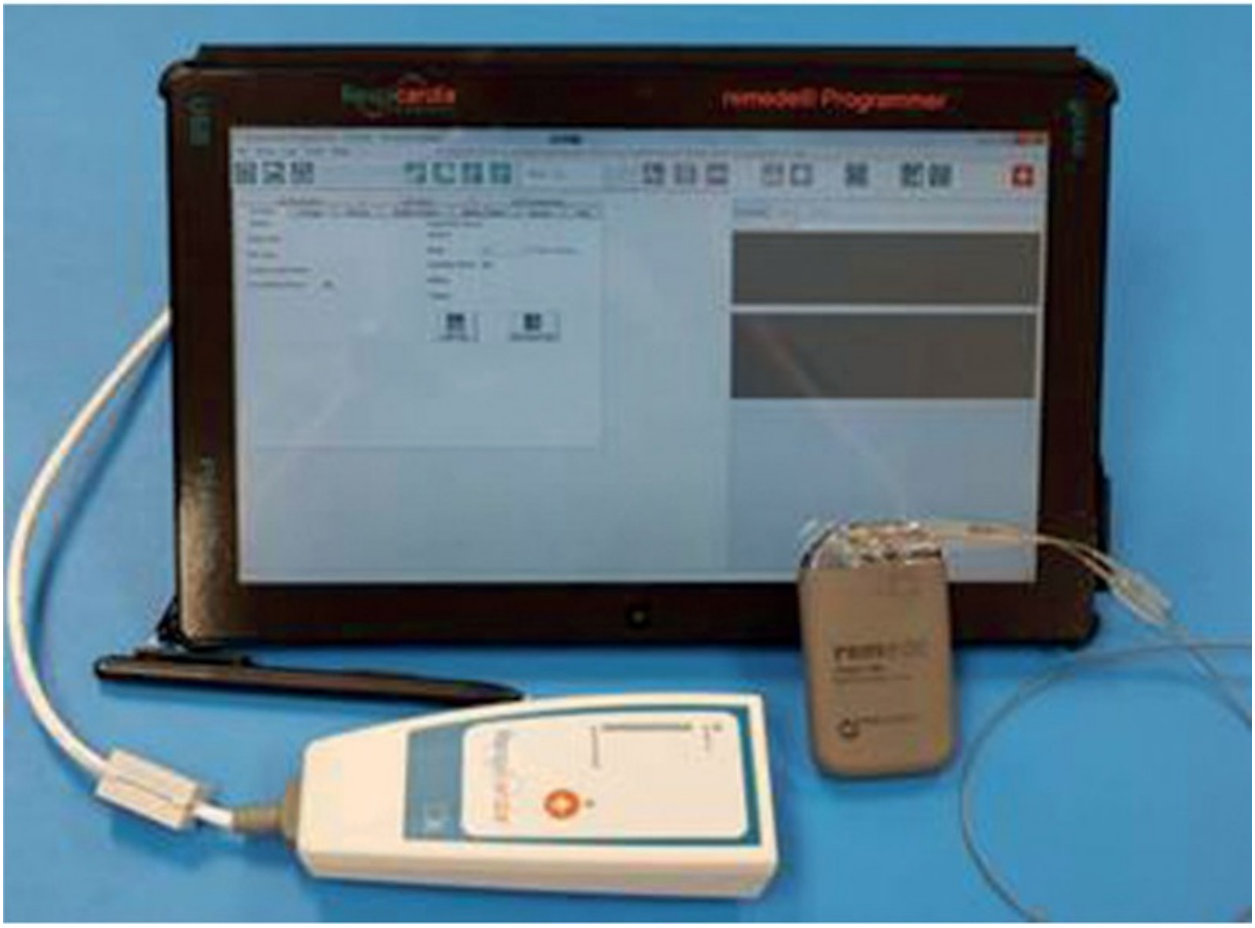

FIGURE 20.4 The Remedé system.

The findings of both the clinical trials of the Inspire system and the Remede–system indicate that by reducing AHI episodes and improving nocturnal oxygen levels, these novel devices may be helpful in reducing cardiovascular morbidity and mortality in those patients who fail CPAP therapy.

ALTERNATIVE AND SURGICAL TREATMENTS FOR THOSE WHO FAIL NOVEL THERAPIES

Oral Devices

There are currently over 100 FDA-approved dental devices that are available to patients to help relieve obstruction in sleep apnea.[88] These devices are designed to hold the lower jaw forward to prevent pharyngeal obstruction during sleep. This treatment is excellent for reducing snoring, although the effect on OSA is sometimes more limited. As a result, dental devices are best used for mild cases of OSA when relief of snoring is the main goal. Failure to tolerate and accept CPAP is another indication for dental devices. Although dental devices are not as effective as CPAP for OSA, some patients prefer a dental device to CPAP. Side effects of dental devices are generally minor, but may include changes to the bite with prolonged use.

Surgical Options

Surgery is an alternative therapy for patients who cannot tolerate or do not improve with nonsurgical treatments such as CPAP or oral devices. Surgery can also be used in combination with other nonsurgical treatments.

There are different types of surgical procedures that can be used in OSA to reshape structures or reposition bone and soft tissue.

1. Uvulopalatopharyngoplasty (UPPP) removes the uvula and excessive tissue in the throat, including the tonsils, if present, to help relieve upper airway obstruction. UPPP is the most common surgical procedure in OSA, but it has variable outcomes. The overall success rate is approximately 50%, with success defined as a 50% reduction in AHI and a post-surgical AHI reduction to less than 20 events/hour.[89] New UPPP variants have been showing more promise in improving OSA outcomes in ongoing clinical trials.
2. Other procedures, such as maxillomandibular advancement (MMA) and tracheotomy,[90] address both the upper and lower pharyngeal airway more globally. These two procedures have been shown to have high success rates and improved PSG outcomes. MMA may have a higher success rate, particularly in people with an abnormal jaw, but it is the most complicated procedure and is typically reserved for patients with severe OSA who have

failed prior targeted surgical attempts.[91] In a meta-analysis that included 627 patients undergoing MMA, the overall success rate, which was defined as an AHI <20 events/hour and reduced by at least 50%, was 86%. Cure of OSA, which was defined as an AHI less than five events per hour was achieved in 43% of patients.[92]

All surgical treatments require discussions about the goals of treatment, the expected outcomes, and potential complications.

SUMMARY

Sleep-disordered breathing is a highly prevalent medical condition, particularly in cardiac patients. Utilizing a system evidence-based pathway can identify patients who require treatment and direct them to the appropriate management plan.

Patient and Family Information for: THE MANAGEMENT OF SLEEP APNEA IN THE CARDIAC PATIENT

Sleep apnea is a very common medical condition that affects 60 million Americans. There are different types of sleep apnea, the most common being obstructive sleep apnea or OSA. OSA is caused by collapse of the upper airway during sleep, leading to obstruction of breathing. Symptoms that suggest that one might have sleep apnea are excessive sleepiness during the day, waking up with headaches, insomnia, and frequent nighttime awakenings. Bed partners may also confirm that there is excessive snoring or periodic episodes of stopping breathing at night. CSA results in a lack of breathing during sleep caused by disrupted signals from the brain to initiate breathing.

Factors that may predispose patients to develop sleep apnea are male gender, obesity, and having a small mouth and throat. Sleep apnea also becomes more common as people age. Sleep apnea is common in patients with high blood pressure (BP), stroke, heart failure (HF), and atrial fibrillation. Undiagnosed and untreated sleep apnea in patients with any of these conditions can result in adverse outcomes. If a physician suspects sleep apnea based on known cardiovascular conditions and the presence of the risk factors previously stated, he may administer the Berlin Questionnaire (BQ) to determine the risk of having sleep apnea.

The BQ is a three-part questionnaire. Section one has five questions that address snoring habits. A bed partner may also be asked to help answer the questions. Section two addresses symptoms of daytime sleepiness. Section three has a question regarding the presence of high BP. The patient will also score a point if he/she is obese and has a BMI of 30 or higher. On the basis of the score, the physician might order a sleep study, also known as PSG testing.

The diagnosis of sleep apnea is confirmed by PSG testing. This is based on how many times per hour the patient stops breathing during the test. If diagnosed with sleep apnea, the physician will likely recommend CPAP for usage at nighttime in conjunction with lifestyle modifications, such as losing weight and avoiding alcohol and sedating medications before sleep. CPAP is a noninvasive method of providing oxygen while asleep. The oxygen is delivered by a face or nasal mask to keep the nasal passages open and to prevent collapse of the airway. Some oral dental devices are also available; however, they are not effective for every patient with sleep apnea.

If the attempt to use CPAP for sleep apnea does not work, there are new and emerging therapies that can be tried depending on the type of sleep apnea the patient has. The Inspire system is a new technology for patients with OSA who fail CPAP therapy. An implanted system, it delivers mild stimulation to important airway muscles to help keep the airway open during sleep. The device is controlled by a small, handheld remote. Patients with central sleep apnea who fail CPAP therapy can be referred for a Remedé system. The Remedé device is placed by a cardiologist in the electrophysiology laboratory. This is a minimally invasive procedure by which the device is placed under the skin and delivers impulses to the muscles that control breathing.

Surgery is also an option for patients who have severe OSA or do not respond or qualify for the abovementioned treatments. UPPP is the most common surgery for OSA and involves removing and repositioning the soft tissues in the throat to help relieve the obstruction that occurs during sleep. These surgeries have been shown to be very effective for some patients in resolving symptoms of sleep apnea. However, it is important that the patient discusses the treatment goals and concerns with the physician to decide what the best treatment option for sleep apnea is.

Bradycardia and Heart Block

Normal heart rate (HR) is considered to range from 60 to 100 beats per minute (bpm). Therefore, bradycardia refers to an HR of 60 bpm or less. Bradycardia may be associated with symptoms such as weakness, fatigue, syncope or near-syncope, dizziness, shortness of breath with exercise, confusion, and symptoms of heart failure. On occasion, however, bradycardia may be asymptomatic. This occurs especially in otherwise healthy, young, athletic subjects and is usually responsive to exercise. Asymptomatic bradycardia can also happen during sleep secondary to reduced sympathetic and increased parasympathetic tone. These types of asymptomatic, physiologic bradycardias almost never warrant aggressive interventions. However, bradycardia due to extremely slow sinus rate or secondary to conduction block is usually pathologic even in the absence of symptoms because it carries a risk for further adverse cardiovascular outcomes.

The management of bradycardia is dependent on the symptom severity and the reversibility of the cause. A stable patient may be observed while being evaluated, but the unstable patient usually requires treatment with positive chronotropic drugs or temporary pacing until a more permanent solution can be employed.

ANATOMIC CONSIDERATION – SINOATRIAL NODE

Anatomically, the sinoartrial node (SAN) lies in the proximity to the junction of

the superior vena cava and the sulcus terminalis, at the high lateral border of the right atrium (RA). Blood supply derives from the SAN branch of the right coronary artery (RCA) in 60% and left circumflex coronary artery (lCx) in 40% of the population. Collateral blood supply is common, which explains the rarity of sinus node infarction.[1] The SAN is densely innervated by both the sympathetic and the parasympathetic (vagus nerve) nervous system. Conduction down to the atria and atrioventricular node (AVN) is through preferential pathways that help in uniform and synchronous activation of the atrial muscle and timely transfer of the generated impulse to the AVN. The main pathways include the anterior internodal tract from which the Bachman bundle separates and courses through the roof of the atria toward the left atrium (LA). The posterior internodal tract ("slow pathway") and the middle internodal tract also preferentially transmit SAN impulses to the AVN.

The AVN is located at the apex of the triangle of Koch in the inferomedial part of the RA and is located anterior and superior to the coronary sinus ostium. It derives its blood supply from a branch of the RCA (in 90% of the population) or the lCx artery. The bundle of His (HB) connects the distal part of the AVN with the bundle branches. It crosses the membranous interventricular septum to the left side and divides into the right bundle branch (RBB) and the left bundle branch (LBB). Blood supply to the HB is dual, both from the left anterior descending (LAD) coronary artery and posterior descending coronary artery. The RBB and the left anterior fascicle branch of the LBB are supplied mainly by septal branches of the LAD coronary artery. The left posterior fascicle, on the other hand, has dual blood supply, both from the LAD and the RCA.

SINUS RHYTHM

When the SAN is the dominant pacemaker of the heart, the sinus rhythm is present. It is characterized by a P wave that is positive (upright) in the inferior leads, and biphasic in lead V1 (first positive deflection from RA activation is followed by a negative deflection from LA activation). The P wave is negative in lead aVR. Leads V2–6 show positive P waves. The duration of the P wave is generally 120 ms (three small boxes) and its amplitude is <0.25 mV (2.5 small boxes). Larger values may indicate atrial pathology (enlargement) or conduction delay in the atria. The consecutive P waves are identical in morphology and the PR intervals are stable from beat to beat. The SAN has an intrinsic automaticity,

but the rate of impulse generation is controlled by the autonomic nervous system. Sympathetic stimulation increases, whereas parasympathetic (vagal) stimulation decreases the SAN firing rate.

SINUS ARRHYTHMIA

Sinus arrhythmia is defined as an irregular sinus rhythm (P-P variation >120 ms), with normal-looking P waves. It is very common and considered to be normal. Differential diagnosis of irregular sinus rate includes wandering atrial pacemaker or frequent premature atrial contractions, both with different P-wave morphologies. Respiratory sinus arrhythmia is the most common type and is related to alteration in the autonomic tone with respiration. Inspiration and expansion of the lung tissue inhibits the parasympathetic tone, thus increasing the sinus rate. This type is usually benign, very common in young individuals but may be associated with obesity and hypertension. In contrast, the effects of respiration on the sinus rate diminish with age and in patients with diabetic neuropathy. Nonrespiratory sinus arrhythmia may be seen in a normal or diseased heart, or may be associated with medications (such as digitalis). Ventriculophasic sinus arrhythmia is typically seen in patients with complete or second-degree heart block. P-P intervals that contain a QRS are shorter in comparison to the following P-P intervals that do not contain a QRS. The mechanism is probably related to increase in stroke volume, which triggers a baroreceptor response and results in widened P-P interval in the following beat.

SINUS NODE DYSFUNCTION

Sinus node dysfunction (SND) is an intrinsic disease of the sinus node and its presentations include the following:

1. Sinus bradycardia (SB), including sinoatrial exit block and sinus pauses
2. Tachycardia-bradycardia syndrome
3. Conversion pauses following termination of atrial arrhythmia
4. Chronotropic incompetence

SB is defined as sinus rate (with normal-appearing P waves) of less than 60

bpm (**Figure 21.1A**. The major causes of SB are depicted in **Table 21.1**. SB may be caused by intrinsic disease of the sinus node or by extrinsic causes, such as medications and metabolic and hormonal changes (see subsequent text).

TABLE 21.1 Major Causes of Sinus Bradycardia

INTRINSIC	EXTRINSIC
Idiopathic degeneration (aging)	Autonomical mediated
Ischemia	Neurocardiogenic syncope
Rheumatic fever	Carotid sinus hypersensitivity
Pericarditis	β-Adrenergic blockers
Infiltrative disease	Calcium channel antagonists
Sarcoidosis	Clonidine
Amyloidosis	Digoxin
	Antiarrhythmic agents
Systemic lupus erythematosus	Parasympathetic agents—pyridostigmine, donepezil
Rheumatoid arthritis	Sympatholytic agents—methyldopa, clonidine
Scleroderma	I_f blockers—ivabradine
Myotonic dystrophy	Lithium
Surgical trauma during cardiac surgery	Hepatitis C drugs—sofosbuvir, daclatasavir
Familial disease	Hypothyroidism
Infectious disease	Hypothermia
Chagas disease	Neurologic disorder
Infectious endocarditis	
Lyme disease	Hypokalemia Hyperkalemia Hypoxia Intracranial hypertension

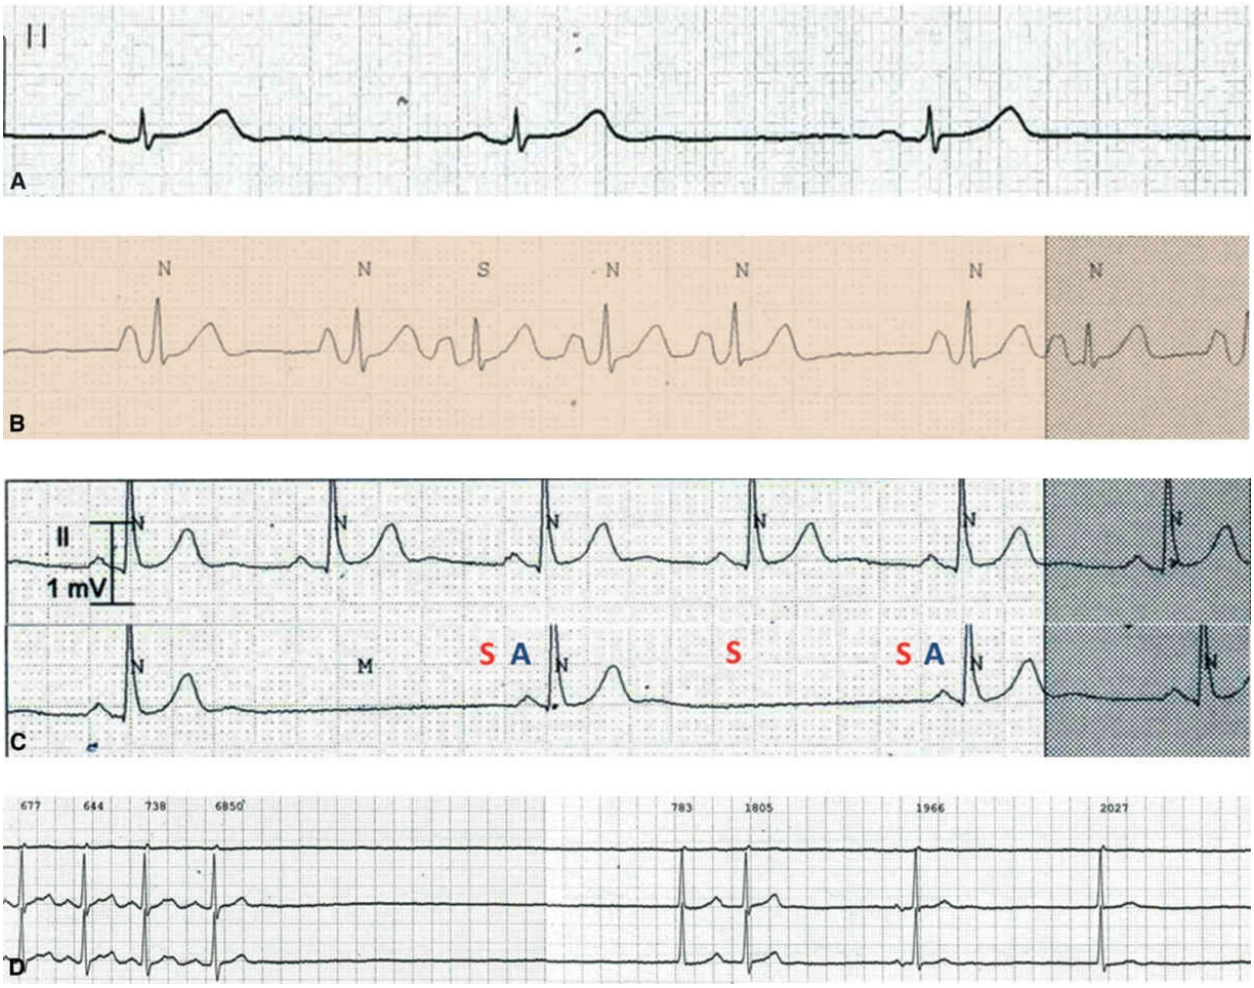

FIGURE 21.1 Sinus node dysfunction. A, Sinus bradycardia of 35 bpm in a young, trained, asymptomatic male. B, Second-degree sinoatrial block, type I (Wenckebach). Note a slight P-P interval prolongation. The pause duration is less than the two preceding P-P intervals. C, Second-degree type II sinoatrial block. The pause duration is exactly twice the regular P-P interval. *S* denotes the expected sinus activity and *A* denotes the atrial activity. D, Conversion pause due to prolonged sinus node recovery time shown in a Holter monitor of a woman with recurrent syncope. Following termination of atrial flutter, a prolonged pause of 6.85 seconds is seen with no P waves, and the first escape beat has no proceeding P wave. Therefore, it is a junctional escape beat.

ETIOLOGY OF SINUS BRADYCARDIA

Increased vagal tone—chronic increase in the parasympathetic tone is typical in trained athletes and during sleep (**Figure 21.1A**). Episodic increase in the vagal tone may occur during vasovagal response. Typically, conduction slowness (prolonged PR interval) and peripheral vascular dilatation also exists in addition to other vagal symptoms (pallor, diaphoresis, nausea), sometimes leading to hypoperfusion of the central nervous system and resultant brief episodes of loss of consciousness. Vagal tone may also be increased by the Valsalva manuever,

applying pressure on the carotid body or globe, cough, and acute myocardial infarction (MI), especially of the inferior wall (also known as the Bezold–Jarisch reflex).

Obstructive sleep apnea may also result in SB and pauses during apneic episodes. A large number of *medications* may cause SB, including sympathetic blockers (beta-blockers, methyldopa, clonidine), parasympathetic agents (digoxin, cholinomimetics), calcium channel antagonists, and antiarrhythmic drugs. Recently, the direct pacemaker-current (*If*) blocker, ivabradine, has been introduced for the treatment of heart failure and inappropriate sinus tachycardia. This medication may also cause SB.

Metabolic derangements that are associated with SB include hypothyroidism and myxedema coma, hypothermia, hypoxia, and hypokalemia. Common *infectious agents* associated with relative SB include *Legionella*, *Salmonella*, and *Trypanosoma cruzi* causing Chagas disease.

SINUS BRADYCARDIA OR PAUSE, SINUS ARREST, AND SINOATRIAL EXIT BLOCK

Sinus pause or arrest results from failure of sinus node impulse generation. It may occur because of intrinsic disease of the SAN, drugs that depress the SAN activity (beta-blockers, anti-arrhythmic drugs) or from increased vagal tone. Sinoatrial exit block occurs because of the failure to conduct the impulse generated by the SAN to the surrounding atrial tissue. On the surface electrocardiogram (ECG), it is manifested as a pause due to the absence of an expected P wave. The P-P cycle is longer than the P-P interval of the underlying sinus rhythm, but it is always less than two consecutive P-P intervals.

Sinoatrial Exit Block

This arrhythmia results from failure of the impulse generated in the sinus node to depolarize the surrounding atrial tissue. It is usually transient. It can occur because of ischemia or myocarditis, or secondary to medications and excessive vagal tone. With first-degree SA exit block, each SAN impulse is conducted to the atria with a delay. This cannot be diagnosed with surface ECG. **Figure 21.1B** shows an example of second-degree SA exit block of Wenckebach type (Mobitz I). The P-P interval slightly prolongs until a pause occurs. The pause is not a multiplication of the regular P-P interval and its duration is less than the two preceding P-P intervals. An escape from a lower pacemaker (i.e. from the AVN)

is often seen, and may result in retrograde conducting P waves with superior axis (negative P waves in II, III, and aVF). In **Figure 21.1C,** expected SAN activity is marked in S, whereas the atrial activity (the P wave) is marked in A. The pause seen is an exact multiplication of the P-P intervals; this is an example of type II second degree SA block.

Conversion Pauses

Following termination of an atrial arrhythmia, the diseased sinus may recover only after a pause (**Figure 21.1D**). Many times the atrial arrhythmia itself is asymptomatic, but the conversion pause can result in prolonged asystole and resultant syncope. Permanent pacemaker placement will eliminate the pauses and enable safe medical treatment for the atrial tachyarrhythmia.

TREATMENT

The treatment of SND depends mainly on symptoms. Asymptomatic SB is common and usually requires no therapy.[2] Symptomatic SND of any type may result in weakness, effort dyspnea, heart failure, and syncope. Here, permanent pacing is required. As a general rule, no oral medication can reliably increase the sinus rate. However, theophylline, a methyl xanthine which is also a phosphodiesterase inhibitor, may increase the sinus rate. It can be tried in patients with contraindications for pacing.[3]

ATRIOVENTRICULAR BLOCK

Atrioventricular block (AVB) is defined as a delay or interruption of impulse conduction from the atria to the ventricles. The conduction disturbance can be transient or permanent. Conduction may be delayed, intermittent, or absent (with or without a lower escape rhythm). The commonly used terminology includes the following:

First-degree AVB—slowed conduction without loss of AV synchrony, manifest in the surface ECG with prolonged PR interval, greater than 200 ms (**Figure 21.2A**). The conduction delay is usually at the level of the AVN. Normally, the PR will shorten during exercise test (due to physiologic shortening of the AV nodal refractory period) and a 1:1 conduction will be seen throughout the exercise despite increased sinus rate. Although no treatment is needed in most of the cases, caution should be taken with administration of negative chronotropic and nodal blocking agents (i.e. beta-blockers, calcium channel

antagonists, and anti-arrhythmic drugs).

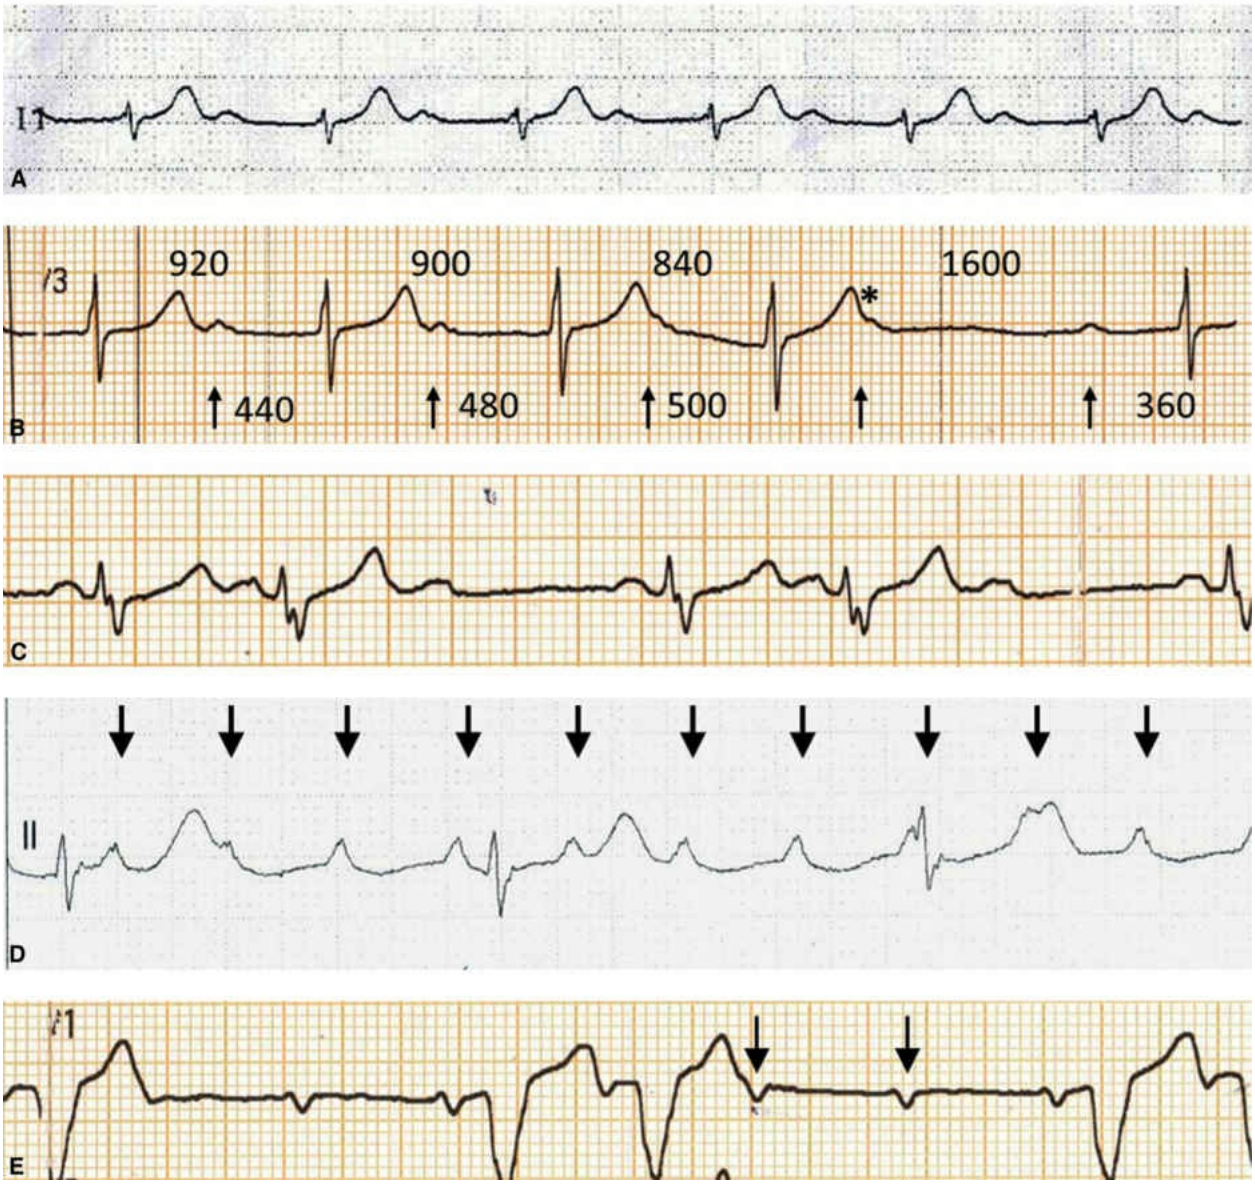

FIGURE 21.2 Types of AV conduction abnormalities.A, First-degree AV block with prolongation of the PR up to 440 ms in an asymptomatic man. B, Second-degree AV block, Mobitz type I (Wenckebach). Progressive PR prolongation is seen (P waves marked with an arrow and the values of the PR are given next to the arrows). Note the decrease in the ΔPR, resulting in a decrease in the RR intervals (denotes above the strip). Following a nonconducting P wave (*), PR shortening is seen and the pause is less than twice the preceding RR. The QRS is narrow, and the conduction delay is most probably at the level of the AV node. C, Second-degree AV block, Mobitz type II. Every third P wave is a block. The PR is fixed. The QRS is wide and the PR is normal (160 ms). The conduction delay is most probably below the level of the AV node. D, Complete AV block with no relationship between the P waves (arrows) and the QRS complexes. E, Advanced AV block with two consecutive blocked P wave (arrows). AV, atrioventricular.

Second-degree AVB—intermittent loss of AV conduction, often in a regular pattern (e.g. 2:1, 3:2, or higher degrees of block).

- In second-degree AVB type I (referred to as Wenckebach type), the PR interval progressively prolongs from beat to beat until AVBs occur and result in a dropped beat, which means failure of conduction of an SAN-generated impulse from the atria down to the ventricles. The PR interval following the pause returns to its baseline value and the sequence starts again. **Figure 21.2B** shows a typical example. The top numbers represent the R-R interval, whereas the bottom numbers represent the PR interval. The PR interval in the last conducted beat was 500 ms, and it was shortened to 360 ms after the blocked sinus beat. The pause following the blocked P wave (marked with an asterisk) is shorter than twice the preceding R-R. The QRS is usually narrow unless the underlying bundle branch block (BBB) is chronically present. The conduction delay is usually at the level of the AVN. Unless symptomatic, with a clear correlation between the ECG finding and the symptoms, this type of conduction abnormalities do not require therapy.
- Second-degree type II block (Mobitz II) is characterized in the surface ECG by a fixed PR interval before and after the blocked sinus beat (**Figure 21.2C**). The QRS is often wide. The conduction block is almost always below the level of the AVN. This type of AVB is usually permanent and often progresses to higher degree or even complete heart block. Implantation of a permanent pacemaker is required, regardless of symptoms.

Third-degree or complete AVB (CAVB)—no conduction is seen from the atria to the ventricles (**Figure 21.2D**). Lower escape rhythm may be seen. The higher the anatomic level of the conduction block, the faster and more stable the escape rhythm. AVB at the level of the AVN will usually give rise to a relatively fast escape rhythm of 40 to 60 bpm with a narrow QRS (unless BBB is chronically present). Lower anatomic level of the block, located at the His-Purkinje bundles, will result in a slow (<40 bpm) escape rhythm, often unstable with a wide QRS complex. As a general rule, the more distal the block, the slower will be the escape pacemaker. Low pacemakers have a rate of 40 bpm or less and are often unreliable, resulting in a very slow rate or asystole and often hemodynamic instability.

AVB should not be confused with other types of AV dissociation, in which there is no conduction from the atria to the ventricle due to other reasons, such as slowing of the sinus and accelerated nodal escape rhythm.

The term *advanced AVB* is referred to as two or more consecutive blocked sinus beats (**Figure 21.2E**).

The causes of AVB are depicted in **Table 21.2**. The main etiologies are discussed here in detail.

TABLE 21.2 Major Causes of Atrioventricular Block

PHYSIOLOGIC AND PATHOPHYSIOLOGIC	IATROGENIC
Increased vagal tone	
Fibrosis and sclerosis of the conduction system	Medications
Ischemic heart disease	β-Blockers, calcium channel antagonists, digitalis, antiarrhythmic medications
Cardiomyopathy and myocarditis	Cardiac surgery
Congenital heart disease	TAVI or closure of septal defects
Familial forms of AV block	Alcohol septal ablation for hypertrophic obstructive cardiomyopathy
Other	
Hyperkalemia, infiltrative malignancies and benign tumor, neonatal lupus syndrome, hypothyroidism, trauma, neuromascular diseases	

AV, atrioventricular; TAVI, transcatheter aortic valve implantation.

PHYSIOLOGIC AND PATHOPHYSIOLOGIC ATRIOVENTRICULAR BLOCK

Increased vagal tone—enhanced vagal tone can normally occur during sleep, in athletes, and as a result of various vagal triggers such as pain, cough, carotid sinus massage, or carotid sinus hypersensitivity. All of these can result in AVB from Mobitz I to even complete AVB.[4] Typically, increased vagal tone results in SB in addition to the conduction abnormality and the QRS is narrow unless BBB is chronically present (**Figure 21.3**).

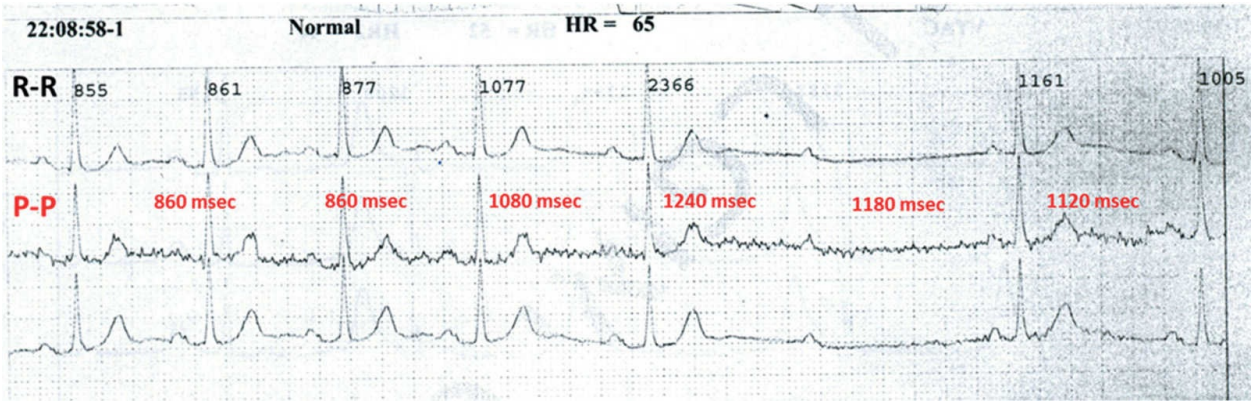

FIGURE 21.3 Vagal AV block. The top numbers (in black) denote the R-R intervals. The numbers in the middle (in red) denote the P-P intervals. Gradual prolongation of the P-P interval is present in addition to

the AV block. The patient was asleep during the recording. AV, atrioventricular; HR, heart rate.

IDIOPATHIC PROGRESSIVE CARDIAC CONDUCTION DISEASE

Fibrosis and sclerosis of the conduction system accounts for about one-half of cases of AVB. Progressive cardiac conduction defects, referred to as Lenegre or Lev disease, are characterized by progressive impairment of the conduction system:

- The term *Lenegre disease* has been traditionally used to describe a progressive, fibrotic disease of the conduction system in younger individuals. It is frequently associated with slow progression to complete heart block and may be hereditary.
- Lev disease refers to sclerosis of the left side of the heart in older patients. Common associated findings include aortic and mitral valve calcifications. Fibrosis of the mitral ring and central fibrous body is common in elderly patients and result in congenital atrioventricular block with a narrow QRS complex. Aortic valve calcifications are commonly associated with fibrosis of the HB and bundle branches. Thus, the QRS complex is usually wide.

ISCHEMIC HEART DISEASE

Both acute and chronic ischemia may result in any degree of AVB. Recognition of the blood supply of the conduction system is important for understanding the mechanism of AVB during ischemia (see the section “Anatomic Consideration”). Up to 20% of patients with acute MI develop conduction abnormalities, but most of these abnormalities are transient.[5] Inferior MI may cause a heightened vagal tone that results in an AVB at the level of the AVN. Prolonged PR, Wenckebach type, and CAVB may be seen, almost always transient and respond to intravenous (IV) atropine. The escape rhythm is of narrow QRS with a rate of 40 to 60 bpm, and thus usually the patients are asymptomatic. In contrast, anterior MI may cause ischemia of the septum, resulting in a slower escape rhythm (<40 bpm) with wider QRS. It is usually seen with an extensive MI due to occlusion of the proximal LAD, and therefore the prognosis is poor. Temporary pacing is often needed.

CARDIOMYOPATHY AND MYOCARDITIS

AVB can be seen in patients with cardiomyopathies, most commonly with infiltrative processes such as amyloidosis and sarcoidosis, and in patients with

myocarditis due to a variety of causes including rheumatic fever, Lyme disease, diphtheria, viruses, systemic lupus erythematosus (SLE), toxoplasmosis, bacterial endocarditis, and syphilis. The development of AVB in myocarditis is often a poor prognostic sign.

CONGENITAL HEART DISEASE

Congenital complete heart block may be an isolated lesion or may be associated with other types of congenital heart disease. When isolated, it results from transplacental passage of maternal anti-Ro/SSA and/or anti-La/SSB antibodies in women with SLE. Treatment is indicated mainly in symptomatic patients.

FAMILIAL DISEASE

Familial AV conduction block, characterized by a progression in the degree of block in association with a variable apparent site of block, may be transmitted as an autosomal dominant trait. Genetic mutation may be observed, usually in the *SCN5A* gene, encoding the fast sodium channel. Presentation can occur at any age, but progression of the conduction abnormalities with aging is seen. When presenting at an older age, it is often called hereditary Lenegre disease. It has been proposed that heterozigosity combined with aging leads to a progressive decline in conduction.

AV conduction disturbance can also appear in the setting of inherited arrhythmic syndromes (long QT syndrome type 3, Brugada). In these conditions, ventricular arrhythmias are not uncommon and may result in sudden cardiac death. Therefore, an implantable cardioverter-defibrillator rather than a pacemaker may be required.

MUSCULAR DYSTROPHIES

Muscular dystrophies are often associated with conduction abnormalities. The major syndromes include myotonic dystrophy and Emery–Dreyfuss muscular dystrophy. Muscular symptoms are often easily noticed and aid in diagnosis.

ELECTROLYTE DISTURBANCE

Most commonly seen with hyper- and hypokalemia, the QRS is wide and the treatment is focused on correcting the potassium level. One should keep in mind that primary bradycardia may result in hypotension, acute renal failure, and

hyperkalemia, which exacerbates the conduction abnormality. In this setting, pacing is indicated.

IATROGENIC

Cardiac surgery may result in AVB, in particular replacement of calcified aortic and mitral valve and/or closure of ventricular septal defects. CAVB is seen in 5% to 20% of patients undergoing transcatheter aortic valve replacement, especially in patients with prior conduction abnormalities such as right BBB. Alcohol septal ablation for the treatment of hypertrophic obstructive cardiomyopathy is complicated with CAVB in 10% of the cases. AVB might happen during or following catheter ablation of certain arrhythmias, most commonly ablation of AV nodal reentrant tachycardia and focal tachycardias or ablation of accessory pathways located in the septal region. However, the frequency of this complication is low.

MEDICATIONS

A variety of drugs can impair AV conduction, occasionally resulting in AVB. Examples include β-blockers, digitalis, calcium channel antagonists (especially verapamil and, to a lesser extent, diltiazem), amiodarone, and adenosine. The block is usually in the AVN and may be reversible with discontinuation of the drug. In comparison, antiarrhythmic drugs that modulate the sodium channel, such as quinidine, procainamide, flecainide, propafenone, amiodarone, and sotalol can produce block in the more distal His-Purkinje system. Some of these medications (i.e. amiodarone and sotalol) exhibit significant beta-blockade activity and may cause a conduction delay at any level.

Most patients with AVB who are taking drugs that can impair conduction probably have underlying conduction system disease. This was suggested by a study of 169 patients with second- or third-degree AVB associated with medication. Drug discontinuation resulted in resolution of the AVB in 40% of the patients, but half of them recurred even after discontinuation of the drug.[6]

ATRIOVENTRICULAR DISSOCIATION

With AV dissociation, independent activation of the atria and ventricles is seen as a result of absent conduction through the AVN. There is no fixed relationship between the P waves and the QRS complexes, and the PR intervals are variable in a random manner. Assessment of the jugular venous waveform can disclose

"cannon" A waves, indicative of contraction of the RA against the closed tricuspid valve. Several conditions may result in AV dissociation (**Figure 21.4**):

FIGURE 21.4 Atrioventricular dissociation. A, Sinus bradycardia with junctional escape. The sinus and the junctional escape rate are similar. The first P wave conducts to the ventricle, whereas the second and the last P waves do not conduct (the PR interval is too short). The last P wave is buried in the QRS. The third P wave probably does conduct because the PR is normal and the R-R is shorter in comparison to other R-R in the strip. B, Accelerated idioventricular rhythm (AIVR) during reperfusion of an occluded coronary artery. Some P waves are marked with an arrow. C, AV dissociation due to complete AV block. N mark the QRS signal. All R-R intervals are equal, despite alternating relationship between the P wave and the R wave. D, AV dissociation due to ventricular tachycardia (VT). The QRS is relatively narrow because the VT's exit is near the septum. Arrow denotes the dissociated P waves.

- Slowing of the SAN with an escape junctional or ventricular rhythm without retrograde conduction to the AVN may result in AV dissociation. The junctional or ventricular rate is isorhythmic or faster than the sinus rate; thus, the interval between the QRS complexes is similar to or shorter than the PP interval. With isorhythmic AV dissociation, the PR may seem to be very short or the P waves may be buried within the QRS complex and therefore not seen (**Figure 21.4A**). As seen in the figure, the first P wave conducts, whereas the

second and the last P waves do not conduct to the ventricle (the PR interval is too short).

- Acceleration or enhanced automaticity of lower or subsidiary pacemakers, such as an accelerated junctional or ventricular rhythm, or with a ventricular tachycardia, and rarely with a junctional tachycardia, may cause AV dissociation. There is a retrograde block of impulse conduction through the AVN (no ventriculoatrial conduction); thus, there is no atrial activation and the sinus node is not suppressed. The RR interval is shorter than the PP interval. Accelerated idioventricular rhythm (AIVR) is a ventricular rhythm typically seen during reperfusion of cardiac ischemia (typically seen with thrombolysis in the setting of ST-elevation myocardial infarction) (**Figure 21.4B**).
- AVB, type II or III can result in AV dissociation (**Figure 21.4C**).
- Ventricular tachycardia with retrograde ventriculoatrial block (**Figure 21.4D**).

TREATMENT

The degree of the block and the presence or absence of reversible causes determines the treatment. First-degree and second-degree AVB of Wenckebach type usually requires no treatment. For advanced AVB with no reversible cause (second-degree Mobitz II and complete AVB), permanent pacemaker implantation is indicated regardless of symptoms.[7] An exception to that is asymptomatic congenital AVB. These patients usually have a reasonable inotropic response of the escape rhythm on one hand, and high rate of complications if a permanent pacemaker is implanted at a young age.

MANAGEMENT OF BRADYCARDIA AND HEART BLOCK

Initial assessment should focus on the stability of the patient, including symptoms of bradycardia (see preceding text) and hemodynamic status. **Figure 21.5** depicts the 2015 Advanced Cardiac Life Support (ACLS) bradycardia algorithm. A major modification in this algorithm, which was initially introduced in 2010, is to define the HR for intervention to less than 50 bpm (instead of the previously used formal definition of less than 60 bpm). One should keep in mind that while slow HR of 50 to 60 bpm usually will not cause symptoms and, in fact, may be physiologic, it may be inadequate for certain patients with other comorbidities (such as anemia, sepsis, heart failure). In these cases, holding

medications that may lower the HR and increasing HR with anticholinergics or sympathomimetics may be indicated.

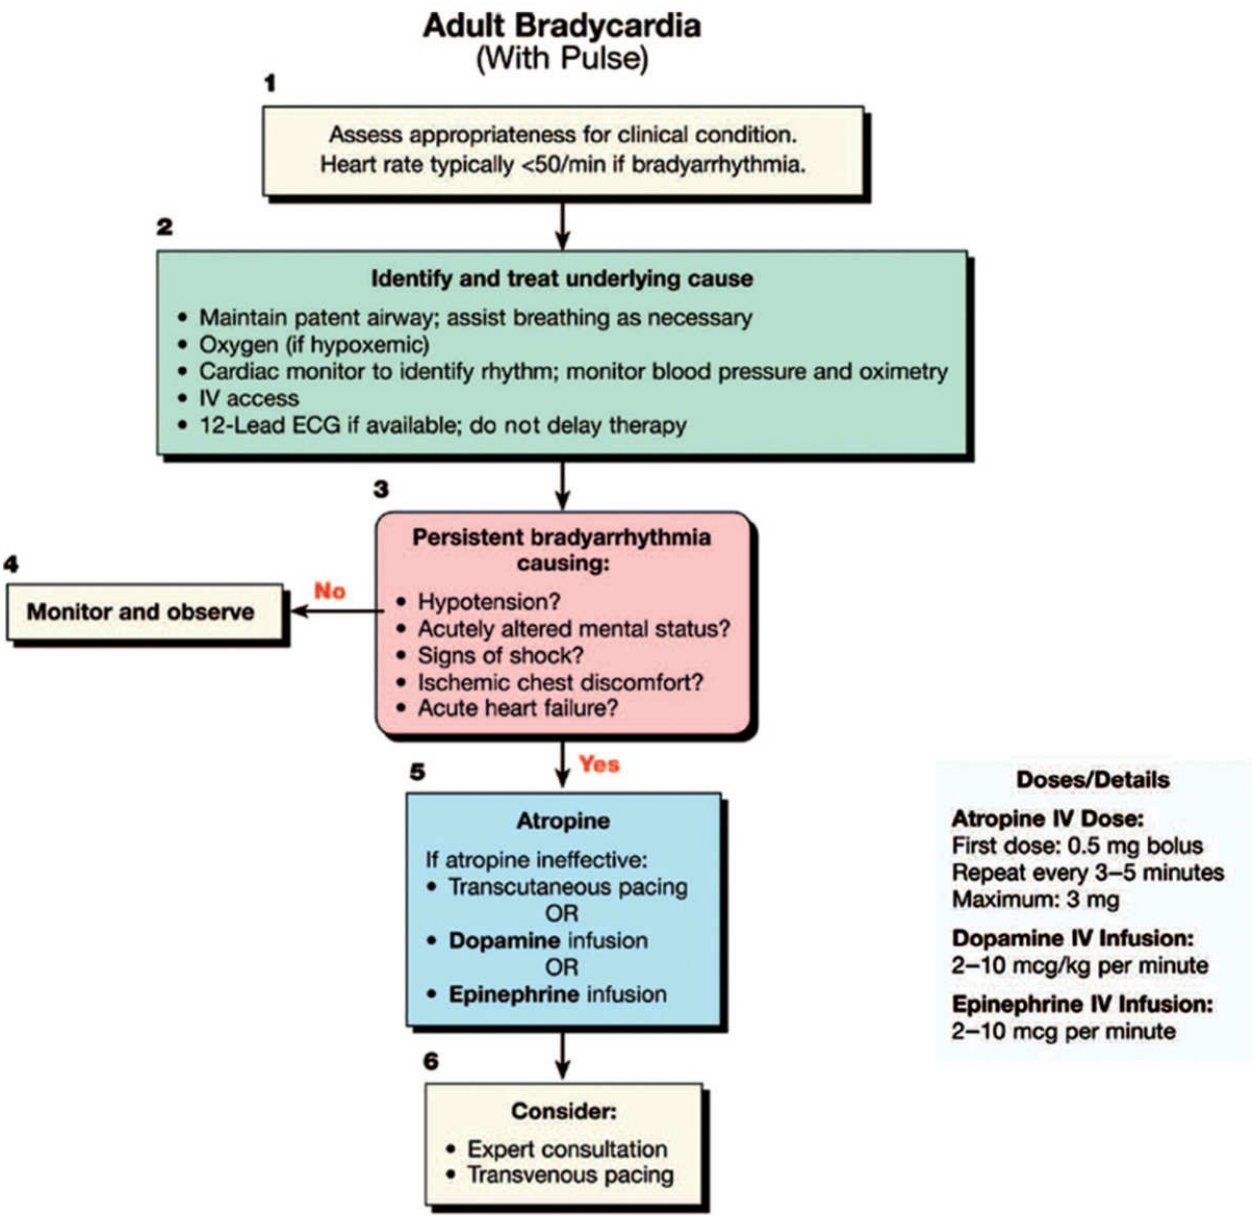

FIGURE 21.5 ACLS adult bradycardia algorithm. ACLS, Advanced Cardiac Life Support; ECG, electrocardiogram; IV, intravenous. (Reproduced from 2015 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care.)

Mean blood pressure will often be relatively conserved because of compensatory vasoconstriction. Owing to increased stroke volume and prolonged diastolic time, systolic blood pressure increases while the diastolic blood pressure decreases, resulting in widened pulse pressure. The increased systolic pressure usually requires no treatment. Other patients may have signs and symptoms of hemodynamic compromise such as shock, orthostatic symptoms, oliguria, and confusion. Heart failure symptoms (shortness of breath,

orthopnea, and edema) and signs of congestion may appear. Unstable patients should be treated immediately regardless of the diagnosis (SB or AVB). Therapeutic options may include atropine (IV push of 0.5 to 1 mg), sympathomimetics (dopamine or epinephrine infusion), and temporary pacing (**Table 21.3**). However, caution should be exercised if atropine or sympathomimetics are given to a patient with infra-hisian AVB because these medications can increase the sinus rate and aggravate the degree of the block. Patients with asymptomatic bradycardia should be followed up without any immediate intervention. Reversible causes should be sought while a decision regarding placement of a temporary or permanent pacemaker is taken. Important reversible causes include hypothermia, electrolyte disturbance (especially hypokalemia and acidosis), hypoxia, cardiac ischemia, medication use, and overdose.

TABLE 21.3 Medication Used for Bradycardia

	MECHANISM OF ACTION	DOSE	SIGNIFICANT SIDE EFFECTS
Atropine	Anticholinergic (ACH-R antagonist)	IV, 0.5–2.0 mg	Tachyarrhythmia, glaucoma, bronchospasm, urinary retention
Isoprenaline	β-Receptor agonist	IV, 1–4 μg/min; IV drip of 15–60 mL/h of 0.4 mg/100 mL NS	Tachycardia, ischemia, hyper- or hypotension, headache
Theophylline	PDE-5 inhibitor	PO, 200 mg bid	Abdominal discomfort, tachycardia, restlessness

ACH-R, acetylcholine receptor; IV, intravenous; NS, normal saline; PDE-5, phosphodiesterase-5.

TEMPORARY PACING

Temporary pacing is indicated in symptomatic bradycardia whenever there is a potentially reversible cause, or when permanent pacing is not available or carries a high risk at that moment (i.e. ongoing infection, risk of bleeding due to drugs, thrombocytopenia, and coagulopathy). If the cause is irreversible and permanent pacing is available, it should be preferred over temporary pacing. However, many unstable patients will require the insertion of a temporary wire to allow safe implantation of a permanent pacemaker.

Temporary pacing may be achieved transcutaneously using external pads, transvenously using an electrode (“wire”), epicardially using an atrial or ventricular epicardial electrode placed during a cardiac surgery, or through an

esophageal electrode (mainly for atrial pacing).

TRANSCUTANEOUS PACING

External pads can deliver immediate pacing. Anteroposterior position is the most effective, although anterior-apical can also be tried (**Figure 21.6**). This is reserved for cases with asystole or severe bradycardia and hemodynamic instability and serves only until achieving pacing with other methods. **Figure 21.7A** shows an example of an external pacemaker-defibrillator unit from a specific manufacturer. The arrow indicates the location of the pacing button. In the external monitor-defibrillator, the current is programmed at a high energy (i.e. 80 mA). The pulsations need to be verified, ideally by palpating the radial or femoral pulses. Carotid artery palpation is best avoided in this situation. On occasion, an arterial line can deliver exact information about the blood pressure. Pacing artifacts are usually large and limit the ability to assess capture using the cardiac monitor. The capture should be assessed continuously as a slight movement by the patient or pad movement may result in noncapture. If palpation of the arterial pulse is absent, the pad location needs to be adjusted or the current needs to be increased. Pad malfunction owing to improper contact with the skin (usually due to diaphoresis or hair over the chest) should be excluded. It should be mentioned that most patients will need some sedation to tolerate the pain involved with pacing, due to cutaneous nerve stimulation and skeletal muscle contractions. The rate of pacing is typically between 60 and 80 bpm. Because of the limitations associated with transcutaneous pacing, this method should be considered only as a temporizing measure for unconscious patients or those in whom sedation can be administered, until either temporary or permanent transvenous pacing can be established.

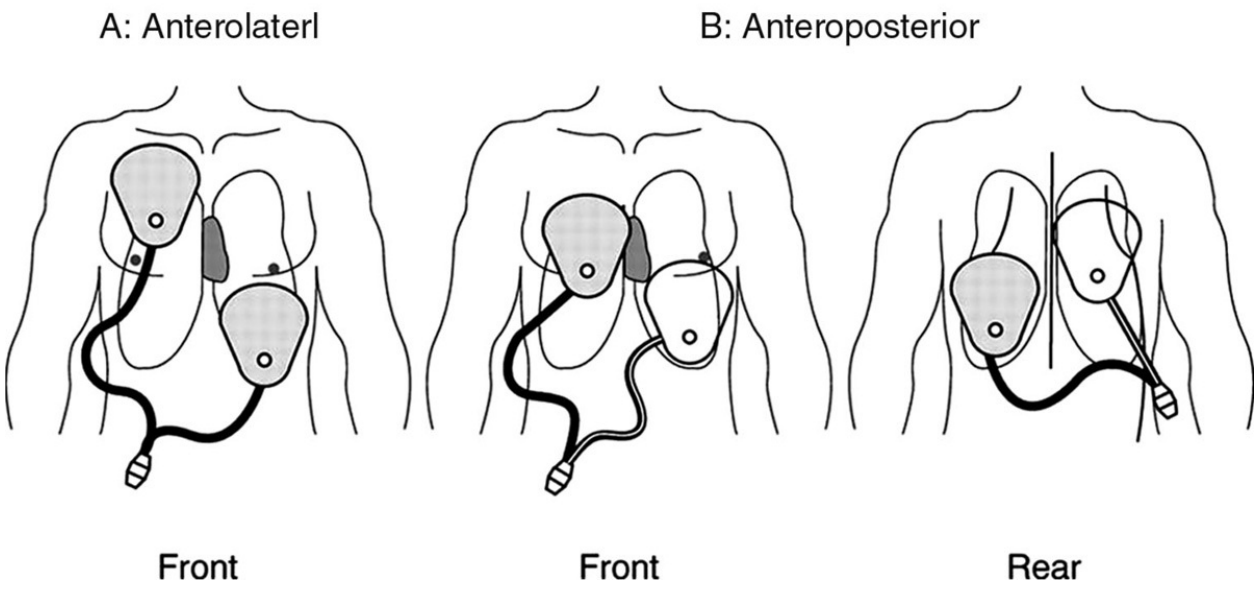

FIGURE 21.6 Pacemaker pads position. A, Apical and lateral. B, Anterior-posterior.

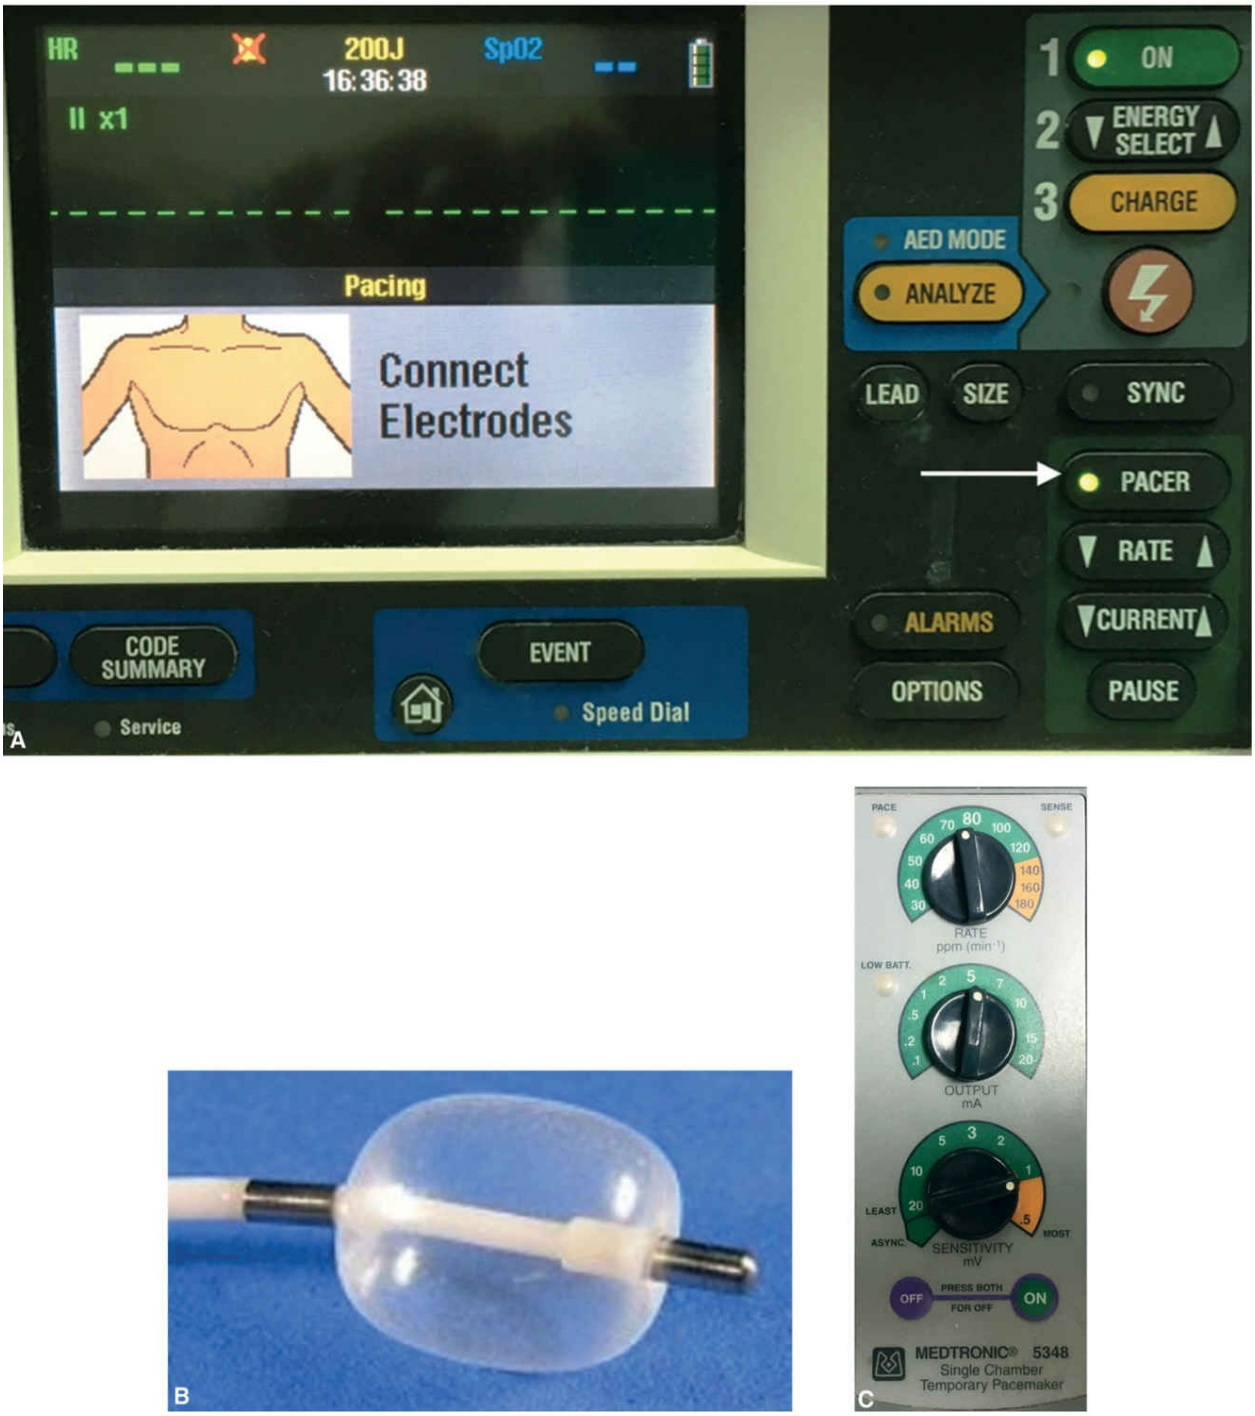

FIGURE 21.7 Temporary pacing units. A, External monitor-defibrillator. The white arrow denotes pacer button. Once pushed, the external pacemaker will pace at the set rate and output (notice green light on the left side of the button). The rate and current buttons are used for setting. Pacing may be started at 60 to 80 bpm with current of 80 mA. The current may be lowered, provided that capture is still manually verified. B, A tip of a temporary wire with distal inflatable balloon. C, Temporary pacing unit. The top button is used to set the rate, the middle button is used to set the output, and the lower button is used to set the sensitivity. The sensitivity is usually set to high (< 1 mV) to avoid pacing immediately after intrinsic activity, unless electrical noise is expected.

TRANSVENOUS PACING

Insertion of a temporary wire is best done by an expert physician under fluoroscopy guidance or at the bedside using a pacing wire with an inflatable balloon at the distal end (**Figure 21.7B**). The right jugular or subclavian veins are the optimal access sites for temporary pacing. These sites allow patient mobilization once the pacing wire is secured. However, access-related complications are high unless ultrasound guidance is used. The femoral vein may also be used, especially when done in the cardiac catheterization laboratory for a short duration. Disadvantages of using the femoral vein access include higher risk of infection and inability to mobilize the patient. The temporary wire is often positioned in the RV apex. Some of the wires contain a distal balloon (**Figure 21.7B**), to help advancing the tip of the wire under low-flow conditions. The balloon should be checked for leaks before insertion, inflated once in the vein, and deflated after positioning in the RV. The physician caring for paced patients should be familiar with the programming of the temporary pacing unit (**Figure 21.7C**). Once positioned in the RV apex, if there is an intrinsic activity, the sensing light will flash (top left of the pacing unit).

The upper button sets the pacing rate, usually at 60 to 80 bpm. The middle button sets the output delivered. The capture threshold is the minimal amount of output (in mA) required for capture. Threshold test is needed every 8 hours or whenever the patient position is changed (i.e. transferred to an intensive care unit [ICU] bed) (**Figure 21.8**). To test for the threshold, increase the pacing rate 10 to 20 bpm above the intrinsic rate (not less than 60 bpm) and slowly decrease the output till capture is lost (absence of QRS complex following the pacing artifacts). At that point, increasing the output should be done quickly. Output can be programmed to five times the threshold, usually at least 5 mA. This safety margin is required because the temporary electrode’s stability is less than those of the permanent leads.

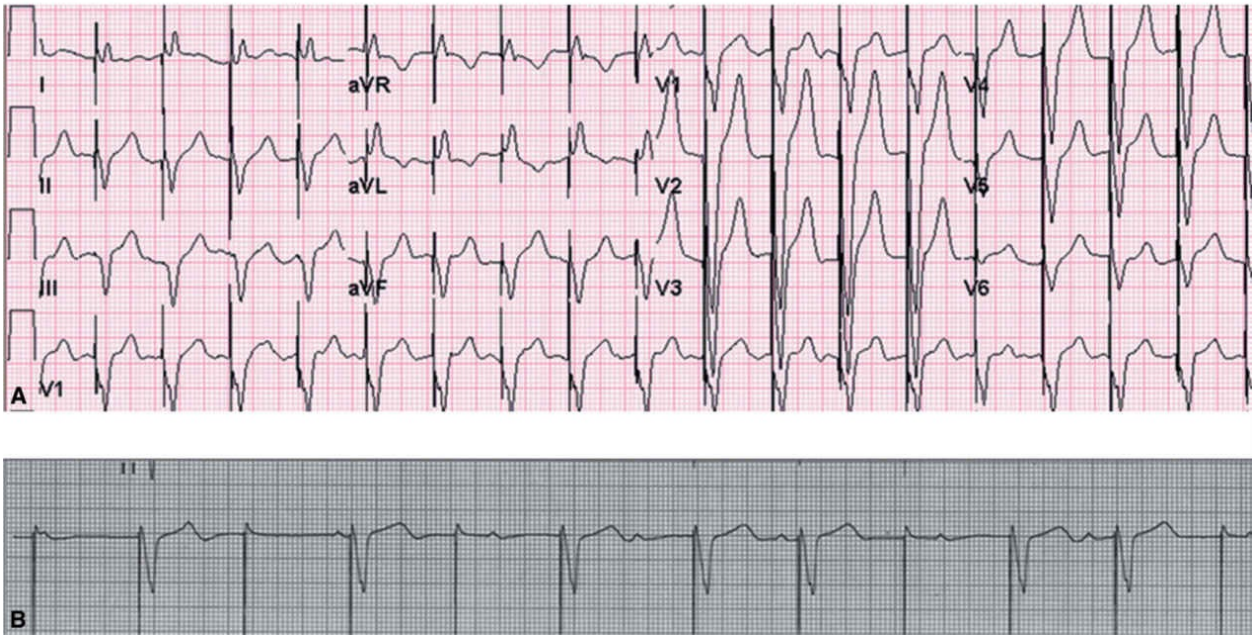

FIGURE 21.8 ECG recordings from patients with a temporary pacemaker. A**,** Paced ECG showing superior axis (negative in inferior limb leads) and LBBB pattern, typical for an electrode located in the RV apex. B, Pacemaker malfunction. Some of the pacemaker artifact (i.e. first, third, and fifth) are not followed by a QRS, indicating intermittent loss of capture. ECG, electrocardiogram; LBBB, left bundle branch block; RV, right ventricle.

SENSING

This term relates to the ability of the pacemaker to sense the intrinsic electrical activity. To determine an adequate sensing, set the pacemaker rate to 10 to 20 below the intrinsic rate, if possible. Set the sensitivity to the maximal level (**Figure 21.7C**, lower button, indicated by “least”). The sensing light (**Figure 21.7C**, top right) will stop flashing because it will not sense any activity. Slowly decrease the sensitivity threshold until the sensing light flashes. This is the sensing threshold, that is, the minimum intracardiac signal that will be sensed (seen) by the pacemaker and inhibit its activity. The sensitivity should be set to a low value (1 mV, indicated by “most”), not higher than the sensitivity threshold, to prevent pacing on intrinsic activity. However, when external noise is expected (during implantation of the permanent pacemaker with the use of electrocautery), the sensitivity should be programmed to the minimum (high value of 20 mV, depicted in **Figure 21.7C** as “least”).

Figure 21.8 shows examples of ECG from paced patients. In**Figure 21.8A**, typical pacing is shown. Each pacing artifact is followed by a QRS. The QRS morphology is typical for RV apical pacing with left BBB pattern and a superior

axis (negative QRS in the inferior limb leads). In **Figure 21.8B**, pacemaker intermittent loss of capture is seen. Notice how some of the pacing artifacts (first, third, fifth, ninth, and last) are not followed by a QRS.

The temporary wire is removed once the bradycardia is resolved or a permanent pacemaker is implanted. On occasion, temporary wires perforate the thin RV wall during implantation. It is not uncommon to observe pericardial effusion and tamponade upon removal of a temporary wire which had sealed a perforation, especially in anticoagulated patients.

PERMANENT PACEMAKER

Sinus node dysfunction resulting in bradycardia is an indication for pacemaker implantation mainly when symptomatic. Asymptomatic sinus bradycardia does not carry a risk for syncope or sudden death (2). In contrast, second-degree Mobitz type II, Advanced AV block and CAVB require permanent pacing regardless of symptoms.

Table 21.4 denotes the pacemaker nomenclature endorsed by the NASPE (North-American society of pacing and electrophysiology). The most common pacemaker is coded as DDDR, thus pacing and sensing is available in both atrium and ventricle, the sensing may trigger or inhibit pacing and rate modulation is possible. This type of pacemaker allows for atrio-ventricular synchrony. VDD pacing is a suitable option for patients with a conduction abnormality but a normal sinus function. This pacemaker has one lead which is positioned at the right ventricular apex, with a bipolar sensor located about 15 cm from the distal end of the lead and allows for sensing in the atrium. The nomenclature of this type of pacemaker (VDD) denotes that pacing is possible only in the ventricle (first letter, “V”, in the nomenclature). The major advantage of this type of pacemaker is that its single lead allows for AV synchronous pacing. VVI pacemakers can sense and pace the ventricle alone and is used mainly for patients in persistent atrial fibrillation or in patients in sinus rhythm but only infrequent bradycardic episodes. The last letter in the nomenclature, *I*, denotes that pacing is *inhibited* if the pacemaker senses an intrinsic ventricular activity of the patient. Similarly, AAI pacemaker allows for sensing and pacing in the atrium alone. While it is suitable for patients with sinus node dysfunction and intact AV conduction, it is only infrequently used for fear of later development of a conduction abnormality (**Table 21.5**). The routine management post-pacemaker implantations include prophylactic antibiotic therapy (usually for 24 hours with anti-staphylococcal agents), analgesics, chest X-ray to verify

lead position and rule out pneumothorax, and bed restriction (3 hours to overnight, depend in the local policy). Most patients will be discharged within 24 hours, unless their clinical status was not yet stabilize.

TABLE 21.4 NASPE Generic Code for Pacemakers

POSITION	I	II	III	IV
Category	**Chamber(s) paced**	**Chamber(s) sensed**	**Response to sensing**	**Rate modulation**
	O = none	O = none	I = inhibition	O = none
	A = atrium	A = atrium	T = triggered	R = rate modulation
	V = ventricle	V = ventricle	D = dual (I+T)	
	D = dual (A+V)	D = dual (A+V)

Patient and Family Information for: BRADYCARDIA AND HEART BLOCK

WHAT IS BRADYCARDIA?

Specialized heart cells in the right atrium are called sinus node and are responsible for electrical impulse formation, resulting in a resting HR in most healthy people of 60 to 100 beats per minute. Bradycardia is a slow heart beat (<60 bpm) caused either by abnormal electrical impulse formation (sick sinus syndrome) or by its delayed propagation to the rest of the heart (heart block). During sleep and in well-trained individuals, bradycardia is common and adequate and therefore does not require any treatment.

WHAT CAUSES BRADYCARDIA?

Bradycardia can be caused by the following:

- Changes in the heart that are the result of aging.
- Diseases that damage the heart's electrical system. These include coronary artery disease, heart attack, and infections such as endocarditis and myocarditis.
- Conditions that can slow electrical impulses through the heart. Examples include having a low thyroid hormone level (hypothyroidism) or an electrolyte imbalance, such as too much potassium in the blood.
- Some medicines for treating heart problems or high blood pressure, such as β-blockers, calcium blockers, antiarrhythmic drugs, and digoxin.

WHAT ARE THE SYMPTOMS?

As the HR declines, the heart may not pump enough blood to meet the body's needs. A very slow HR may cause a person to experience the following:

- Feel dizzy, lightheaded
- Feel short of breath and find it harder to exercise
- Feel tired
- Have chest pain or a feeling that the heart is pounding or fluttering (palpitations)
- Feel confused or have trouble concentrating
- Faint, if a slow HR causes a drop in blood pressure

Some people do not have symptoms, or their symptoms are so mild that they think these are just part of getting older. The pulse rate can be assessed by checking it manually with the fingers or with an electronic device such as blood pressure machines and smartphone applications.

If the heart beat is slow or uneven, talk to a doctor.

HOW IS BRADYCARDIA DIAGNOSED?

A doctor may be able to diagnose bradycardia by doing a physical examination, asking questions about past health, and doing an ECG. An ECG measures the electrical signals that control heart rhythm, so it is the best test for bradycardia. Bradycardia often comes and goes, so a standard ECG done in the doctor's office may not find it. An ECG can identify bradycardia only if the person is actually having it during the test. There may be a need to use a portable (ambulatory) ECG device. This lightweight device is also called a Holter monitor or a cardiac event monitor. The person wears the monitor for a day or more, and it records the heart rhythm while he/she goes about the daily routine. Blood tests may also be necessary to find out whether another problem is causing the slow HR.

HOW IS IT TREATED?

The treatment of a slow heartbeat depends on what is causing it and what are the accompanying symptoms. Sometimes, there is no need for any intervention,

especially if the bradycardia is asymptomatic.

If damage to the heart's electrical system causes the heart to beat too slowly, the person will probably need to have a pacemaker. A pacemaker is an electronic device, placed under the chest skin and connected to the heart with electrical wires, which helps correct the slow HR. Older people are most likely to have a type of bradycardia that requires a pacemaker. If another medical problem, such as hypothyroidism or an electrolyte imbalance, is causing a slow HR, treating that problem may cure the bradycardia. If a medicine is causing the heart to beat too slowly, the doctor may adjust the dose or prescribe a different medicine. If the person cannot stop taking that medicine, a pacemaker may be needed. The goal of treatment is to raise the HR so the body gets the blood it needs. If severe bradycardia is not treated, it can lead to serious problems. These may include fainting and injuries from fainting, as well as seizures or even death.

WHAT CAN BE DONE AT HOME FOR BRADYCARDIA?

Bradycardia is often the result of another heart condition, so taking steps to improve heart health will usually improve overall health. The best steps to take are to ensure the following:

- Control cholesterol and blood pressure
- Eat a low-fat, low-salt diet
- Get regular exercise; a doctor can tell what level of exercise is safe
- Stop smoking
- Limit alcohol
- Take medicines as prescribed
- See the doctor for regular follow-up care

People who get pacemakers need to be careful around strong magnetic or electrical fields, such as magnetic resonance imaging machines or magnetic wands used at airports because they may interfere with their functioning. If a pacemaker is placed, the doctor will give information about its type and what precautions are to be taken. Once a cardiac pacemaker is implanted, most patients enjoy a normal life without even noticing its presence.

Supraventricular Arrhythmias

INTRODUCTION

Of the supraventricular arrhythmias that are encountered in the cardiac care unit (CCU), sinus tachycardia and atrial fibrillation (AF) are most frequently seen owing to their higher incidences among patients with acute myocardial infarction (MI), respiratory failure, sepsis, structural or valvular heart disease, and cardiomyopathy. Because of the distinctness of AF as a clinical entity, it is discussed in conjunction with atrial flutter (AFL) in a separate chapter. This chapter focuses on the general approach to the classification and management of narrow QRS complex tachycardias followed by a description of the common forms of supraventricular tachycardias (SVTs). The algorithms defined in this chapter apply to the most typical clinical scenarios and are not intended to be exhaustive or highly specific.

SVTs are commonly seen in the CCU and in otherwise healthy patients without structural heart disease, with an overall prevalence estimate of 600,000 and annual incidence of 90,000 in the United States alone.[1]They represent a heterogeneous group of tachyarrhythmias that originate in the supraventricular tissue or utilize it as part of a reentrant circuit,[2] and are characterized by a spectrum of electrocardiogram (ECG) findings that are clinically important to understand, identify, and differentiate. SVTs typically present with a regular rate

(160–200 bpm) and a narrow QRS complex (<120 milliseconds) on ECG because they follow the normal pathway of atrioventricular (AV) conduction and ventricular activation via the His-Purkinje system. Occasionally, SVTs present with a wide QRS complex (≥ 120 milliseconds) because of baseline bundle branch blocks, rate-related aberrancy, or conduction via accessory pathways (APs).

Sinus tachycardia, by far the most common SVT, is not a pathologic arrhythmia (with the rare exception of inappropriate sinus tachycardia) but rather is an appropriate cardiac response to a physiologic event. Sinus tachycardia is gradual in onset and recession. The heart rate is regular and classically does not exceed 220 beats per minute (bpm) minus the patient's age. In sinus tachycardia, P waves precede the QRS complex. Sinus tachycardia is virtually always a compensatory response, and it should not be considered the cause of hemodynamic instability. Instead, the underlying precipitant of sinus tachycardia (eg, ischemia, infection, heart failure) must be identified and addressed.

GENERAL APPROACH TO NARROW QRS COMPLEX TACHYCARDIAS

SYMPTOMS AND HEMODYNAMIC IMPACT

SVTs are not usually life threatening to otherwise healthy individuals; however, patients admitted to the CCU who present with narrow QRS complex tachycardias should be thoroughly assessed for clinical signs and symptoms potentially *attributable to* the arrhythmia. These may include hypotension, diminished peripheral pulses and tissue perfusion, shortness of breath, and chest pain. In contrast to patients without organic heart disease, many CCU patients may have ischemic cardiomyopathy, severe valvular stenosis or regurgitation, or reduced left ventricular function. Among such patients, the tachycardia can lead to reduced diastolic filling and decreased cardiac output, which may hasten myocardial ischemia and decompensated heart failure. That said, it is equally important to differentiate these scenarios from those in which the underlying disease is the cause of hemodynamic instability and the precipitant for the SVT. For example, sepsis with vasodilatory shock or acute pulmonary embolism can be a *driver* of the tachyarrhythmia. After careful delineation of these relationships, if the SVT is thought to be the *cause* of hemodynamic instability, expeditious treatment (eg, electrical cardioversion) guided by established

Advanced Cardiac Life Support (ACLS) protocol is warranted (**Figure 22.1**).[3]

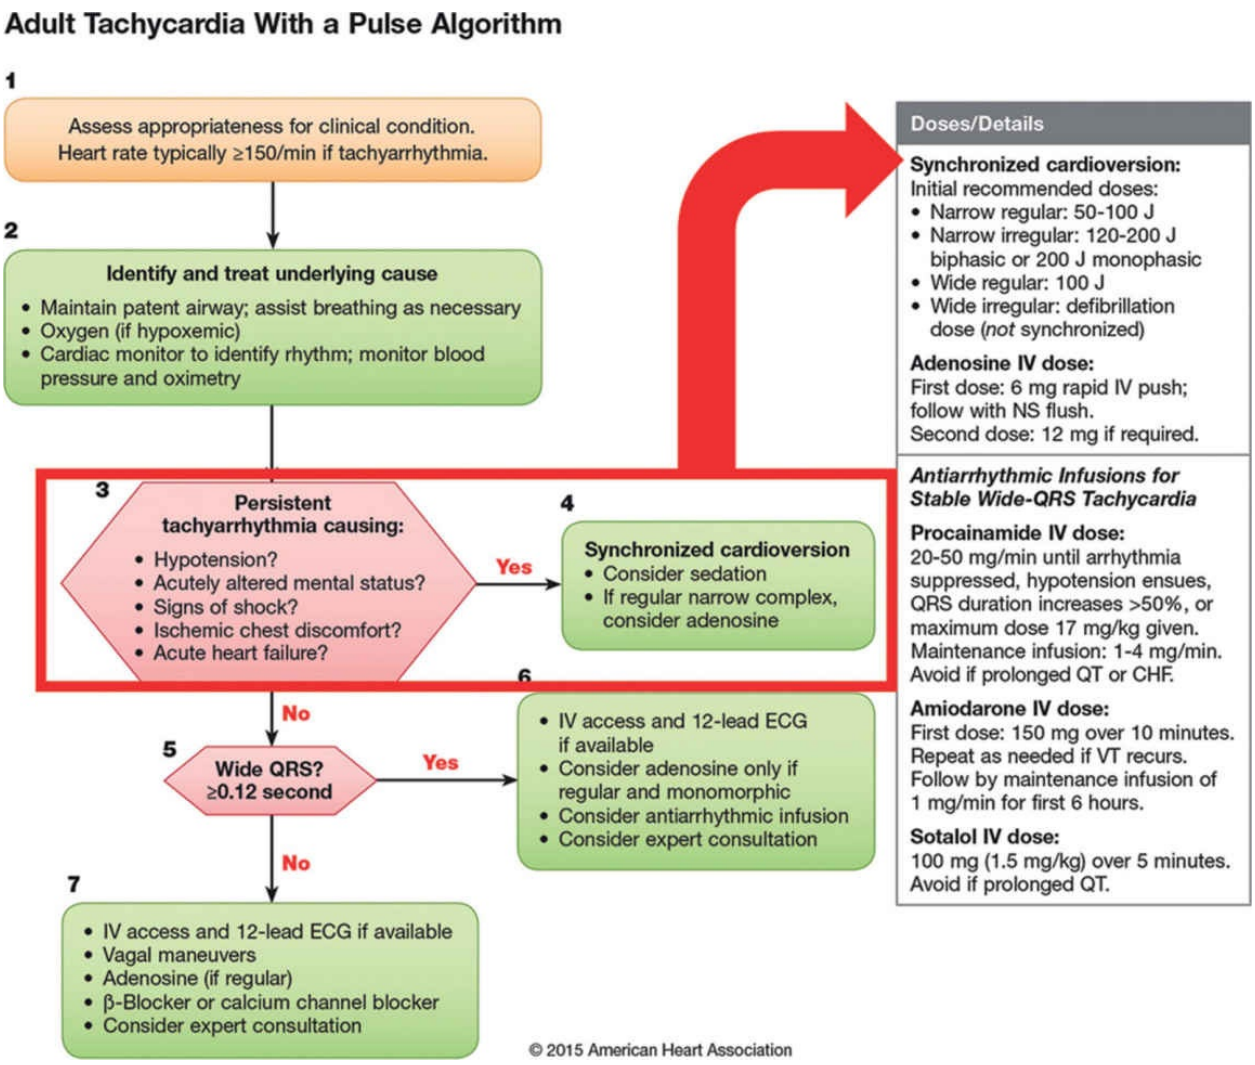

FIGURE 22.1 Algorithm for appropriate use of synchronized electrical cardioversion in the management of unstable patients with persistent narrow QRS complex SVTs. From the American Heart Association (AHA) Advanced Cardiac Life Support (ACLS) algorithm for adults with tachycardia and a pulse.[3]

CLASSIFICATION BASED ON ELECTROCARDIOGRAM FINDINGS

REGULARITY OF THE RHYTHM

A 12-lead ECG is the cornerstone in diagnosing SVT and should be carefully inspected for regularity of QRS complexes. This can be done most accurately using calipers to sequentially compare R-R intervals (**Figure 22.2**) and allows for rapid initial differentiation into two major categories: irregular and regular rhythms (**Figure 22.3**).[4–6] Careful inspection and repeat measurements are

usually sufficient to establish regularity; however, irregular SVTs including AF and AFL with variable AV conduction or multifocal atrial tachycardia (MAT) may exhibit very rapid ventricular conduction that can sometimes mask their irregularity. In such instances, the use of heart-rate–slowing maneuvers (ie, increased vagal tone) can be effective in resolving any ambiguity (**Table 22.1**).After the regularity has been assessed, the ECG should be analyzed for the presence of P waves and their morphology.

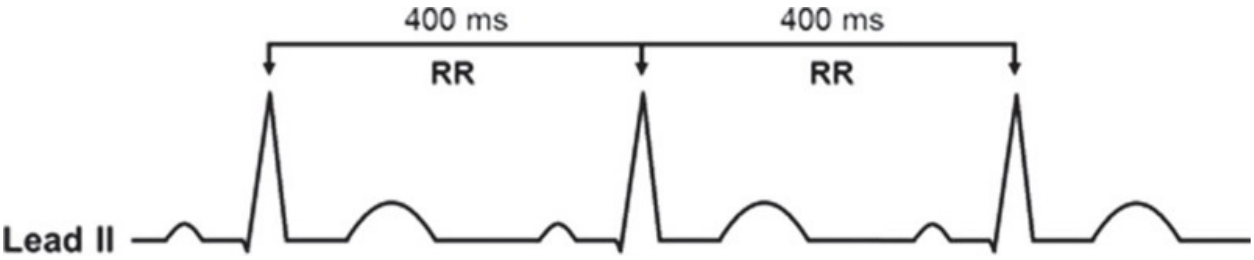

FIGURE 22.2 Determining the regularity of narrow QRS complex SVTs on ECG via measurement of the R-R interval. ECG, electrocardiogram; SVT, supraventricular tachycardia.

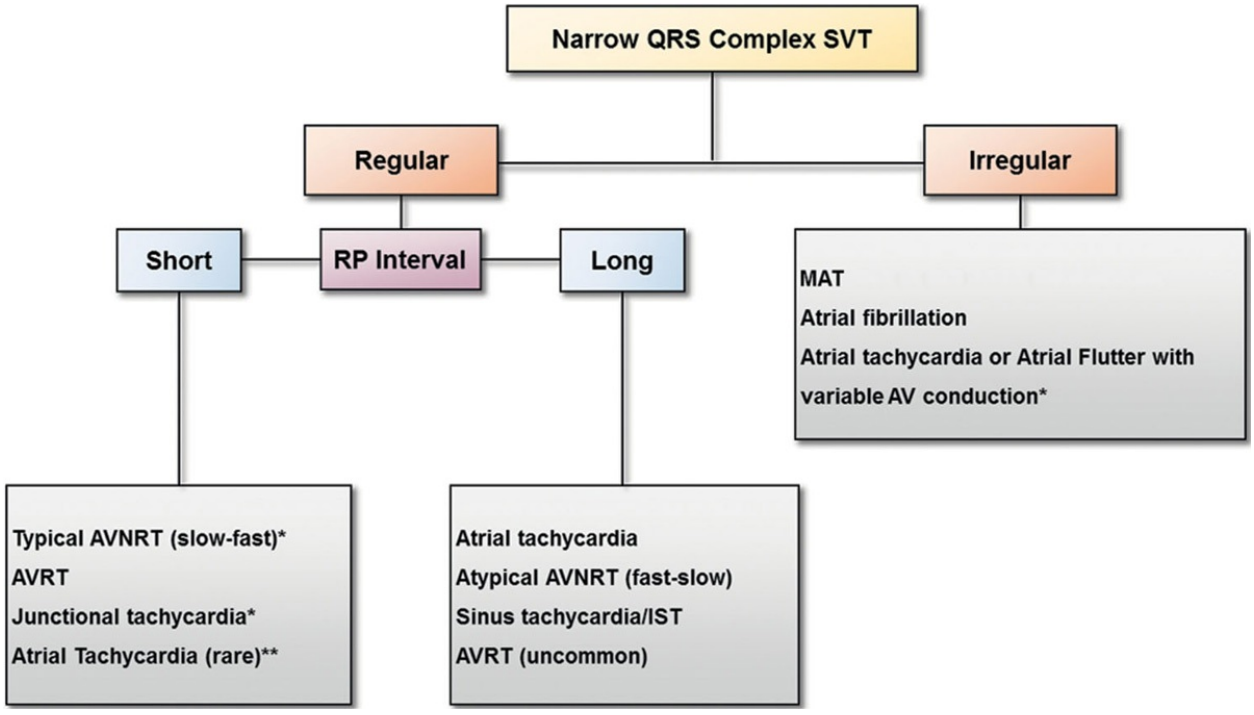

FIGURE 22.3 General approach to classifying narrow QRS complex tachycardias. TABLE 22.1 Common Methods of Transiently Slowing av Conduction to Allow for Definitive Diagnosis in the Classification of Narrow QRS Complex Tachycardias

Modalities that Transiently Slow Av Conduction:	Vagal Maneuvers: • Carotid Massage • Valsalva maneuvers	AV Nodal Medications: • Adenosine • β-blockers (metoprolol) • Nondihydropyridine calcium channel blockers (verapamil, diltiazem)	
Responses of Individual Svts to Transient Slowing ofAv Conduction:	**AVNRT**	**AVRT**	**AT**
Abrupt termination with a P wave after the last QRS complex.	Yes	Yes	Very unlikely
Abrupt termination with a QRS complex.	Yes	Yes	Yes
Some/gradual slowing of the ventricular rate without termination.	No (excludes)	No (excludes)	Common

AT, atrial tachycardia; AV, atrioventricular; AVRT, atrioventricular reentrant tachycardia; AVNRT, atrioventricular nodal reentrant tachycardia; SVT, supraventricular tachycardia.

PRESENCE AND MORPHOLOGY OF P WAVES

Identification of P waves and their morphologic patterns are essential for further characterization of regular narrow QRS complex SVTs, as well as their relative origin within the supraventricular conduction system (ie, sinoatrial [SA] node vs atrial vs AV node). This requires familiarity with P-wave appearance during normal (sinus) conduction on 12-lead ECG, and experience with recognition of oftentimes subtle variations.[7] Cases in which P waves are not well identified might indicate that the activation of the atria and ventricles is occurring almost simultaneously, resulting in a P wave that is buried within or just following the QRS complex. The most common etiologic example of this ECG pattern is atrioventricular nodal reentrant tachycardia (AVNRT), followed less commonly by unifocal atrial tachycardia (AT) and junctional tachycardia (JT). Sinus P waves are positive in the inferior leads (ie, II, III, and aVF) due to normal anterograde conduction, whereas P waves in AVNRT are always negative in the inferior leads (pseudo–S) due to retrograde conduction from the AV node to the atria (**Figure 22.4**). This is similarly seen in atrioventricular reentrant tachycardia (AVRT); however, nonretrograde P waves are sometimes present depending on the location of the AP. The importance of differences in P-wave

patterns and timing is not only inherent to AVNRT and AVRT. P waves originating from a different focus (ie, ectopic AT) or multiple foci (ie, MAT) in the atria can have variable morphologies and may even mimic sinus P waves (eg, crista terminalis origin). Therefore, comparison of P-wave characteristics with those found on the baseline ECG, as well as onset/termination properties of the tachycardia, is extremely useful in differentiating focal or reentrant tachycardia from sinus tachycardia.

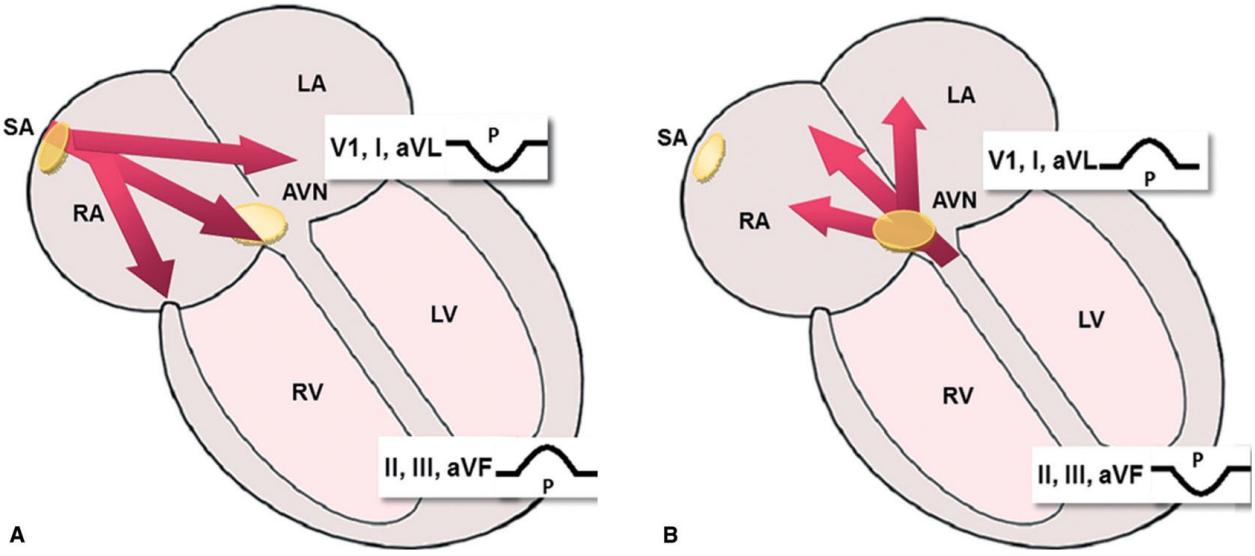

FIGURE 22.4 Differences in P-wave morphology in the inferior leads (II, III, aVF) based on direction of atrial activation. A, In normal antegrade sinus conduction positive P-wave deflections are seen in the inferior leads. B, With AVNRT, the atria are activated in a retrograde direction from the AV node, resulting in P waves that are negative in the inferior leads and positive in V1. AVN, atrioventricular node; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; SA, sinoatrial node.

R-P INTERVAL

Following identification of P waves and their morphologies, the next step is examining the relationship of the P wave to the QRS complex. This is done by measuring an RR interval and then the distance from the initial R wave to the next discernable P wave. If the RP interval is less than one-half of the RR interval, the tachycardia is a short-RP tachycardia; otherwise, it is a long-RP tachycardia (**Figure 22.5**). The RP interval alludes to the relative timing of atrial (P) and ventricular (QRS) activation during SVT.

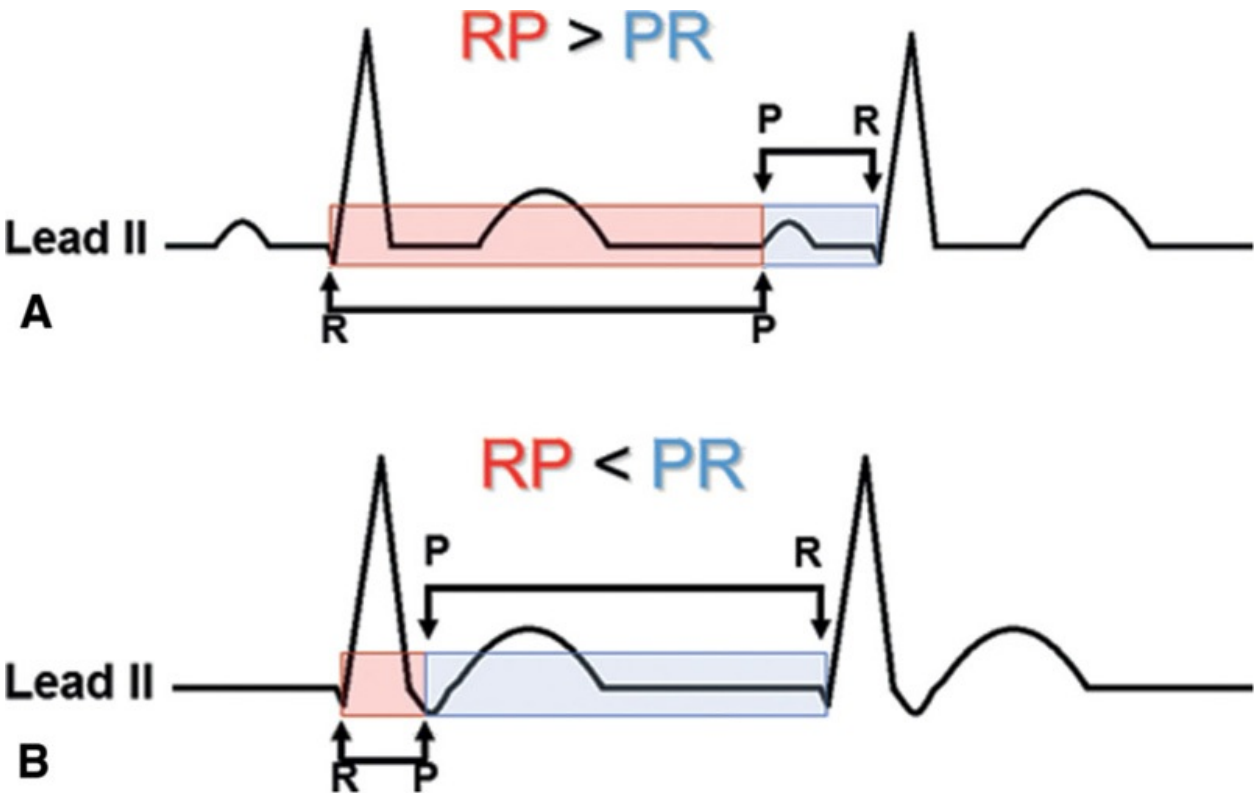

FIGURE 22.5 A, Measurement of the RP (and PR) intervals in ECG lead II. A, Narrow QRS complex tachycardias with RP intervals that are more than one-half of the RR interval (RP > PR) are called long RP tachycardias, whereas (B) those with an RP interval that is less than one-half of the RR interval (RP < PR) are known as short RP tachycardias.

As previously mentioned, atrial and ventricular activation occurs almost simultaneously (P waves buried within/just after QRS complex) in typical forms of AVNRT and AVRT, which represent the two most common short-RP tachycardias. AVNRT stems from dual-AV nodal physiology, whereas AVRT develops in patients with an extranodal AP that electrically connects the atrium and ventricle. Typical AVRT conducts down the AV node and up the AP resulting in a short-RP interval that may be slightly longer than that of AVNRT. Focal AT typically results in a long-RP tachycardia on ECG (**Figure 22.6A –B**).

FIGURE 22.6 A, 12-Lead ECG showing narrow QRS complex, *long-RP* tachycardia at a cycle length of 420 ms. Take note of the negative P waves preceding each QRS complex in the inferior leads (II, III, aVF; arrows). This patient subsequently underwent a successful radiofrequency catheter ablation for focal AT. B, CARTO-3 3D electroanatomic map for focal atrial tachycardia originating from the high crista terminalis.

ADDITIONAL DIAGNOSTIC MANEUVERS

As part of the systematic approach to identifying and classifying narrow QRS complex SVTs, it is often essential to transiently slow AV conduction to allow for more definitive assessment of regularity, presence of P waves, and RP intervals.[8, 9] This is commonly attempted first using bedside vagal maneuvers such as Valsalva and carotid sinus massage, followed by medications (commonly

adenosine, sometimes β -blockers and calcium channel blockers [CCBs]) that temporarily block or slow conduction through the AV node.

Before performing carotid sinus massage, it is crucial to revisit the patient's medical history and physical examination to check for contraindications such as cerebrovascular disease, recent MI, or carotid bruits. Maneuvers should always be performed with the patient in the supine position, and steady pressure should be applied unilaterally for 5 seconds. Bilateral carotid massage should never be performed. It is worthwhile to note that vagal maneuvers are not usually effective in terminating the tachycardia unless the AV node is part of a reentrant circuit (eg, AVNRT, AVRT).

If vagal maneuvers are ineffective, adenosine can be given as a rapid intravenous (IV) bolus followed by saline flush. Patients should be on continuous ECG monitoring during administration of adenosine to aid in diagnosis and to differentiate between treatment failure and termination with rapid reinitiation of SVT. The initial dose of adenosine is 6 mg, which can be followed by 12 mg if no response is seen. Patients should be forewarned that they are likely to experience side effects such as flushing, chest tightness, and shortness of breath, but these are very short-lasting. Although adenosine has a high tendency to terminate AVNRT and AVRT (AV node is part of the circuit), it is very unlikely to terminate AT or AFL. Nonetheless, it may unmask the underlying arrhythmia for more definitive diagnosis. Of note, adenosine can precipitate transient AF in up to 12% of patients, which poses a potential risk to patients with known Wolff–Parkinson–White (WPW) syndrome.[10] However, ventricular fibrillation (VF) and transient asystole in response to adenosine administration are rare.

Other agents such as IV β -blockers (eg, metoprolol) and CCBs (eg, diltiazem) may be effective in slowing AV conduction for di agnostic purposes, and may even terminate the SVT.[11] **Table 22.1** provides a listing of maneuvers and medications that are utilized diagnostically to transiently slow AV conduction, as well as the respective responsiveness of common SVT subtypes to these therapies.

OVERVIEW AND SAMPLES OF INDIVIDUAL SUPRAVENTRICULAR TACHYCARDIAS

ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA

AVNRT is the most frequently encountered of the regular narrow QRS complex tachycardias. The development of AVNRT and inherent behavior of the circuit is dependent on the presence of a particular electrophysiologic (EP) property of the AV node, termed dual-AV node physiology.[12] It is explained by the presence of two pathways with different conduction properties and refractoriness: the *fast pathway*, which conducts more rapidly with a longer refractory period, and the *slow pathway*, which conducts more slowly with a somewhat shorter refractory period (**Figure 22.7**).Normal (anterograde) AV conduction takes place in a forward direction down the *fast pathway*; however, if the *fast pathway* is refractory from a premature atrial complex (PAC), the sinus impulse may conduct over the *slow pathway*. If enough time passes for the *fast pathway* to recover, the impulse can conduct (retrograde) backward up the *fast pathway* and initiate a reentrant circuit that manifests on ECG as a regular tachyarrhythmia at 130 to 250 bpm (**Figure 22.8).**

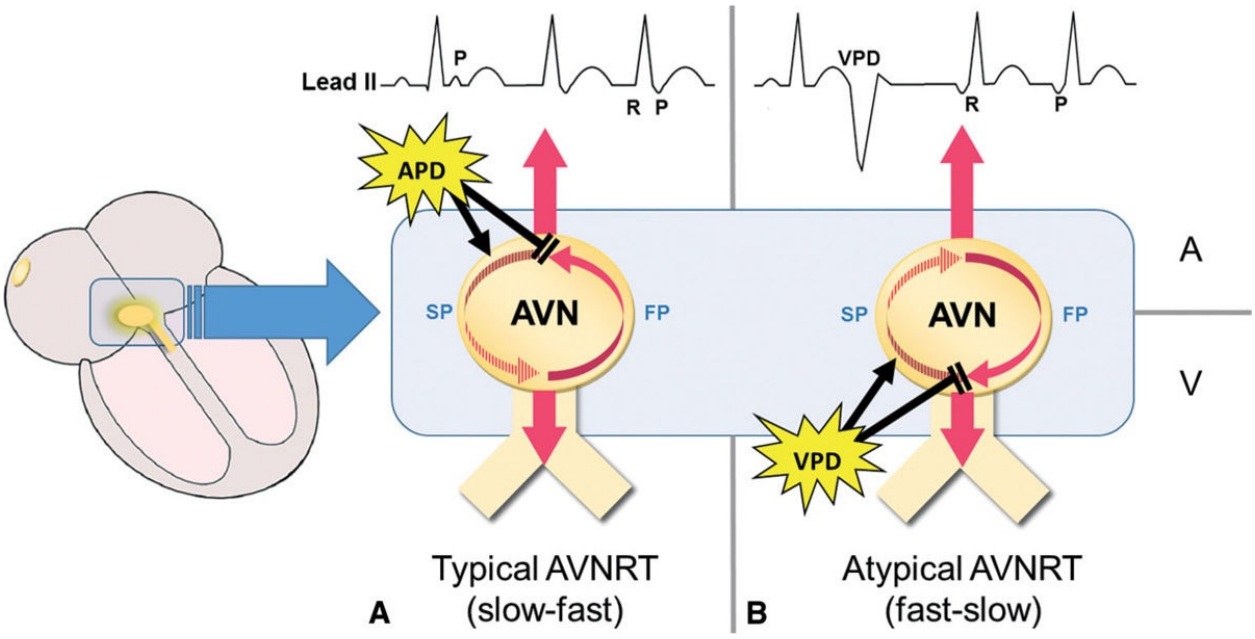

FIGURE 22.7 Mechanisms of atrioventricular nodal reentrant tachycardia (AVNRT), showing each atrioventricular node (bottom) and surface ECG lead (top). Solid arrows indicate conduction over the fast pathway (FP), and striped arrows represent conduction over the slow pathway (SP). A, Typical AVNRT: an APD blocks in the FP and conducts down the SP, followed by retrograde conduction up the FP. Note the nearly simultaneous timing of P waves and QRS complexes during typical AVNRT (RP < PR). Pseudo-S waves at the end of QRS complexes (inferior ECG leads) are a result of the retrograde P' waves. B, With atypical AVNRT, a VPD blocks at the FP and travels retrograde up the slow pathway, followed by antegrade conduction down the FP. Inverted P' waves are visible before the onset of the QRS complex in atypical AVNRT (RP > PR). A, atrial; APD, atrial premature depolarization (PAC); AVN, atrioventricular node; AVNRT, atrioventricular nodal reentrant tachycardia; P, P wave; R, R wave; V, ventricular; VPD, ventricular

premature depolarization (PVC).

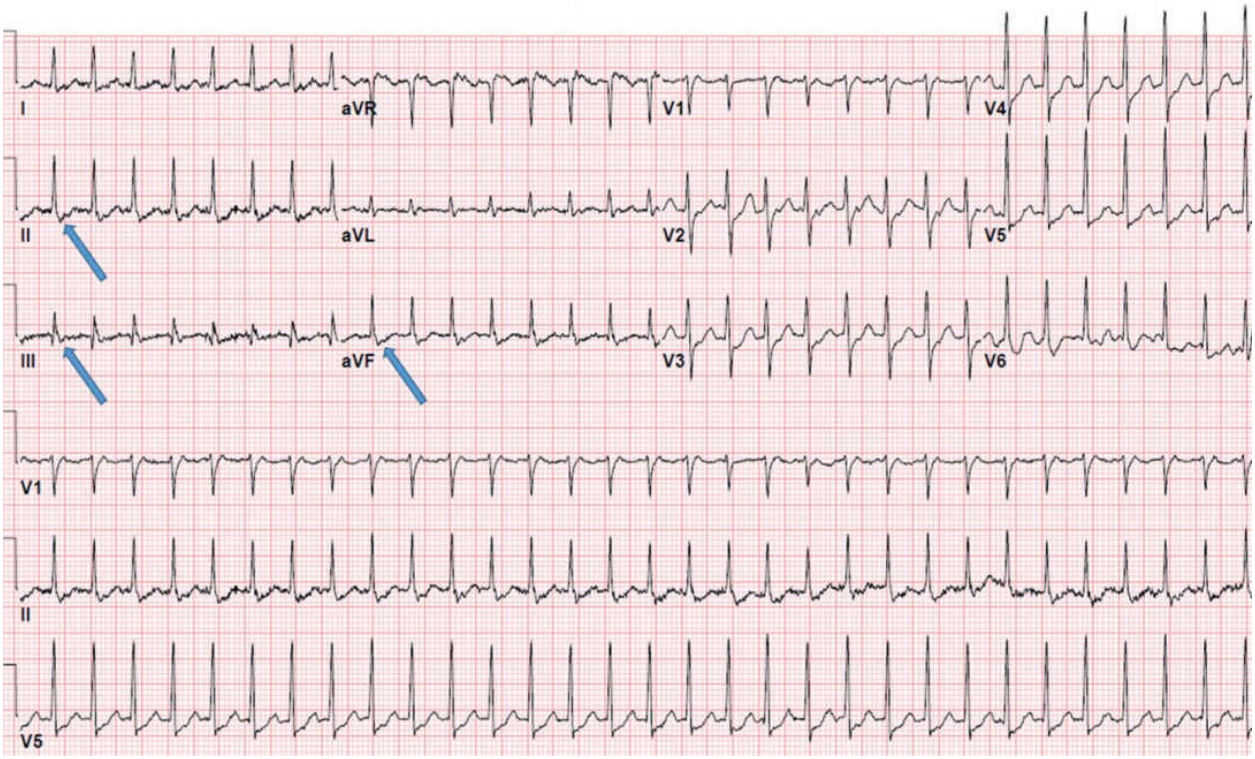

FIGURE 22.8 Typical (slow-fast) atrioventricular nodal reentrant tachycardia on 12-lead ECG. P waves are often not visible because they are buried in the QRS complexes owing to simultaneous activation of the atria and ventricles. In this example, take note of the pseudo s′ waves, which appear at the inferior leads (II, III, aVF) at the end of the QRS complex (arrows).

P waves are unidentifiable or can be seen just beyond the QRS complex because of the nearly simultaneous activation of the atria and ventricles. The P wave would look like a pseudo-S wave in leads II, III, aVF, and like an r’ wave in lead V1, which is the *sine qua non* in the diagnosis.

The rhythm is termed *typical* AVNRT (most common, 90%) if it follows the aforementioned EP properties, whereas in the *atypical* form of AVNRT the impulse travels down the *fast pathway* and up the *slow pathway* (uncommon, 10%) which manifests as a similar ECG finding except that P waves would be further away from the QRS.

As with any SVT, acute treatment of AVNRT should begin with assessment of hemodynamic stability, and patients who are hypotensive should be electrically cardioverted immediately. It is uncommon for AVNRT to cause major hemodynamic instability, and thus vagal maneuvers should be attempted to prolong the refractoriness of AV nodal conduction with a resultant transient

anterograde block and termination of the tachycardia. If vagal maneuvers are ineffective, administration of adenosine has been shown to terminate more than 95% of AVNRTs. [13, 14] Additional AV nodal agents such as IV (or PO) nondihydropyridine CCBs (ie, diltiazem) or β-blockers are second-line options.

Despite their effectiveness in terminating AVNRT, it is important to keep in mind that the ability of CCBs to slow AV nodal conduction may result in more rapid conduction down an AP in the presence of preexcited AF, leading to VF and sudden cardiac death (SCD). They can also be dangerous for patients with significant systolic heart failure because of their negative inotropic and vasodilatory properties. β-Blockers (ie, metoprolol) are a safer choice in that setting, and amiodarone might be a reasonable third-line option, although robust data on its efficacy is lacking.

ATRIOVENTRICULAR REENTRANT TACHYCARDIA

AVRT is a form of short-RP tachycardia that develops in patients with an AP, a cluster of extranodal tissue that provides an alternative atrio-ventricular electrical connection, which bypasses the AV node and His-Purkinje system. APs can conduct in antegrade, in retrograde, or in both directions. They are described as *manifest* if they conduct antegrade more rapidly than the AV node, demonstrating a characteristic *preexcitation* pattern on resting ECG with slurring of the QRS upstrokes known as *delta*waves, resulting in a broader QRS (> 110 ms) and shortened PR interval (less than < 120 ms); *concealed* if they conduct exclusively retrograde; or *latent* if they have the capability to conduct antegrade under certain conditions. When associated with paroxysms of SVT, this pattern is known as WPW syndrome, and the pre excitation pattern on ECG during sinus rhythm signifies early ventricular activation due to rapid anterograde conduction down the *manifest* AP (**Figure 22.9**).

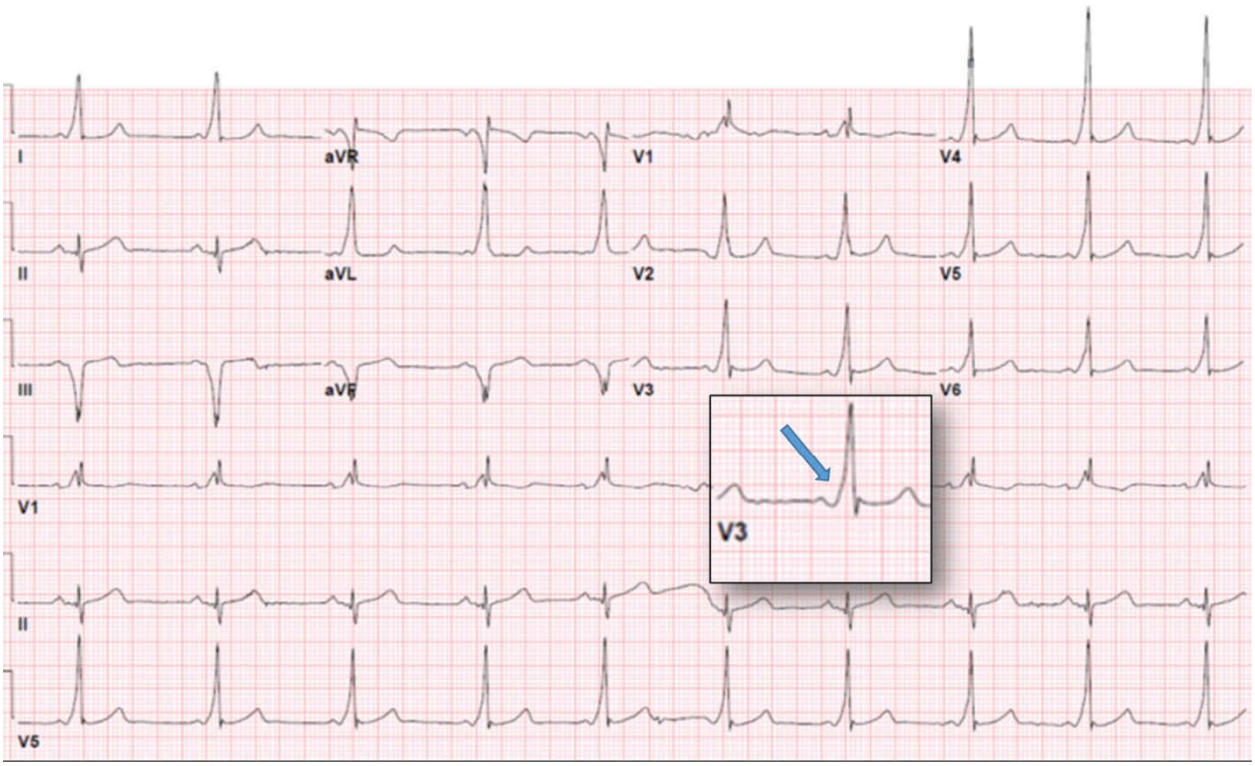

FIGURE 22.9A 12-lead ECG in sinus rhythm with preexcitation (delta wave). Delta waves on resting ECG are a result of ventricular preexcitation due to concomitant rapid anterograde conducting accessory pathway. Note the characteristic shortened PR interval and broad QRS with slurring of the initial upstroke (arrow).

The most common form, *orthodromic* AVRT (95%), results from an impulse (eg, PAC) that blocks at the AP (during refractory period), travels down the AV-node His-Purkinje system to the ventricle, then travels retrograde to the atrium via the AP, and reenters the AV node, continuing the tachycardia (**Figure 22.10**). The RP interval is slightly longer in *orthodromic* AVRT (P wave on top of ST segment) compared with AVNRT (P wave at end of QRS complex), but the difference may be subtle on ECG. *Antidromic* AVRT is a much less common form of AVRT (5%) in which an impulse blocks at the AV node, travels down the AP, and returns retrograde to the atrium via the AV node. This results in a distinctive *wide QRS complex* tachycardia on ECG. It is important to remember that preexcited *antidromic* AVRTs with a *manifest* AP that conducts rapidly from the atrium to the ventricle carry a low (< 1%) but tangible risk of SCD, particularly in the setting of AF, AFL, and AT. This is due to rapidly conducted atrial impulses via the AP to the ventricle, which can cause VF. The risk is most pronounced in the first two decades of life, but can be heightened in patients in the CCU receiving AV nodal blocking agents for rate control (ie, β-blockers,

CCBs), which could promote anterograde conduction down the AP.

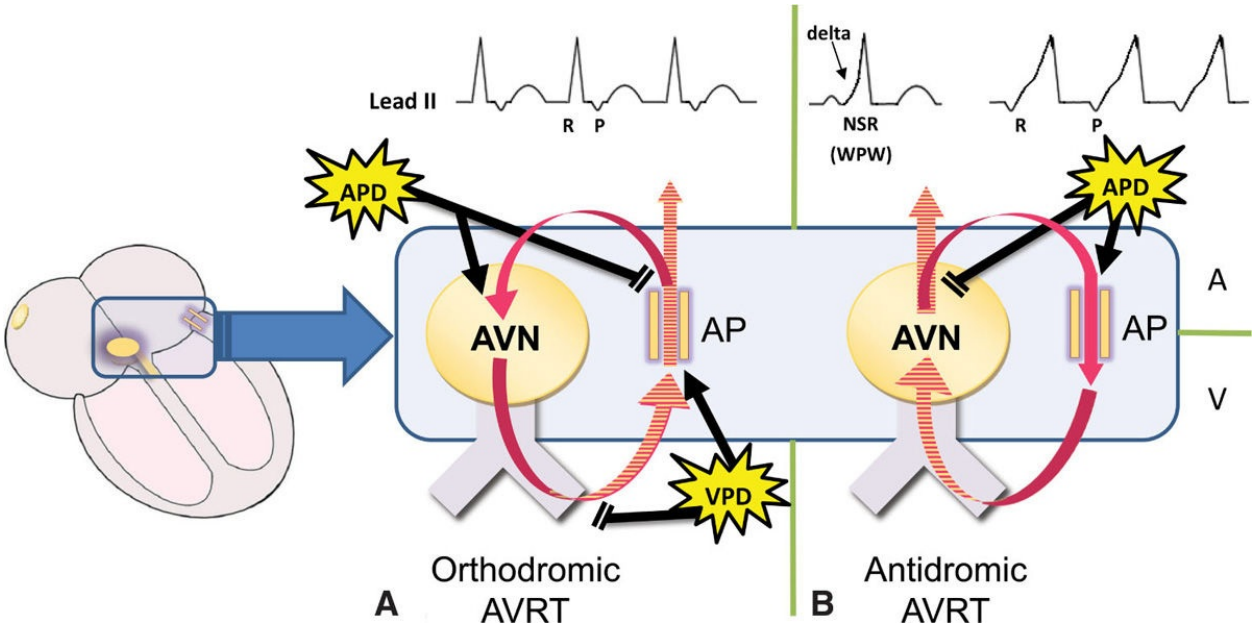

FIGURE 22.10 Mechanisms of atrioventricular nodal reentrant tachycardia (AVRT). A, During orthodromic AVRT, no delta wave is seen because all anterograde conduction is over the AV node (AVN) and His–Purkinje system. Retrograde P waves are seen after each QRS. B, Mechanism of AVRT in patients with the Wolff–Parkinson–White (WPW) syndrome. In sinus rhythm, the slurred QRS upstroke (delta wave) is due to rapid anterograde conduction over the accessory pathway (AP) and early activation of the ventricle (V). During antidromic AVRT, maximal preexcitation results in wide distorted QRS complexes due to V activation exclusively from anterograde conduction over the AP. A, atrium; APD, atrial premature depolarization; AVN, atrioventricular node; NSR, normal sinus rhythm; VPD, ventricular premature depolarization.

Acute treatment of AVRT may focus on either the AV node or on the AP. In *orthodromic* or *antidromic*AVRT, the AV nodal conduction is a viable target for maneuvers and medications that delay or block anterograde or retrograde impulses, respectively. As with AVNRT, vagal maneuvers may slow conduction at the AV node and lead to block and termination of the tachycardia. If unsuccessful, antiarrh tissue refractoriness and block AP conduction. However, these should not be used in patients with structural or ischemic heart disease.[1]Amiodarone is less efficacious than procainamide and may be considered as a last-line option for elderly patients or those refractory to other medications. Owing to its efficacy in delaying extranodal and blocking AP conduction, IV procainamide is considered first line for acute management of *antidromic*AVRT. Predictors of high-risk patients with WPW for SCD are younger males <40 years of age, manifest preexcitation on ECG at all times,

multiple APs, and short antegrade effective refractory period of the AP (< 240 msec).

ATRIAL TACHYCARDIA

AT is a less common form of SVT that initiates from the atria and (unlike AVNRT or AVRT) does not require that the AV node participates in sustaining the arrhythmia. In other words, the atrial origin *drives* the arrhythmia with an atrial rate that can range from 100 to 250 bpm (**Figure 22.11**). The course of AT is typically benign; however, sicker patients in the CCU may exhibit more incessant forms and be at higher risk for developing tachycardia-induced cardiomyopathy or decompensated heart failure.

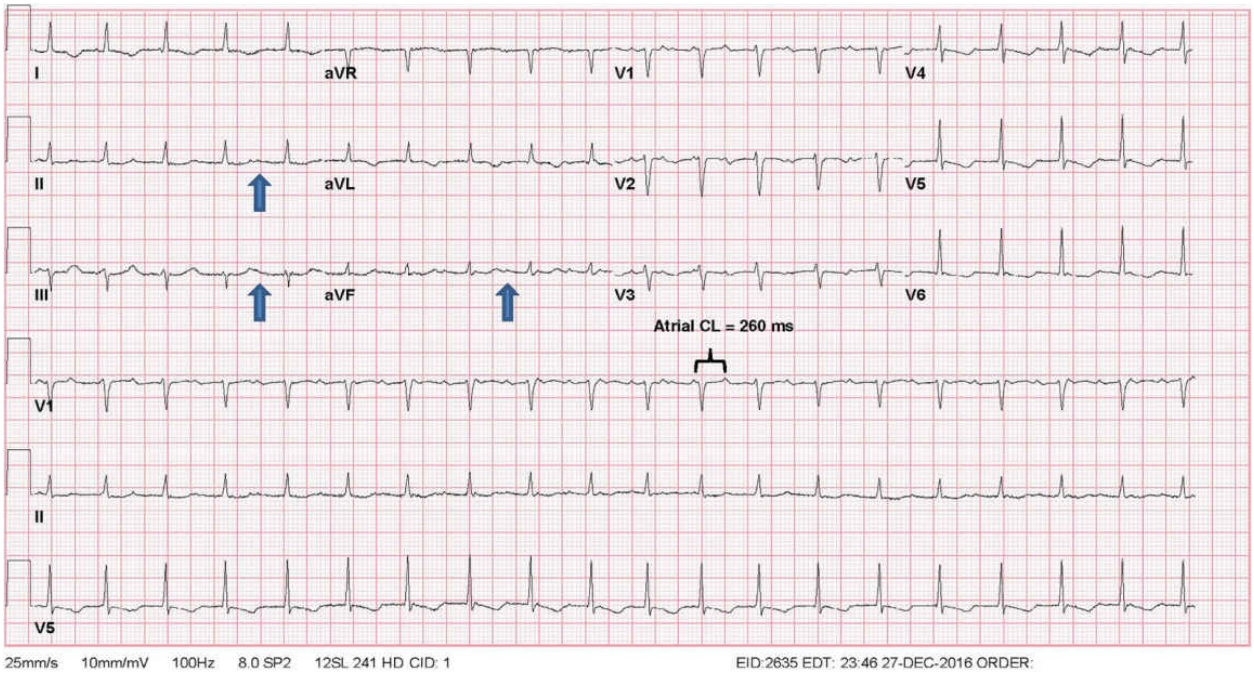

FIGURE 22.11 Atrial tachycardia on 12-lead ECG. Note the upright P waves in the inferior leads (II, III, AVF; arrows) with an atrial cycle length (CL) of 260 ms. ECG, electrocardiogram.

ATs can generally be divided into three types (**Figure 22.12**): (1) focal, (2) multifocal, and (3) macro-reentrant. Focal ATs are characterized by centrifugal spread of atrial activation from a small defined area, and are further described in terms of their EP mechanisms including abnormal automaticity, triggered activity, and microreentry.[16, 17] MAT is a less understood but not an uncommonly encountered AT in the CCU setting. It is typically seen as secondary to a number of underlying cardiopulmonary conditions, particularly

respiratory failure due to chronic obstructive pulmonary disease (COPD). ECG findings should include an irregular tachycardia (ventricular rate ≥100 bpm) with at least three distinct P-wave morphologies and an isoelectric baseline between P waves (**Figure 22.13**). Unfortunately, in the presence of rapid AV nodal conduction, ECG analysis is insensitive for differentiating between ATs.

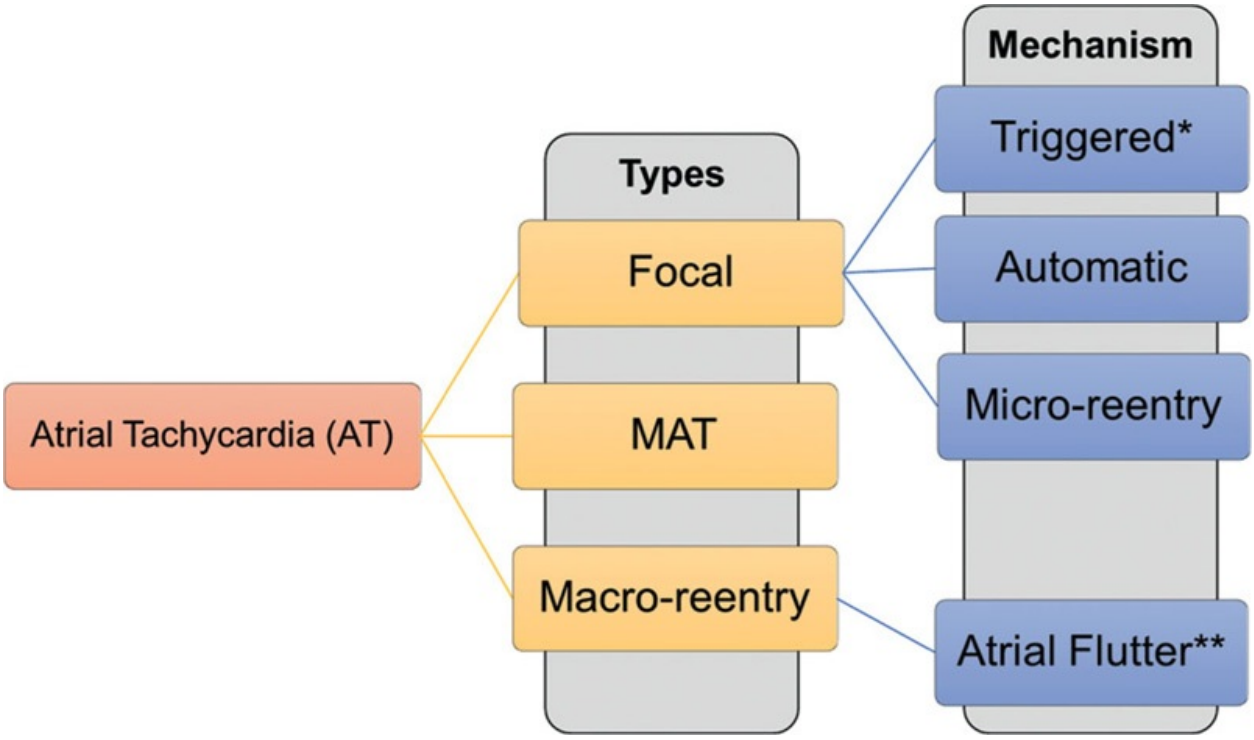

FIGURE 22.12 Classification of AT by type and mechanism. Focal atrial tachycardias (ATs) can commonly occur as a result of early or late afterdepolarizations (triggered activity) or cells with enhanced firing rates compared with normal pacemaker cells (automaticity), or as a result of a small reentrant loop (micro-reentry), which is frequently difficult to locate despite advanced EP mapping software in the lab. Multifocal atrial tachycardia (MAT) is a poorly understood, irregular form of AT characterized by at least 3 different P-wave morphologies. It is often seen as a feature of acute cardiopulmonary illness, especially respiratory failure due to COPD. *Likely etiologic mechanism of a majority of focal ATs. **Atrial flutter discussed in another chapter.

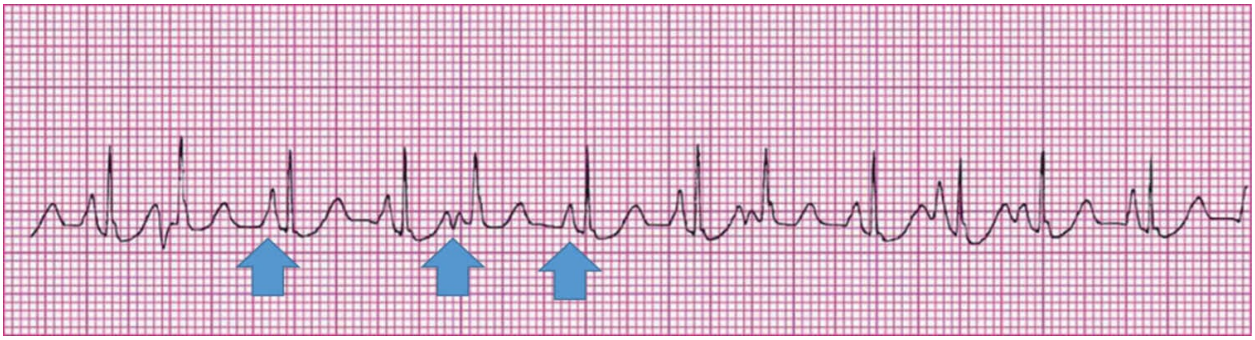

FIGURE 22.13 Multifocal atrial tachycardia (MAT) on a telemetry strip. It is characterized by three distinct P-wave morphologies, with irregular P-to-Pintervals, and ventricular rate >100 bpm. MAT is frequently seen during bouts of acute illness, especially respiratory failure due to decompensated COPD.

Thus, to make a definitive diagnosis, it is especially useful to employ vagal maneuvers or adenosine when encountering an AT. Vagal maneuvers usually do not terminate focal ATs, but can result in a transient AV nodal block that allows for clearer delineation of P waves. Similarly, the antiadrenergic and AV nodal blocking properties of adenosine are very effective in differentiating focal from macroreentrant (ie, AFL) ATs, and can provide additional mechanistic information based on resultant termination (eg, triggered AT) or suppression (eg, automatic AT) of the arrhythmia. The importance of a high-quality ECG rhythm strip during adenosine administration cannot be overstated in this scenario. Additional options for acute management of ATs include AV nodal blocking agents for ventricular rate control (ie, IV verapamil or β-blockers), as well as class IC drugs (flecainide, propafenone) with variable efficacy. In contrast to focal ATs, hospitalized patients with MAT may portend higher morbidity and mortality, and rate- or rhythm-controlling strategies that are typically employed tend to be ineffective. As a mainstay, their predisposing condition should be managed aggressively to offer the best outcomes. Electrical cardioversion is of variable utility depending on the mechanism of AT, and patients with sustained ATs or continued symptoms often benefit (at lower risk) from radiofrequency (RF) catheter ablation as first-line treatment.

INAPPROPRIATE SINUS TACHYCARDIA

In contrast to sinus tachycardia, which is always a normal secondary physiologic response, inappropriate sinus tachycardia (IST) is defined as a sinus tachycardia that cannot be explained by normal physiologic stressors. It is further described by associated symptoms such as weakness, dizziness, and palpitations, which are also not attributable to secondary causes such as thyroid disease, anemia, or drugs. Resting heart rates in patients with IST are typically > 100 bpm, with a mean 24-hour heart rate > 90 bpm.[1]Etiologies such as neurohormonal dysregulation, sinus node hyperactivity, and dysautonomia have been suggested, but the precise cause is uncertain. There has been some association seen with anxiety disorders, and anxiety can be a trigger. Overall, IST carries a benign prognosis, and no specific recommendations for acute management have been published. For ongoing management, ivabradine was found to reduce the

inherent pacemaker activity of the sinus node and has recently been approved by the U.S. Food and Drug Administration for use in patients with concomitant systolic heart failure.[19, 20]

JUNCTIONAL TACHYCARDIA

Junctional tachycardia (JT) is seen infrequently in adults, but may be encountered in patients in the CCU following cardiac surgery. The underlying mechanism is abnormal automaticity from a focus at the AV junction.[21] On ECG, JT manifests as a rapid, regular (occasionally irregular), narrow QRS complex tachycardia with ventricular rates ranging from 100 to 220 bpm, and retrograde (in or after the QRS) P waves (**Figure 22.14**). It is not uncommon to misdiagnose other SVTs (ie, AVNRT, AVRT, MAT) because of the often absent P waves and sometimes irregular appearance on ECG. The course of adult patients with JT is essentially benign, and given the low incidence of JT in this population, there is little data regarding diagnosis and management. Nonetheless, IV β -blockers, verapamil, diltiazem, and procainamide may be reasonable in the acute setting. A far more commonly encountered paroxysmal JT in adults is accelerated junctional rhythm. It exhibits a slower ventricular rate (60-100 bpm) than does JT and is frequently seen in the setting of acute MI or digoxin toxicity. Acute management primarily focuses on treating the underlying condition, but there are some data to suggest that β-blockers, verapamil, or adenosine may terminate the arrhythmia.

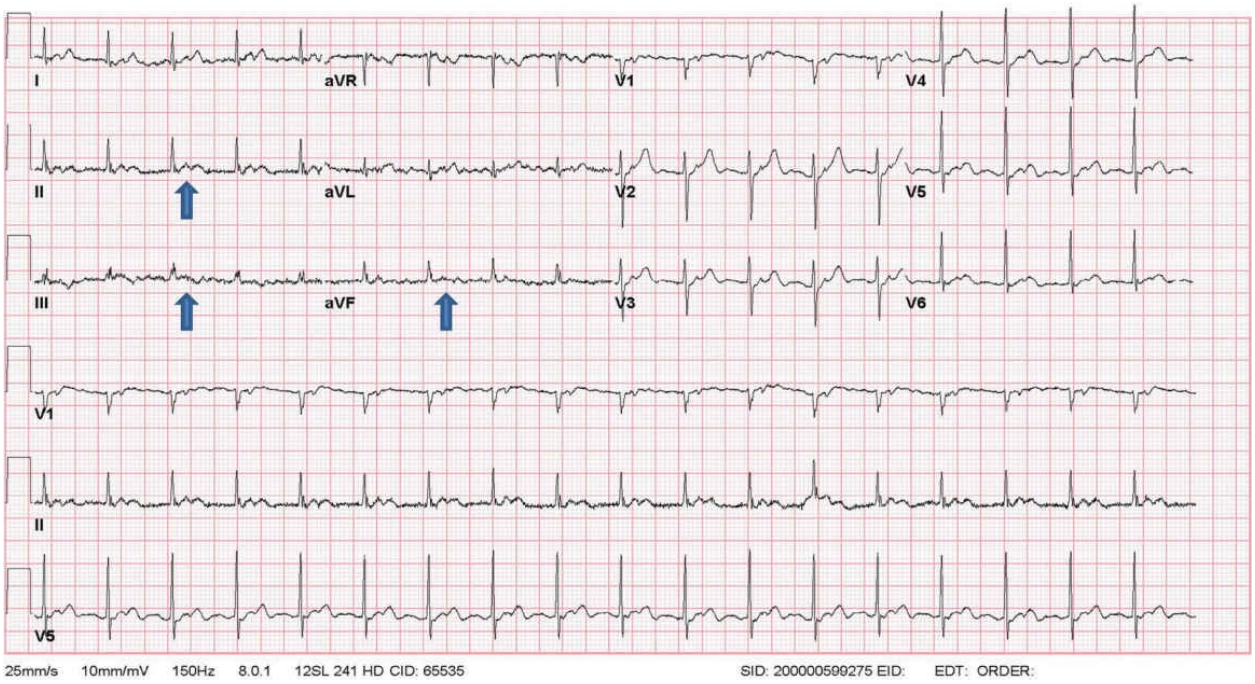

FIGURE 22.14 Junctional tachycardia (JT) or accelerated junctional rhythm. Note the absence of P waves preceding each QRS complex which appear to be buried in the proceeding T waves (arrows).

LONG-TERM MANAGEMENT OF PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIAS

Patients with infrequent episodes of AVNRT that are well tolerated can be managed long term with prophylactic AV nodal blocking medications (eg, PO β-blockers, verapamil, diltiazem). Although antiarrhythmic medications such as flecainide and propafenone are reasonable secondary options in patients without structural or ischemic heart disease, their use in a younger patient is not preferred. Patients with frequent symptomatic episodes, intolerance to medication, or preference of not using long-term medications can undergo curative RF catheter ablation via *slow* pathway modification (**Figure 22.15**) as first-line therapy. [22, 23] Technological advances have greatly increased the safety, efficacy, and cost-effectiveness[24] of this approach with success rates of 95% to 99% and less than 1% risk of any complications.

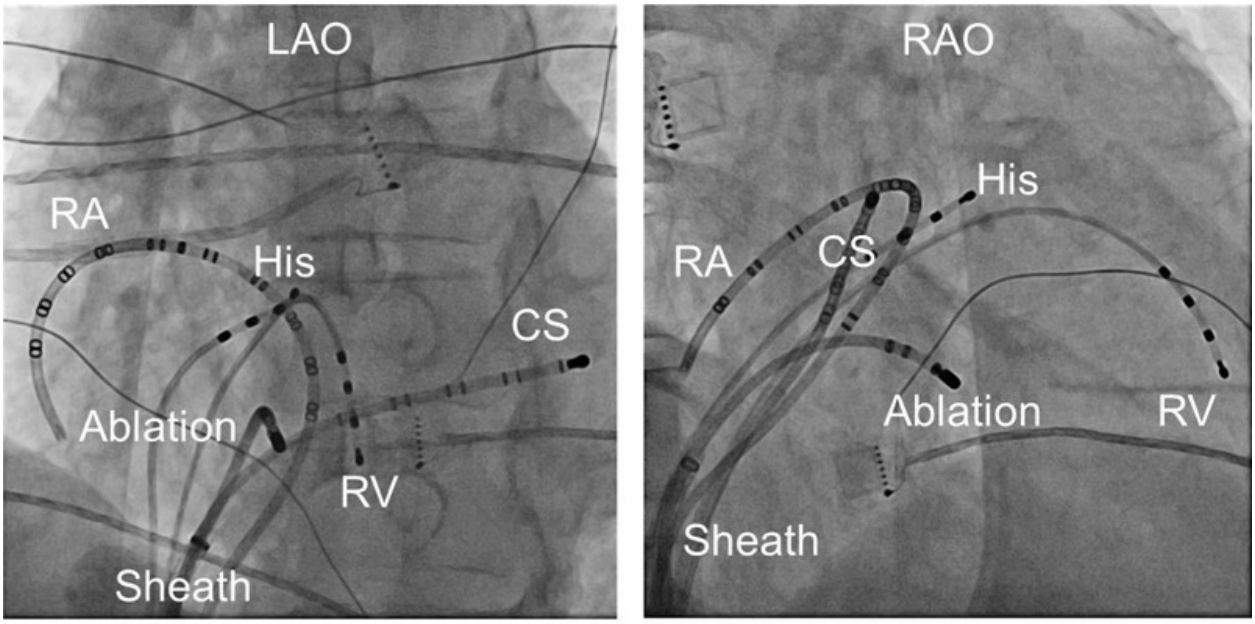

FIGURE 22.15 Catheter positions during slow-pathway modification via radiofrequency ablation for AVNRT. CS, coronary sinus; LAO, left anterior oblique; RA, right atrium; RAO, right anterior oblique; RV, right ventricle; AVNRT, AV nodal reentrant tachycardia.

With similarly high success rates, catheter ablation should be strongly considered for long-term management of symptomatic patients with AVRT and WPW syndrome with high-risk features for SCD. Patients who are not inclined to undergo ablation can be given PO class IC (flecainide, propafenone) or class III (amiodarone) agents in the setting of *antidromic* AVRT.

Controversies exist on the management of asymptomatic patients with WPW; this is due to the complexity of the nature of history of asymptomatic WPW. Certainly, the asymptomatic pediatric population is at higher risk of SCD than is the adult asymptomatic population. Intrinsic EP properties of APs, rather than symptoms can quantify this risk and further delineation with an EP study should be encouraged.

Focal ATs can be managed with a rate-control strategy utilizing AV nodal blocking medications such as PO verapamil, diltiazem, or β-blockers. Catheter ablation is a safe and viable option for symptomatic patients or those with incessant ATs, with variable success rates ranging from 70% to 100%.

MAT is most typically seen in patients with advanced lung disease, but can be additionally correlated to structural heart disease and congestive heart failure. Treatment entails a rate-control strategy with AV nodal agents, but remains centered on management of the underlying condition.

SUMMARY

SVTs are commonly encountered in the CCU. Aside from AF, the SVTs most typically seen (in order of frequency) are AVNRT, AVRT, and AT. Narrow QRS complex tachycardias require a systematic approach to differential diagnosis and treatment. Sinus tachycardia is virtually always a compensatory response that requires identification and treatment of the underlying cause. Early identification of patients with hemodynamic compromise due to SVTs with prompt electrical cardioversion is essential. The initial approach to hemodynamically stable patients with SVT should include vagal maneuvers, followed by medications that transiently slow AV conduction and may potentiate termination of the arrhythmia. Long-term management must be individualized and may include PO AV nodal agents and RF catheter ablation.

Patient and Family Information for:SUPRAVENTRICULAR ARRHYTHMIAS

WHAT IS SUPRAVENTRICULAR TACHYCARDIA?

Supraventricular tachycardia (SVT) is a general term used to classify abnormally fast heartbeats (tachycardias) known as arrhythmias, which originate above (supra-) the ventricles (lower chambers) in the atria (upper chambers) of the heart. The term *paroxysmal* is sometimes used to describe SVTs that start and stop suddenly or intermittently, without warning. Although normal heart rates range from 60 to 100 beats per minute (bpm), heart rates during SVT are usually greater than 130 bpm and may climb above 200 bpm in some instances. The fast heartbeat can last minutes or even hours, and it can happen during rest or with exercise. In a hospital setting, additional stress from the patient's illness(es) may provide a trigger for SVT to occur more frequently. SVT is not a single disease; rather, it encompasses a number of arrhythmias that have different causes and may each require unique treatment strategies. The three most common types of SVT are called atrioventricular nodal reentrant tachycardia (AVNRT), atrioventricular reentrant tachycardia (AVRT), and atrial tachycardia (AT). Atrial fibrillation and atrial flutter with rapid heart rates are also types of SVT and are discussed in detail in a separate chapter.

HOW IS SUPRAVENTRICULAR TACHYCARDIA RECOGNIZED?

Some patients may not experience symptoms during episodes of SVT. If

symptoms are present, the patient may have a sensation that his or her heart is beating very rapidly, forcefully, and/or irregularly (also known as palpitations). In addition, the patient may feel tired, dizzy, faint, and, in some instances, pass out because of lack of adequate blood flow to the brain when the heart is beating very rapidly. Patients who also have coronary artery disease or congestive heart failure may also experience symptoms such as difficulty breathing and tightness or pain in the chest. Although symptoms are useful in recognizing arrhythmias, determining specific types of SVT requires careful examination of the 12-lead electrocardiogram (ECG). Because of the intermittent nature of most SVTs, longer-term monitoring is sometimes required. In the hospital or cardiac care unit (CCU) setting, this can be done readily using standard continuous telemonitoring devices worn by many or all patients. A cardiologist may ask the outpatient to wear an external monitoring device for up to one month or may refer him or her to a cardiac electrophysiologist (electrical specialist of the heart), who can implant a longer-lasting device under the skin to provide monitoring for two years or more. On some occasions, a more invasive study called an electrophysiology (EP) study is performed to better pinpoint the exact type of SVT. The procedure is done in a closely monitored laboratory setting using multiple catheters that are introduced into the heart from veins in the legs. Using this minimally invasive technique, abnormal electrical circuits in the heart can be accurately located and mapped.

SINUS TACHYCARDIA VERSUS SUPRAVENTRICULAR TACHYCARDIA

Not to be confused with SVT, sinus tachycardia refers to a fast heart rate, typically 100 to 130 bpm, which originates from and travels through the normal electrical circuits in the heart. It is a normal reaction of the heart to exertion, exercise, and stressors such as anxiety, fever, and pain. It is also commonly associated with various illnesses that directly or indirectly affect the heart such as heart failure, heart attack, infections (e.g., pneumonia), and blood clots in the lungs (pulmonary embolism). Thus, sinus tachycardia is almost always a means by which the body compensates during illness or stress, and it does not require specific treatments aside from managing the underlying stressor. In contrast, SVT is always abnormal (pathologic) and requires treatment.

HOW IS SUPRAVENTRICULAR TACHYCARDIA TREATED?

Paroxysmal SVT most often starts and stops abruptly, but when it occurs, it can result in a spectrum of clinical findings from uncomfortable palpitations to life-threatening hemodynamic instability (low blood pressure) or organ ischemia (low blood flow), requiring urgent intervention. If the patient is unstable, conversion (cardioversion) to normal sinus rhythm can be immediately attempted by applying an electric current (shock) over the chest to the heart. Electrical cardioversion is a generally safe and effective (over 90%) way to quickly restore a normal heart rhythm, and patients are given sedatives and pain medication prior to delivery of the shock if possible. In situations where blood pressure is stable and the patient has a good pulse, doctors may try vagal maneuvers to slow the heart rate and terminate the arrhythmia without medications. Vagal maneuvers affect the nervous system, which then signals the heart to respond by reducing the heart rate. One of these techniques used by doctors is called carotid sinus massage, and is performed by briefly pressing (for 5 to 10 seconds) on a specific area of the neck overlying the carotid arteries that carry blood to the brain. This is done while closely monitoring the patient's ECG and vital signs, as it can cause slowing of the heart rate and may lower the blood pressure. Carotid massage should not be performed by the patient or on patients who have blockages in their carotid arteries. Alternatively, doctors may instruct the patient to try Valsalva maneuvers such as holding a deep breath and straining (as during a bowel movement). Both carotid massage and Valsalva maneuvers can slow the heart rate to better identify the type of SVT or may terminate it completely.

If vagal maneuvers do not work, certain medications can be given orally or intravenously (IV) to try and terminate the SVT. The most commonly used medication is IV adenosine. This medication works by slowing the heart rate and temporarily blocking impulses traveling from the upper to the lower chambers of the heart, which can break the abnormal electrical circuit in the heart and terminate the arrhythmia. After injection, patients often feel brief uncomfortable symptoms such as skin flushing, chest tightness, and shortness of breath, which quickly subside because of adenosine's short duration of action. Other medications that may be used to slow the heart rate or terminate SVT include beta-blockers (e.g., metoprolol), specific calcium channel blockers (e.g., diltiazem, verapamil), and specialized antiarrhythmic medications. If the

episodes of SVT are infrequent and patients are not highly symptomatic, daily oral medications to control heart rates during episodes or prevent attacks may be sufficient. In patients with severe symptoms and frequent episodes, an EP study followed by an ablation procedure can be performed to cure the arrhythmia. Like EP studies, ablations are procedures that are done in the EP laboratory and use catheters that are guided into the heart. Catheters are then directed to the specific spots in the heart, from where the SVT is thought to originate, and then tiny controlled burns (called radiofrequency ablation) or extreme cold (cryoablation) is applied to destroy the abnormal electrical circuits that are causing the arrhythmia. In most patients with SVT, the arrhythmia is permanently cured after the ablation procedure.

SUMMARY

Supraventricular arrhythmias are commonly seen in the CCU. Sinus tachycardia should be differentiated from SVT in that it is almost always a normal means by which the body compensates for a stressor such as exercise, fever, or illness. As such, it does not require specific management other than identification and treatment of its underlying cause. In contrast, SVT is always abnormal and can result in a wide range of clinical findings from benign uncomfortable symptoms to ischemia or life-threatening hemodynamic instability. Careful examination of ECG findings can help narrow down specific types of SVT, but pinpointing specific types often requires long-term monitoring because of the intermittent nature of the arrhythmia. Patients who are hemodynamically unstable may require urgent electrical cardioversion to restore normal heart rhythm. After identifying SVT in a stable patient, doctors may attempt vagal maneuvers, followed by IV adenosine in an attempt to slow the heart rate and terminate the arrhythmia. Patients who have severe symptoms or frequent episodes of SVT can have an EP study followed by catheter ablation (radiofrequency or cryoablation) with a high likelihood of permanently curing the arrhythmia. A good basic understanding of the causes and issues related to SVT and its management is important for patients and their families.

Fundamentals of Atrial Fibrillation and Atrial Flutter

ATRIAL FIBRILLATION

Atrial fibrillation (AF) is the most common arrhythmia in the adult population, with continuously increasing prevalence as the population ages; currently, 6 million adults in the United States are diagnosed with AF. It represents a significant influence on morbidity and mortality rates as well as a large economic and public health burden.[1] AF predisposes to a greater risk of stroke and mortality while impairing quality of life.[2] The estimated cost of treating US citizens with AF is $26 billion a year. It is estimated that by year 2050 the prevalence of AF will be close to 12 million. This assumption is based on increasing mean age of population, obesity epidemic, as well as achievements in treatment of cardiovascular diseases.[3]

Men have a 1.5-fold higher risk for developing AF than women, derived from data adjusted for age and predisposing conditions.[4] Although it seems to be less common in African Americans, lifetime risk of developing AF is higher in men of European descent compared with women of European descent (26% vs 23%). AF is strongly age associated, most commonly presenting at age 80 or above (about 1 in 10) and only 1% of patients with AF are less than the age of 60.

Aging of the population is the main underlying factor for rapidly increasing prevalence of AF.[5, 6]

ETIOLOGY

Patients with underlying cardiovascular disease often have abnormal atrial size and function. Enlargement of the atrial chamber, fibrosis, fatty or amyloid tissue deposition, and inflammation can contribute to abnormal functionality and electrical remodeling of the atrium leading to pathologic evolution of AF. Some patients have AF occurring under the influence of autonomic nervous system: vagal form (after meals, during sleep) or adrenergic form (exercise induced).

RISK FACTORS

1. Increasing age: especially >80 year old, one in 10 patients above age 80 will develop AF. This represents >1/3 of patients with AF.[7]
2. Male sex: a 1.5-fold higher risk than in females.[8]
3. Tall stature and obesity: these are independently associated with increased incidence of AF.[9] In the Framingham Heart Study, every unit increase in body mass index (BMI) was associated with an approximate 5% increase in risk.
4. Metabolic syndrome[10]: with its components, hypertension (HTN),[8] obesity,[9] diabetes mellitus, hyperlipidemia, are all associated with higher risk of AF.[11] BMI, waist circumference, and sagittal abdominal diameter could similarly predict AF.[12]
5. Valvular heart disease: the most potent association is with mitral stenosis.
6. Myocardial infarction (MI): AF in the setting of acute MI independently predicts stroke and 30-day mortality[13]; can be seen in up to 10% of patients in the early period after acute MI.[8, 14]
7. Postsurgical AF: there are heterogeneous patterns of AF after cardiac surgery. The incidence is 20% to 25% in patients undergoing coronary artery bypass grafting and up to 40% after valvular surgery. A substantial minority of AF is short-lived and isolated, with no impact on length of stay; however, recurrent or prolonged AF significantly affects outcomes.[15]
8. Heart failure (HF): there is individual variation of cause–consequence relationship.[16]
9. Obstructive sleep apnea (OSA): predisposes by metabolic and autonomic

abnormalities, as well as structural cardiovascular changes.[17] Untreated OSA is associated with much higher risk of development of AF as well as recurrence after AF ablation.[18]

10. Chronic kidney disease.
11. Hyperthyroidism: clinically overt and subclinical, it is associated with higher risk of developing AF.
12. Excessive alcohol consumption, caffeine, cigarette smoking.
13. Excessive physical exertion: athletic lifestyle, especially the one involving endurance activities predisposes to higher risk especially in young patients (due to high vagal tone).
14. Genetic predisposition: parental AF predisposes the offspring by two to three times than in the general population.

PATHOPHYSIOLOGY

The pathophysiology of AF is multifactorial and complex, including genetic and neural system mechanisms. Haissaguerre et al were the first to evaluate and discover pulmonary veins (PVs) as the dominant triggers in the initiation of AF.[19] Focal triggers can lead to reentry in high-frequency rotors, and electrical activation from these rotors may fragment giving fibrillatory conduction. If this process continues for long periods, there is subsequent atrial remodeling at the cellular level (ion channels) and other triggers raise further perpetuating AF, in particular small and large reentrant wavelets. AF induction may occur in the presence of fibrotic and poorly conducting atria (eg, due to hemodynamic overload, as in HTN or HF); genetic disorders affecting refractory period and/or conduction velocity heterogeneously[20]; or AF itself. By shortening the atrial refractory period, reducing conduction velocity, and provoking contractile and structural remodeling, AF may set the stage for self-perpetuation (ie, “AF begets AF”).[21] Structural remodeling of both atria typically happens under the influence of previously mentioned risk factors. This remodeling is mediated by activations of fibroblasts, fibrosis, fatty infiltration, connective tissue deposition, myocyte hypertrophy, necrosis, and inflammatory infiltration. All these processes result in local conduction disturbances and electrical dissociation that leads to micro-reentrant circuits’ formation. Genetic mechanisms associated with AF development include abnormalities in potassium or sodium channels, connexin expression or function, and microRNAs[22] (**Figure 23.1**).

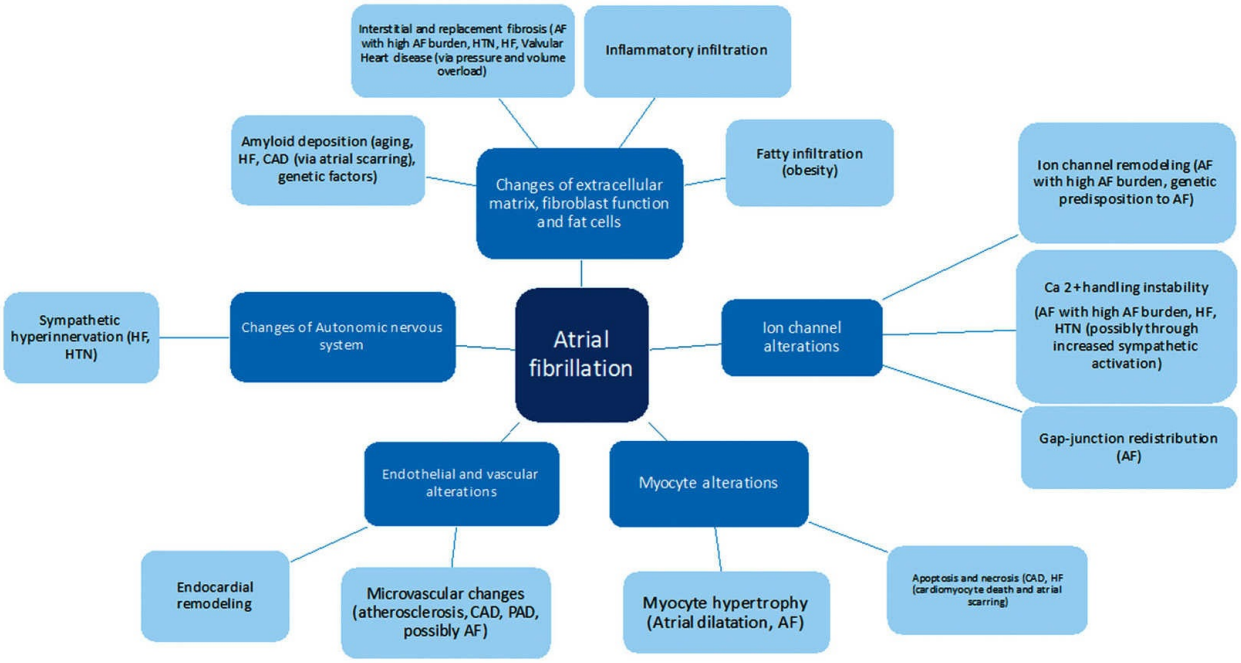

FIGURE 23.1 Key factors in the pathophysiology of atrial fibrillation (AF). CAD, coronary artery disease; HF, heart failure; HTN, hypertension; PAD, peripheral artery disease. Modified from ESC guidelines 2016: management of atrial fibrillation.[22]

CLASSIFICATION

Detecting asymptomatic or minimally symptomatic AF improved with implantable loop recorders (ILRs), pacemakers, and defibrillators.

1. **Lone AF or idiopathic AF:** It used to be defined as patients who have no precipitating cause or associated CV disease. However, the percentage of AF that is considered lone AF decreased from 30% in 1954 to 3% in 2014 based on studies that showed larger proportion of etiologic factors of AF. The term lone AF is generally avoided because it is not fully clear to what extent the workup should be done to consider AF to be idiopathic and also the term is not useful in making treatment decisions.[23]
2. **Asymptomatic AF** (subclinical): Early recognition of AF at times is difficult owing to its often "silent" nature. For one-third of patients with AF, they are not aware that they are in AF. Recent studies using different monitoring tools, ranging from transtelephonic monitoring to pacemakers, have indicated that the correlation between AF episodes and patient symptoms is very poor: many AF episodes are asymptomatic, whereas many AF-like symptoms are

not related to AF episodes.[24] Early detection of the arrhythmia might allow timely introduction of therapies to protect patients from AF complications as well as the possibility of interrupting the progression of AF from a potentially treatable condition to a refractory one. The Asymptomatic Atrial Fibrillation and Stroke Evaluation in Pacemaker Patients and the Atrial Fibrillation Reduction Atrial Pacing Trial (***ASSERT***) monitored patients 65 years or older who had HTN and no prior history of AF and a newly implanted pacemaker or cardioverter defibrillator for development of subclinical atrial tachyarrhythmias (defined as episodes of atrial rate >190 beats per minute [bpm] for more than 6 minutes). At 3 months, 10.1% of the enrolled patients had developed such episodes. Subclinical AF was indeed associated with both an increased risk of clinical AF and ischemic stroke and systemic embolization.[25] More intense and prolonged monitoring is justified in highly symptomatic patients, patients with recurrent syncope, and patients with a potential indication for anticoagulation (especially after cryptogenic stroke).[26]

3. **Paroxysmal AF:** Self-terminating (within 48 hours to 7 days).
4. **Persistent AF:** Continuously present for more than 7 days and up to 1 year.
5. **Long-standing AF:** Continuous AF lasting for ≥1 year.
6. **Permanent AF:** Duration longer than 1 year with failed attempts to restore and maintain sinus rhythm (SR).

ATRIAL FIBRILLATION, A PROGRESSIVE DISEASE

AF is a progressive disease that becomes more difficult to treat with increasing duration. In patients presenting with paroxysmal AF—progression to persistent AF is 10% in 1 year, 25% to 30% in 5 years, and more than 50% in 10 years. In patients with persistent AF lasting more than 1 year, only 40% to 60% remain in SR; and in patients with more than 3 years of duration, only 15% are maintained in SR. Clinical progression, supported by electrical contractile and structural atrial remodeling promotes AF stability and persistence.[21] The HATCH scoring system (based on underlying HTN, age >75 years, history of transient ischemic attack (TIA) or stroke, chronic obstructive pulmonary disease, and HF) was proposed to predict this risk of progression in patients receiving pharmacologic therapy.[27] The clinical outcomes of patients who exhibit progression of AF are worse with respect to hospital admissions and major adverse cardiovascular

events. In the Euro Heart survey, patients with AF who had progressed to persistent or permanent AF had higher rates of hospital admissions, TIA, stroke, MI, and death.[28]

WORKING UP ATRIAL FIBRILLATION

Diagnosis

On initial evaluation of the patient who presents with AF, it is important to obtain:

- Key history: Questions such as symptoms, frequency, and duration to establish the AF pattern, initial onset, history of cardiovascular conditions and noncardiovascular conditions that are associated with AF, and assess the risk of complications such as thromboembolism and left ventricular (LV) dysfunction.
- Electrocardiogram (ECG): To establish suspected diagnosis of AF, assess the rate, evaluate for possible conduction abnormalities, ischemic changes, and signs of structural heart disease.
- Echocardiography: To assess ventricular size and function, left atrial (LA) dimensions (left atrium shown to enlarge by about 5 mm in diameter over 1 year in patients with AF, LA enlargement [>55 to 60 mm] associated with failure to maintain SR after successful cardioversion), and to identify any structural disease such as valvular heart disease.
- Transesophageal echocardiography (TEE): To evaluate for presence of thrombus if patient is to undergo cardioversion; although the presence of spontaneous echo contrast (smoke) is not a contraindication for CV, the risk of stroke is increased in the presence of smoke or reduced left atrial appendage (LAA) emptying velocity.[29]
- Blood tests: Thyroid function, kidney function, and electrolytes abnormalities.
- Exercise stress testing or coronary angiogram: In those cases where there is LV dysfunction, ischemic signs are noted or patient has symptoms of ischemia.
- Monitoring: To assess the adequacy of rate control, relate symptoms with AF recurrences, and detect focal induction of bouts of paroxysmal AF. This can be achieved by a Holter monitor, AF auto-trigger monitor, or mobile cardiac outpatient telemetry. They all carry relative diagnosed yield ranging from 5% to 13% in the 24-hour Holter to 45% to 88% in the outpatient telemetry.[30] Previously undiagnosed AF was found in 1.4% of those aged >65 years,

suggesting a number needed to screen of 70. These findings encourage the further evaluation of systematic AF screening programs in at-risk populations.[31]

- ILR can be used when the AF burden is relatively small and in asymptomatic patients. They typically have the highest diagnosed yield of more than 80%.[32]

Complications

There are many consequences of AF that lead to disease states. Loss of organized atrial contraction often leads to exercise intolerance and HF.[33] Rapid ventricular rhythm can lead to tachycardia-induced cardiomyopathy and precipitate myocardial ischemia.[4] Certainly, aging and systemic vascular risk factors cause an abnormal atrial tissue substrate, or atrial myopathy, that can result in AF and thromboembolism. AF causes contractile dysfunction and stasis, which further increases the risk of thromboembolism. In addition, over time, the AF causes structural remodeling of the atrium, thereby worsening atrial myopathy and increasing the risk of thromboembolism even further. **Figure 23.2** depicts the recently adapted model of thromboembolic stroke in AF.[34]

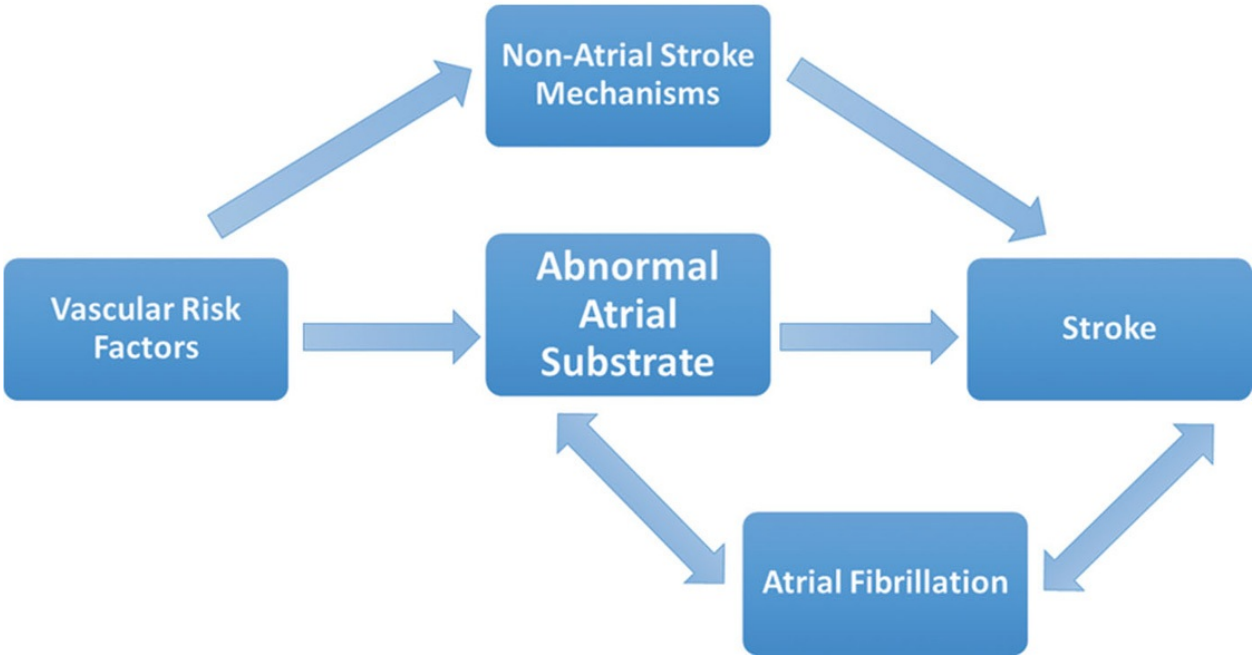

FIGURE 23.2 Recently adapted model of thromboembolic stroke in atrial fibrillation.

AF is associated with increased mortality; 1.5-fold for men and 1.9-fold for women.[35] Other complications are precipitation of ventricular electrical instability, anti-arrhythmic medication adverse effects, and pro-arrhythmic effects.[36]

ATRIAL FIBRILLATION AND STROKE

One in seven strokes is attributed to AF and it is suspected that subclinical AF is a cause of 1 in 4 ischemic strokes. Risk of death from AF-related stroke is 2-fold higher than that of stroke in patients without AF.[25] Premature atrial contractions,[37] paroxysmal supraventricular tachycardia,[38] ECG-defined LA abnormality,[39] and LA size[40] have been associated with stroke independently of AF. It is widely believed that failure of the fibrillating atrium to contract in patients with AF can lead to atrial stretch and dilatation, in turn promoting stasis and thrombus formation inside the LAA.[41] The LAA arises from the PVs and is an embryologic remnant of the left atrium and consists of a trabeculated 2- to 4-cm–long structure in direct continuity with the left atrium. Thus, its unique shape and anatomy may predispose to in situ thrombus formation.[42]

The individual stroke risk may be estimated using the CHA_2DS_2-VASc (C, congestive HF/LV dysfunction; H, hypertension; A_2, age [≥75 years]; D, diabetes; S_2, stroke/TIA attack; V, vascular disease; A, age 65 to 74 years; and S_c, sex category) classification scheme; classification is based on patient characteristics, with higher scores corresponding to a higher risk for stroke **(Table 23.1**). Thromboprophylaxis is the mainstay of stroke prevention in patients with AF.

TABLE 23.1 CHA_2DS_2-VASc Score

RISK FACTOR	POINTS
Congestive heart failure (symptoms of HF or evidence of HFrEF)	+1
Hypertension (BP>140/90 or ongoing treatment with anti-HTN drugs)	+1
Age >75	+2
DM (Fasting Glu>125 or HbA1C>6.5 or ongoing treatment)	+1

Previous stroke, TIA, or VTE	+2
Vascular disease (previous MI, PAD, or aortic plaque)	+1
Age 65–74	+1
Female sex	+1

DM, diabetes mellitus; HF, heart failure; HTN, hypertension; MI, myocardial infarction; PAD, peripheral artery disease; TIA, transient ischemic attack; VTE, venous thromboembolism.

ANTICOAGULATION

On the basis of clinical practice guidelines published by the American College of Cardiology, the American Heart Association, the American College of Chest Physicians, and the European Society of Cardiology, patients with AF should generally receive oral anticoagulation (OAC) with vitamin K antagonist (VKA) or novel oral anticoagulants (NOACs) such as apixaban, dabigatran, rivaroxaban, or edoxaban. OAC therapy has shown to prevent the majority of ischemic strokes in patients with AF and can prolong life.[43] VKA is still the only treatment with proven benefit for valvular AF (moderate or severe mitral stenosis or a mechanical valve). For nonvalvular AF, both VKA and NOACs are effective in preventing stroke. There have been multiple recent studies comparing NOACs with warfarin; and large cohort meta-analysis by Ruff et al that included 42,411 patients suggests that NOACS, while offering same level of stroke reduction as warfarin, is associated with greater reduction in mortality, less intracranial bleeding, and more frequent gastrointestinal bleed.[43] According to the 2016 ESC guidelines for the management of AF, NOACs are the preferred anticoagulants (ACs) over VKA for patients with nonvalvular AF.[22]

Antiplatelet therapy is inferior to AC for prevention of stroke and should not be used alone; however, when patients are required to be both on AC and dual oral antiplatelets (DAPTs), the risk of bleeding is increased.

In all patients who require ACs, bleeding risk should be assessed. The most widely used tool is the HAS-BLED score[45] (**Table 23.2**).

TABLE 23.2 HAS-BLED Score

RISK FACTOR	POINTS
Hypertension	+1
Abnormal renal function (dialysis, transplant, Cr >2.26 mg/dL or >200 µmol/L)	+1

Abnormal liver function (cirrhosis or bilirubin >2x Normal or AST/ALT/AP >3x Normal)	+1
Stroke history	+1
Prior major bleeding or predisposition to bleeding	+1
Labile INR (unstable/high INRs), time in therapeutic range < 60%)	+1
Elderly age >65	+1
Drugs/alcohol use history (≥ 8 drinks/week)	+1

ALT, alanine aminotransferase; AP, alkaline phosphatase; AST, aspartate aminotransferase; INR, international normalized ratio.

The general consensus is that high bleeding score should not avert from using ACs, but the effort should be made to correct identifiable bleeding factors such as (HTN [systolic BP >160], labile international normalized ratio when on VKA, other drugs predisposing to bleeding—DAPTs or NSAIDs, excess alcohol intake [>8 drinks a week]) and potentially modifiable risk factors (anemia, impaired renal function, impaired liver function, and reduced platelet count or function).

Anticoagulation can be risky for some patients and, alternatively, LAA occlusion devices should be considered. Several indications for LAA occlusion may be taken into consideration. Such indications may include stroke reduction: (1) in those with absolute contraindications to OAC, (2) in patients with relative contraindications to OAC, or (3) as an alternative to OAC therapy for those with high fall risk.

Romero et al published data of computed tomography that demonstrated the four most common LAA morphologies: “Cactus” has a dominant central lobe with extending secondary lobes. “Windsock” has a dominant lobe larger than the distal portions of the LAA. “Cauliflower” has no dominant lobe, but has more complex characteristics than other morphologies. “Chicken-wing” presents an obvious bend in the proximal or middle part of the dominant lobe, or folding back on itself which can be a secondary lobe or twig[46] **(Figure 23.3)**. Three percutaneous devices to facilitate LAA closure have been developed and are in use: Watchman, Amplatzer, and the Lariat suture **(Figure 23.4)**. Although the randomized clinical trial PROTECT-AF[47] showed noninferiority of the Watchman device as compared with warfarin therapy for stroke prevention, there are still limited data as to whether the risk of stroke reduction is comparable to OAC and it is therefore recommended to continue OAC for at least 6 weeks after

implantation of the Watchman closure device. The Amplatzer plug has been utilized for percutaneous patent foramen ovale closure and has also been adopted as a method for LAA exclusion, although no randomized clinical trial of its use for this indication currently exists. The Lariat device is placed using a combined percutaneous endocardial and epicardial approach, and no OAC therapy is required after Lariat LAA closure.

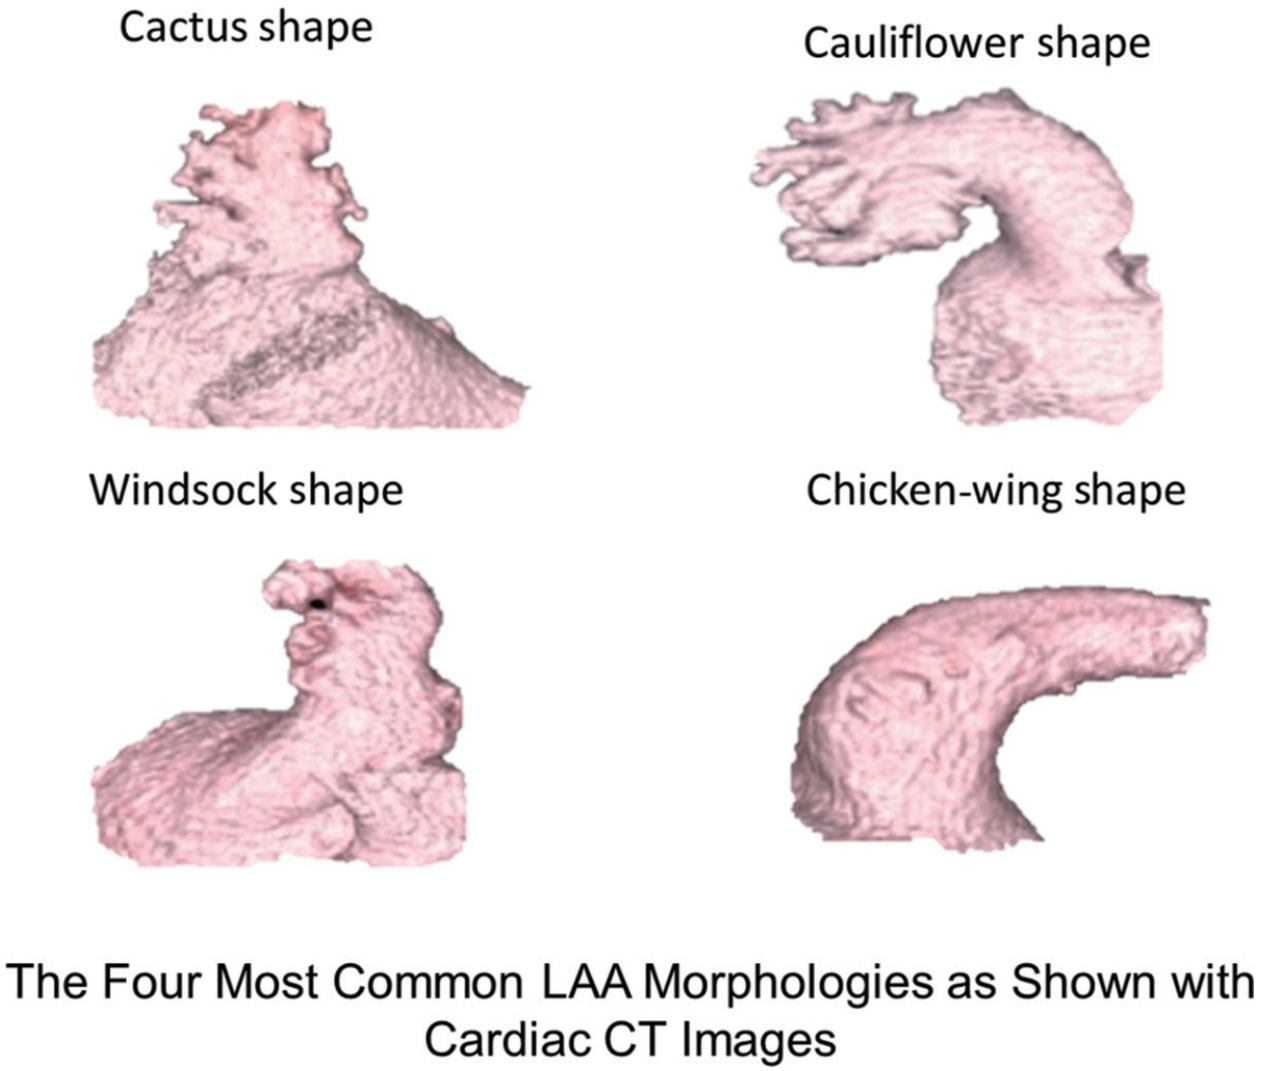

FIGURE 23.3 Left atrial appendage (LAA) morphology as seen by cardiac computed tomography (CT).

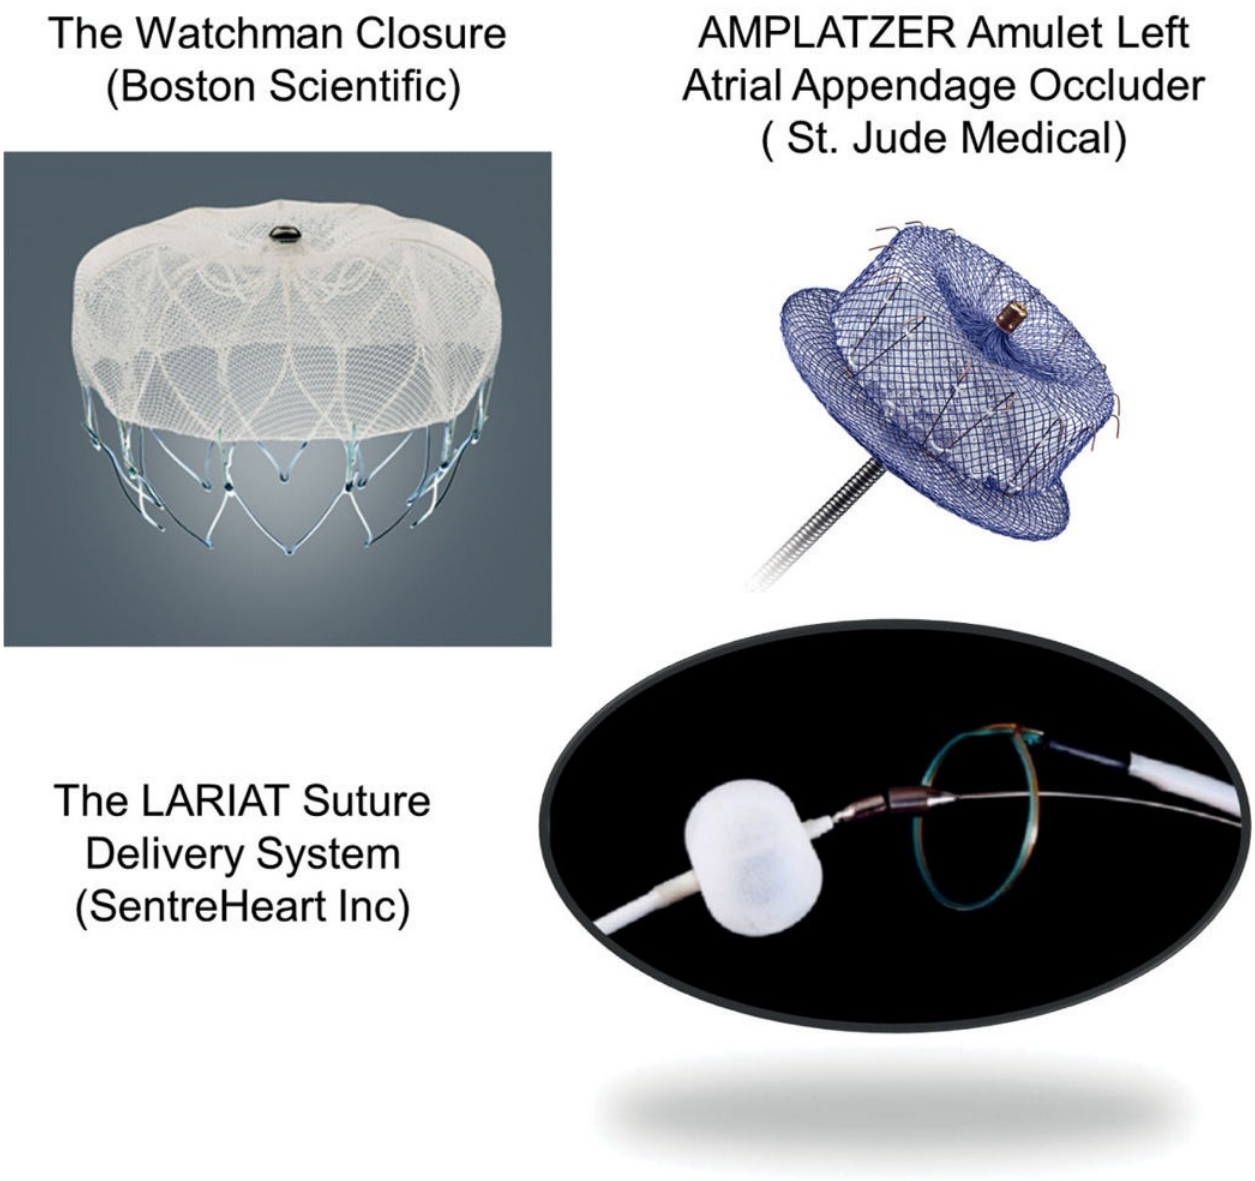

FIGURE 23.4 Available left atrial appendage closure devices.

In case of a TIA, OAC can be resumed 1 day after the event.

In case of a stroke, OAC can be resumed 3 to 12 days after the event, depending on the severity of the stroke.

A controversial question arises when a patient needs OAC and antiplatelet therapy. Two randomized clinical trials are currently testing different antithrombotic combinations for patients on OAC who require stent implantation. The Triple Therapy in Patients on Oral Anticoagulation After Drug

Eluting Stent Implantation (***ISAR-TRIPLE***, clinicaltrials.gov id NCT00776633) trial will address the hypothesis that reducing the length of clopidogrel therapy from 6 months to 6 weeks after implantation of a drug-eluting stent is associated with a reduced net composite of death, MI, definite stent thrombosis, stroke, or major bleeding at 9 months on top of treatment with aspirin and an oral anticoagulant. The Anticoagulation in Stent Intervention (***MUSICA-2***, clinical trials.gov id NCT01141153) trial is investigating the safety and efficacy of a triple antithrombotic regimen of acenocoumarol, low-dose (100 mg/d) aspirin, and clopidogrel versus high-dose (300 mg/d) aspirin and clopidogrel in patients with AF and low-to-moderate risk of stroke (CHADS2 ≤2) referred for percutaneous coronary intervention (PCI).

Currently, it is suggested that patients with AF who are at risk of stroke and who require antiplatelet therapy should minimize the time on triple therapy because of significantly increased risk of bleeding.

TREATMENT

The treatment strategies are subclassified to the acute or new onset of AF and treatment of established AF. **Figure 23.5** illustrates a typical diagram for treatment strategies for acute and chronic AF.

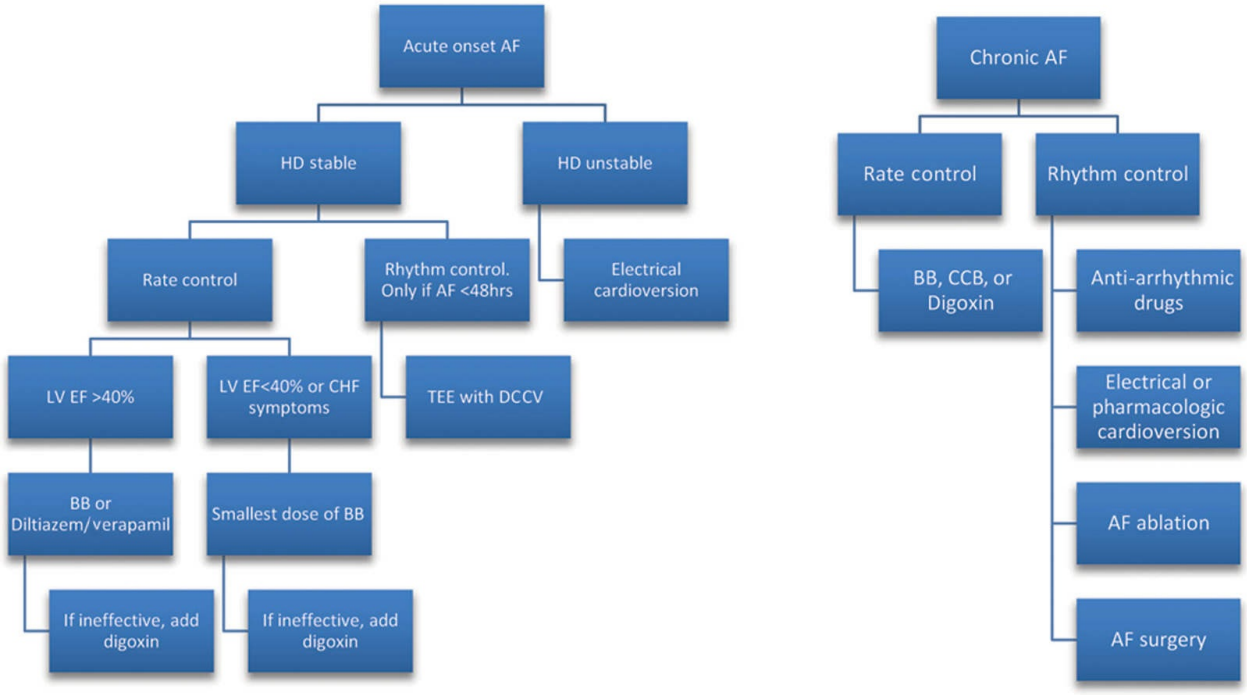

FIGURE 23.5 Treatment strategies for acute and chronic atrial fibrillation (AF). BB, β-blocker; CCB, calcium channel blocker; CHF, congestive heart failure; HD, hemodynamically; LVEF, left ventricular ejection fraction; TEE, transesophageal echocardiography.

Acute- or New-Onset Atrial Fibrillation

Many patients at presentation require heart rate (HR) control after other possible causes of increased HR are excluded such as infection, pulmonary embolism, and endocrine abnormalities. Agents preferred for acute rate control are β-blockers (BBs) and non–dihydropyridine calcium channel blockers (ND-CCBs), that is, diltiazem and verapamil given their rapid onset of action. However, the choice of the agent should be based on existing comorbidities. For example, in patients with left ventricular ejection fraction (LVEF) <40%, CCB should be avoided because of its negative inotropic effect and BBs should be used instead. The typical recommended initial controlled HR target should be <110 bpm. Patients who are hemodynamically unstable require immediate direct current cardioversion to restore cardiac output.

Established Atrial Fibrillation Diagnosis

There are two basic strategies for the treatment of AF, rate and rhythm control,

and each has its own benefits and drawbacks.

- **Rate control:** Target HR for rate control strategy is <110 bpm at rest. Early data from the RACE and the AFFIRM trials showed that there is no difference in CV events, NYHA class, or hospitalizations[48] between groups of patients with lenient or strict heart rate goals. However, the HR target should still be individually set given that some patients are symptomatic at the HR of 110 bpm. First-line rate control agents are BBs because of their potential beneficial effect on symptoms and lack of harm as well as having a good tolerance profile. Patients should be started on a low dose and uptitrated to achieve target HR control. Second-line agents are ND-CCBs (verapamil or diltiazem); however, this class should be avoided in patients with LVEF <40%. Also, avoid concomitant use with BBs. Digoxin can also be used in combination with BBs or CCBs to achieve better HR control (*ESC 2016 class IB recommendations for AF and class IB for AF with HFrEF*).[49] Amiodarone can be used when combination therapy fails to control HR. The last resort for rate control is the ablate and pace technique, in which AV junctional ablation is performed and a dual chamber of BiV pacemaker is implanted. A study by Queiroga et al showed that ablate and pace is associated with a low overall mortality and, interestingly, 48% of patients were still in SR at 72 months.[50]
- **Rhythm control:** Current 2014 AHA/ACC/HRS guideline for the management of patients with AF consider antiarrhythmic medications as the first-line, long-term treatment for symptomatic patients, however long-term follow-up studies have shown that these drugs can also have pro-arrhythmic effects.

Cardioversion to Normal Rhythm

Cardioversion, whether electrical or pharmacologic, is recommended for symptomatic patients with persistent or long-standing AF. Pretreatment with anti-arrhythmic drugs (AADs), usually class IC or III, is recommended to increase the effectiveness of cardioversion.[51] In a study by Cotiga et al, dofetilide had an unusually high pharmacologic conversion rate, demonstrated an incremental dose response, and was well tolerated and safe in a relatively healthy adult cohort with persistent AF.[52]It is recommended to perform TEE for patients who have had AF for more than 48 hours to exclude LAA thrombi before direct current cardioversion. For patients who were in AF for longer than 48 hours or for an unknown duration and who cannot undergo TEE, the

recommendation is to initiate AC for at least 3 weeks before cardioversion and to continue for 4 weeks after CV, unless longer AC is needed because of high stroke risk.

Catheter Ablation for Atrial Fibrillation

Catheter ablation (CA) to cure AF has now evolved as an established method for treating this common rhythm disorder. CA of AF is performed on a daily basis in electrophysiology laboratories in most regions of the world. Cure of AF has had a dramatic impact on quality of life, morbidity, and mortality. The first decade of AF ablation was characterized by new observations and concepts as well as improvement in technology. Most current treatment approaches for AF aim at ablation around the PVs with or without additional ablation lesion lines, a procedure that yields low complication rates and high success rates in both paroxysmal and chronic AF.[53]

Typical pulmonary vein antral isolation (PVAI) of PVs is performed guided by intracardiac echocardiography and a circular mapping catheter to more precisely identify the border of the PV antrum and reduce risk of PV stenosis. PVAI is performed by encircling all PVs based on anatomy, and demonstration of loss of PV potentials and, if possible, inability of signals to go from PV to atrium in the absence of PV potentials.

Figure 23.6A shows intracardiac electrograms (EGMs) from a patient in AF during a PVAI procedure. Note the unorganized atrial activities in the atrium seen on the coronary sinus (CS) catheter, and more organized EGMs seen within the PV circular mapping catheter after isolation of the veins and spontaneous termination of AF to SR. **Figure 23.6B** displays surface ECG in normal rhythm, organized sinus activity seen in the CS catheter, and completely silent (isolated) PV with no activities. In **Figure 23.6C** SR is seen on surface ECG and in the CS, whereas fibrillatory EGMs are seen confined to the PV, confirming complete isolation of the vein with exit block (no external connection to the atrium).

E, Arctic front balloon catheter for cryoballoon ablation *Note:* Red dots mark VisiTags indicating complete circumferential lesion sets around the antra of all pulmonary veins; also notice left atrial voltage map showing complete silence (red color) in the pulmonary veins and in the left atrial posterior wall. LLPV, left lower pulmonary vein; LUPV, left upper pulmonary vein; RLPV, right lower pulmonary vein; RUPV, right upper pulmonary vein. E, Arctic front balloon catheter for cryoballoon ablation

Electroanatomic mapping is typically used during CA to guide in delineating the LA anatomy as well as the anatomy of PVs, and guide the electrophysiologist during the ablation procedure by placing automatic marks at the site of radiofrequency (RF) lesion applications. **Figure 23.6D** represents a CARTO-3

electroanatomic 3D mapping of the left atrium after complete PVAI, the red dots seen mark VisiTags indicating complete circumferential lesion sets around the antra of all PVs. LA voltage map shows complete silence (red color) in the PVs and in the LA posterior wall, indicating good lesion sets and confirming isolation as an endpoint for the ablation procedure.

In recent years, multiple clinical trials have clearly demonstrated the superiority of CA over AAD therapy in terms of long-term freedom from AF, improvement in quality of life, and reduction of hospitalizations.[54, 55] To date, there are few small studies that compared CA as a first line of treatment of AAD. The **RAAFT** was the first randomized trial to show the feasibility, safety, and effectiveness of CA as first-line therapy in patients with symptomatic paroxysmal AF. The outcomes assessed in this trial were recurrence of AF, hospitalization, and quality of life at 1-year follow-up. At the end of follow-up, 63% of patients assigned to AAD therapy experienced at least one recurrence of symptomatic AF, as compared with 13% of those assigned to the PVAI treatment arm, accounting for 80% relative risk reduction with CA ($P < 0.001$). Furthermore, PVAI was associated with a significantly lower rate of hospitalization (9% vs 54%, $P < 0.001$), and better quality of life.[56]

Presented data from the Medical Antiarrhythmic Treatment or Radiofrequency Ablation in Paroxysmal Atrial Fibrillation (**MANTRA-PAF**) trial[57] compared CA with AAD therapy as first-line therapy for symptomatic paroxysmal AF and showed that at 24 months, AF recurred in 15% of patients allocated to CA and in 29% of those receiving AAD, accounting for 48% relative risk reduction ($P = 0.004$). The corresponding number needed to treat with CA to prevent one episode of recurrent AF was 7. Patients assigned to CA also experienced significantly lower AF burden ($P = 0.007$) and improved quality of life.

More recently, the RF ablation versus antiarrhythmic drugs as first-line treatment of paroxysmal AF (**RAAFT-2**) trial showed that among patients with paroxysmal AF without previous antiarrhythmic drug treatment, RF ablation compared with antiarrhythmic drugs resulted in a lower rate of recurrent atrial tachyarrhythmias at 24 months.[58]

Finally, data from the CA versus antiarrhythmic drug treatment of persistent AF: a multicenter, randomized, controlled trial (**SARA study**) showed that CA was superior to medical therapy for the maintenance of SR in patients with persistent AF at 12-month follow-up.[59]

In recent years, cryoballoon ablation (**Figure 23.6E**), has gained some favor as an alternative approach to RF ablation for the treatment of symptomatic drug-

refractory AF with comparable immediate success and complications.[60] The most recent **FIRE AND ICE** trial showed that while patients treated with cryoballoon as opposed to RF ablation had significantly fewer repeat ablations, direct current cardioversions, all-cause rehospitalizations, and cardiovascular rehospitalizations during the follow-up period, both patient groups had improvement in quality-of-life scores after ablation.[61] The result of this study further establishes the call for ablation as the first-line therapy in younger patients with AF.

AC should be started and continue uninterrupted before the ablation with NOAC or VKA and continued for at least 6 months.[62] Generally it is recommended to continue AAD therapy for 12 weeks after ablation, as there is significant evidence showing prevention of early AF recurrences after ablation when AADs are continued for a few weeks.[63]

CA performed the first time has an efficacy of 60% to 80%, and only a few patients require a second procedure to achieve higher rates of effectiveness. If CA fails to restore rhythm, the patient and the cardiologist can decide between further available options: repeat ablation or hybrid therapy (AAD + ablation).

Outpatient Follow-Up of Patients with AF

Follow-up visits should be focused on assessment of patients' symptoms after initiation of the therapy, possibility of changing the strategy, or stepping to the next available treatment option if the patient is still symptomatic. Assessment of the presence of side effects should take place if the patient is on AAD. Special attention should be devoted to the treatment of comorbidities that could decrease the rate of AF recurrences (such as HF, OSA) as well as monitoring of anticoagulation and assessment for further need of it.

Prognosis

AF associated with increased risk of death independent of embolic stroke, partially because of its comorbidities (HF, coronary artery disease, HTN), but independently AF also increases risk of sudden cardiac death from ventricular arrhythmias.

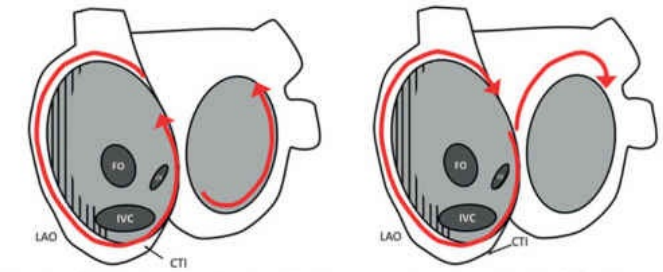
ATRIAL FLUTTER

Atrial flutter (AFL) is a regular atrial arrhythmia with rates up to 300 bpm, and is typically caused by a macroreentrant (MR) circular activation (reentrant) that revolves around a “large” obstacle, arbitrarily defined as being several centimeters in diameter. Typical AFL,[64] facilitated by the anatomic structure of the right atrium (RA), is the most frequent atrial MR tachycardia; however, owing to the increased incidence of heart surgery with atriotomy and to LA ablation for the treatment of AF, further MR tachycardia can be also seen.

The relationships between AFL and AF are complex. Both arrhythmias frequently occur at various times in the same patient and epidemiologic studies have demonstrated a tendency for patients who initially only present with flutter to develop fibrillation after several years. It is imperative to realize that AFL and AF are expressions of a single arrhythmogenic substrate. The background and diseases associated with AFL are similar to those of AF, including HTN, coronary disease, valvulopathy, chronic obstructive pulmonary disease, myocardiopathy, and 15% to 20% of apparently healthy hearts. In some cases, flutter initiates fibrillation and flutter ablation reduces the incidence of fibrillation.

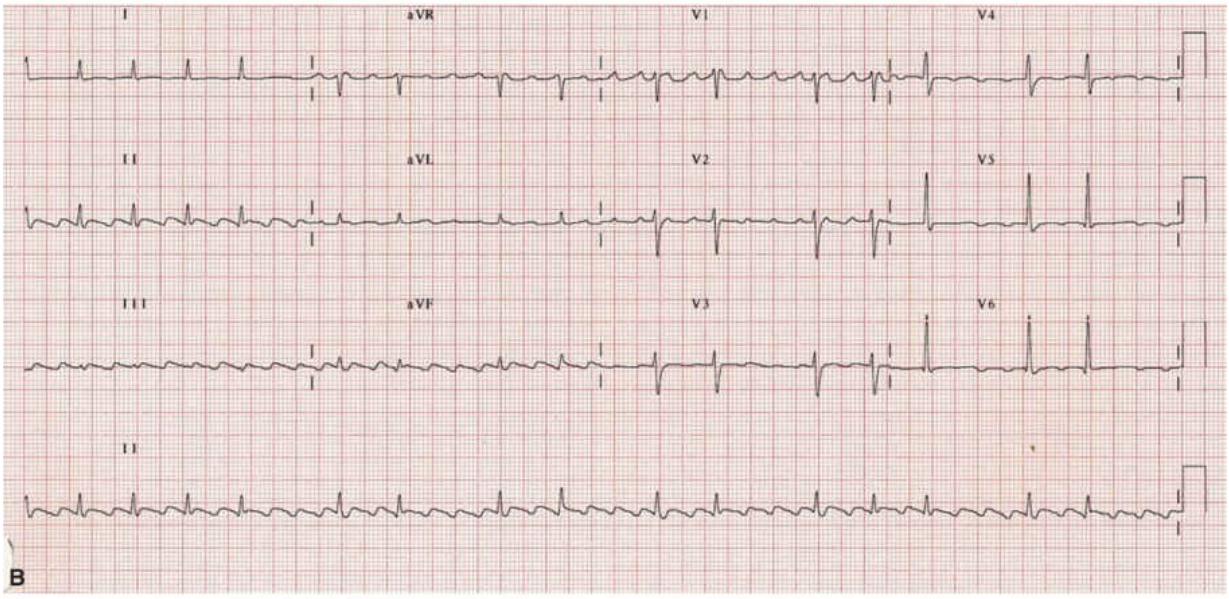
Typical AFL is an MR arrhythmia due to rotational activation around the RA. The circuit is bounded in front by the tricuspid ring and behind by a mixed anatomic and functional obstacle, formed by the vena cava and crista terminalis.[65] The activation wave goes down via the anterolateral RA and goes up via the septal RA (counterclockwise rotation in left anterior oblique view), necessarily passing between the inferior vena cava (IVC) and the lower tricuspid ring, an area known as the cavotricuspid isthmus (CTI). Cycle length (CL) is typically 200 to 240 ms, with great stability (variations of <20 ms), but under pharmacologic treatment or if there is delayed atrial conduction, the CL can reach 300 ms.

The combination of large valvular and venous orifices together with the functional obstacle in the crista terminalis makes the RA an ideal place for reentry, and this is probably the means by which typical AFL has such a characteristic electrocardiographic and functional image (**Figure 23.7A**). Counterclockwise activation (going down via the anterolateral RA) occurs in 90% of typical flutter, but in 10% there is a reverse or clockwise rotation (going up the anterolateral RA and going down the septal RA).

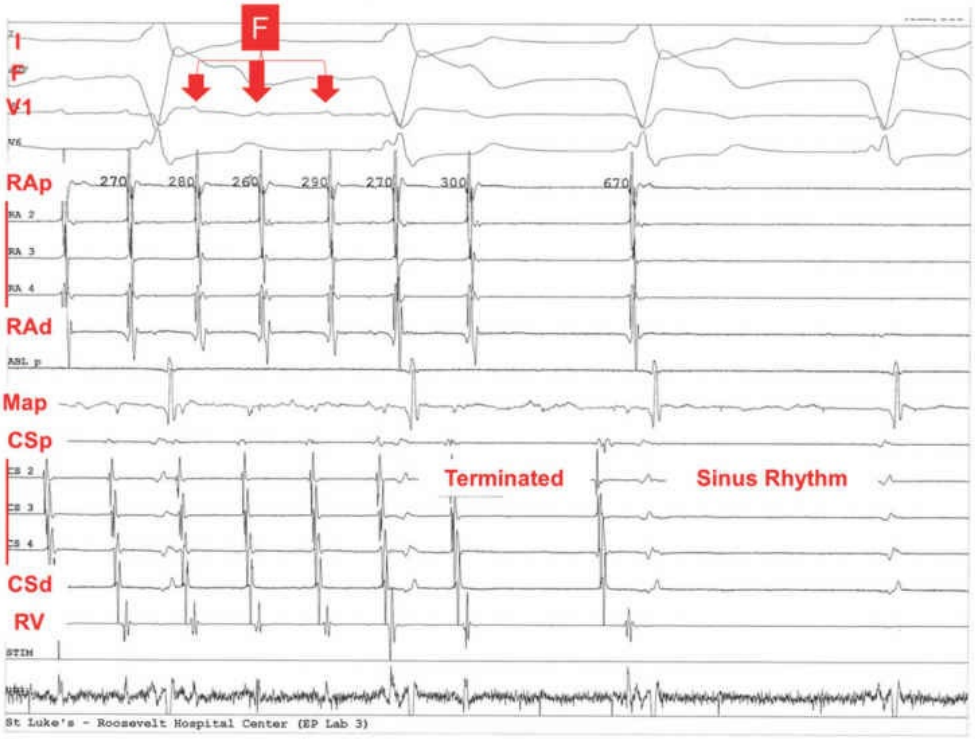


Typical Counterclockwise Flutter Reverse Typical Flutter

A



B



C

FIGURE 23.7 A, Mechanism of typical AFL and reverse typical AFL. B, Typical counterclockwise AFL. (Note the characteristic pattern in leads II, III, and aVF known as "sawtooth pattern." The wave is complex, with a slowly falling segment followed by a negative deflection that changes rapidly to positive to link with the following cycle.) C, Termination counterclockwise AFL during cavotricuspid isthmus (CTI) ablation. Note the beginning of the tracing [F] flutter waves that terminate during the CTI ablation to sinus rhythm. CS, coronary sinus; CSd, distal coronary sinus catheter; CSp, proximal coronary sinus catheter; FO, fossa ovalis; IVC, inferior vena cava; LAO, left anterior oblique; Map, mapping/ablation catheter; Rad, distal right atrium; Rap, proximal right atrium.

Typical AFL has a characteristic pattern in leads II, III, and aVF known as "sawtooth pattern." The wave is complex, with a slowly falling segment followed by a negative deflection that changes rapidly to a positive and links with the following cycle (**Figure 23.7B**). The pattern can be difficult to recognize if AV conduction is 2:1, but can be revealed by increasing the degree of block through massaging the carotid sinus or with intravenous adenosine. Clockwise typical AFL produces positive waves in the inferior leads, frequently with a sawtooth pattern, but what is most typical is a negative sawtooth wave, in lead V1.

AV conduction is frequently 2:1 during flutter, even while resting and under conduction-slowing agents; if the flutter rate is slower, conduction can be up to 1:1. However, ventricular rate can also be irregular because of complex block patterns in the AV node.

Indications for treatment are marked by poor tolerance, the poor or adverse response to antiarrhythmic agents, and the possibility of eliminating the circuit via CA. The ablation target is the CTI, being the narrowest part of the circuit, well delimited anatomically, easily accessible, and distant from the AV node.

RF ablation to produce a complete, bidirectional, and persistent CTI block normally requires several RF applications, between the tricuspid edge of the isthmus and the IVC. The use of irrigated-tip ablation catheter that produces deep lesions at lower energies, results in flutter termination (**Figure 23.7C**) and demonstrating bidirectional block across the CTI in 85% to 90% of cases with a complication risk of <1%.[66]

In general, the same guidelines have been adopted regarding anticoagulation therapy as in patients with AF; however, in cases with a high risk of hemorrhage, these standards could be made more flexible. TEE is typically performed before ablation to rule out a thrombus in the left atrium or the LAA and anticoagulation therapy is maintained for 4 weeks after ablation procedure. Once CTI block is

obtained, flutter recurs in 5% to 10% of cases, usually within 3 months, and reablation is, in general, technically easier.

Patient and Family Information for: ATRIAL FIBRILLATION AND ATRIAL FLUTTER

Atrial Fibrillation (AF) is the most common irregular heart rhythm abnormality. It is caused by abnormal electrical signals that cause the heart to beat irregularly and usually very fast.

Symptoms of AF are palpitations (racing heart, skipped beats, and irregular heartbeats), chest tightness, difficulty breathing, and dizziness.

This irregular heart rhythm can be constant or it can come and go. Sometimes it can be provoked by modifiable reasons such as alcohol, caffeine, or an overactive thyroid gland.

AF is classified according to how often the episodes occur and how quickly they terminate.

- Paroxysmal (intermittent): Irregular heart rhythm episodes that reoccur two or more times and stop on their own within 7 days. The heartbeat often normalizes as quickly as within a few seconds or after a few hours.
- Persistent: Irregular heart rhythm episodes that last more than 7 days, or last less than 7 days but necessitates medical therapy or a procedure to restore a normal heart rhythm (cardioversion). Cardioversion is most often done by sending electric shocks to the heart through electrodes placed on the chest.
- Longstanding persistent: Irregular heart rhythm episodes that continue for more than a year. The heart is in a constant state of fibrillation and the condition is considered permanent. In most cases, cardioversion is either ineffective or cannot be attempted.

When the HR stays fast and irregular for a prolonged time, it requires treatment to avoid complications such as stroke or developing a weak heart.

The two main problems with AF is the risk of developing a blood clot and the

risk of a fast HR that may weaken the heart.

- A blood clot can develop in the upper chambers of the heart because it is beating out of synchronization. The clot can travel outside of the heart along the blood vessels to the brain and cause a stroke. To decrease this risk, patients need to take anti-coagulants (blood thinners).
- Fast HR can be very uncomfortable for some patients, leading to the symptoms of palpitations. The heart is not pumping the blood effectively in this state. If fast HR persists for a long time, it can cause the heart to become weak. To keep the HR in the normal range, patients are prescribed medications to slow it down.

When a decision is made to attempt to restore regular heart rhythm, several options are available. There are medications called antiarrhythmic medications and they are directed to convert the heart rhythm to a normal rhythm. Another treatment option is called cardioversion and involves applying an electrical shock to the heart.

A unique treatment is called ablation. It is a procedural option that is based on the knowledge that areas of the heart are sending excessive signals and causing the upper chambers of the heart to beat irregularly. The procedure involves applying heat or cold (RF or cryoablation) to destroy small areas that are causing the abnormal heartbeat.

Atrial Flutter (AFL) is another common abnormal heart rhythm. In AFL, the upper chambers (atria) of the heart beat very fast. This results in atrial muscle contractions that are faster and out of synchronization with the lower chambers (ventricles). With AFL, the electrical signal travels along a pathway within the RA. It moves in an organized circular motion, or “circuit,” causing the atria to beat faster than do the ventricles. AFL makes a very distinct “sawtooth” pattern on an ECG, a test used to diagnose abnormal heart rhythms. AFL itself is not life threatening. If left untreated, the side effects of AFL can be potentially life threatening. AFL makes it harder for the heart to pump blood effectively. With the blood moving more slowly, it is more likely to form clots. If the clot is pumped out of the heart, it could travel to the brain and lead to a stroke. Ablation procedure is the treatment of choice for AFL, which is performed by inserting a small catheter through the femoral vein and advancing it to the heart till it reaches a specific area called the cavotricuspid isthmus. Delivering RF lesion typically terminates the flutter with a success rate of approximately 85% to 90% and with a complications risk of <1%.

Pathway for the Management of Atrial Fibrillation and Atrial Flutter

Atrial fibrillation (AF) is the most common cardiac rhythm disturbance encountered in clinical practice, and its prevalence is increasing as the population ages.[1, 2] Electrocardiographically, AF is characterized by an irregularly irregular ventricular rhythm, with an absence of discrete P-wave activity. Rather, undulating fibrillatory activity (f waves) are seen on the electrocardiogram (ECG) between QRS complexes and T waves. The American College of Cardiology (ACC), the American Heart Association (AHA), and the European Society of Cardiology (ESC) established guidelines for the management of patients with AF.[3, 4]

In 2010, the estimated numbers of men and women with AF worldwide were 20.9 million and 12.6 million, respectively, with higher incidence and prevalence rates in developed countries. One in four middle-aged adults in Europe and the United States will develop AF in their lifetime.[4]

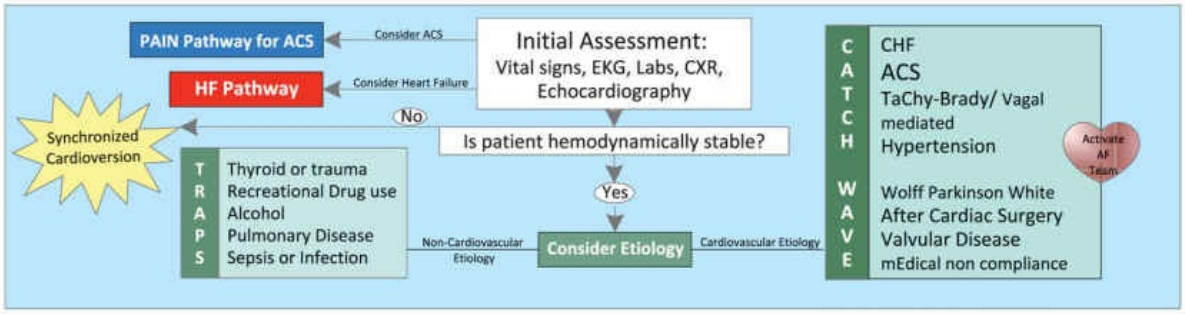
The increase in AF prevalence can be attributed to better detection of silent AF,[5–7] alongside increasing age and conditions predisposing to AF.[8]

Atrial flutter (Afl) is less common and is often associated with or preceded by AF or occurs in an isolated pattern. Guidelines for Afl management were included in the ACC/AHA/ESC Guidelines for the Management of Patients with Supraventricular Arrhythmias. The electrocardiographic findings of Afl in its

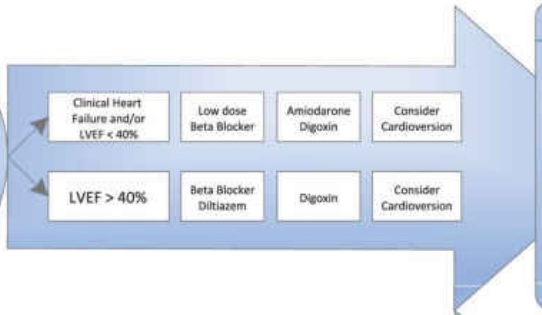
typical counterclockwise form include an atrial deflection with rapid regular undulations that gives rise to a “sawtooth” appearance, mainly in the inferior leads. The atrial rate is usually between 250 and 300 beats/min.

A major limitation of the currently published guidelines for the management of patients with AF and Afl is their complexity, the fact that official guidelines are published separately for each of these arrhythmias, and that they were published several years ago.[3] To address these deficiencies, we have developed a novel pathway for the management of AF and Afl (**Figure 24.1**).

RACE Pathway for Atrial Fibrillation and Atrial Flutter



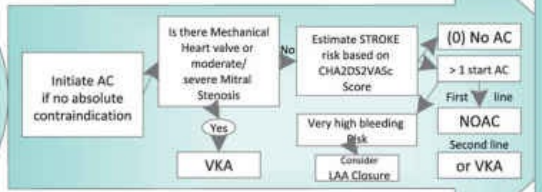
Rate Management



R = Rate Control Medications

	IV		PO
	Loading Dose	Maintenance Dose	Maintenance
Beta Blocker			
Metoprolol	2.5 - 5 mg IV bolus up to 3 doses	NA	25 - 100 mg bid
Esmolol	0.5 mg/kg IV over 1 min	0.05 mg/kg/min over 4 min	NA
Calcium Blocker			
Diltiazem	0.25 mg/kg IV over 2 min	5-15 mg/hr	120-360 mg/d
Verapamil	0.075-0.15 mg/kg IV over 2 min		120-360 mg/d
Digoxin	0.25 mg IV Q2hrs, up to 1.5 mg	0.125 - 0.25 mg daily	0.125 - 0.375 mg daily

Anticoagulation

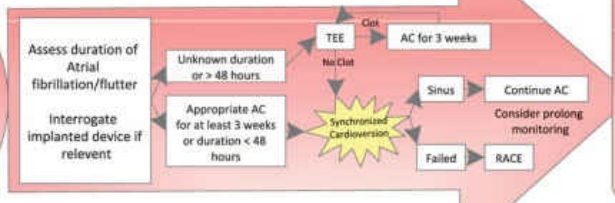


A = Anticoagulation Medications

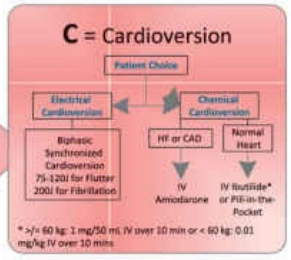
	Dabigatran (Re-LY)	Rivaroxaban (Rocket-AF)	Apixaban (ARISTOTLE)	Edoxaban (ENGAGAE-AF)
Dose	150 mg twice daily	20 mg once daily	5 mg twice daily	60 mg once daily*
Dose for CKD	75 mg twice daily CrCl 15-30 mL/min	15 mg once daily CrCl 15-50 mL/min	2.5 mg twice daily if at least two of age ≥80yrs; weight ≤ 60 kg or Cr ≥ 1.5 mg/dL	30 mg once daily CrCl 15-50 mL/min
Reversal	Idarucizumab 5 g/100 mL infused rapidly	Awaiting Xa-inhibitors Approval		

* approved in US for CrCl 50-95 mL/min
All are not indicated with CrCl <15 mL/min

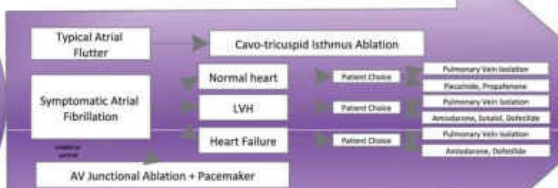
Cardioversion



C = Cardioversion



Electrophysiology Management



E = Electrophysiology / Antiarrhythmic Medication

Class IC	Starting PO dose	Maintenance PO Dose
Flecainide	50 mg Q 12 hrs	May titrate by 50 mg Q12hrs, Q4days to maximum 200 mg Q12hrs
Propafenone	150 mg Q 8 hrs	May titrate in 3-4 day intervals to 225 mg Q8hrs, then 300 mg Q8hrs

Class III	Oral Loading	IV Loading	Maintenance
Amiodarone	800 mg daily in divided doses x 1-3 weeks	150 mg IVPB over 10 mins, then, 1 mg/min x 6 hrs, then 0.5 mg/min x 18 hrs	200-600 mg PO daily
Sotalol*	80 mg bid		80-160 mg bid
Dofetilide* Dosed on CrCl	> 60 mL/min 500 mcg bid 40-60 mL/min 250 mcg bid 20-60 mL/min 125 mcg bid < 20 mL/min Contraindicated		adjust dose based on QTc 2 hrs after initial dose

* Requires 72 hours of telemetry monitoring and 12 lead EKG

FIGURE 24.1 Pathway for the management of atrial fibrillation and atrial flutter. AC, anticoagulant; ACS, acute coronary syndrome; AF, atrial fibrillation; AV, atrioventricular; CAD, coronary artery disease; CHF, congestive heart failure; CKD, chronic kidney disease; CXR, chest X-ray; ECG, electrocardiogram; HF, heart failure; IV, intravenous; IVPB, intravenous piggyback; LAA, left atrial appendage; LVEF, left ventricular ejection fraction; LVH, left ventricular hypertrophy; NOAC, novel oral anticoagulation; TEE, transesophageal echocardiogram; VKA, vitamin K antagonist.

The necessity to develop such a pathway at our institution was compelling, yet typical of the need at many other large medical centers, where it has become increasingly difficult for all house staff to grasp all the subtleties in the management of AF and Afl and to rapidly, efficiently, and accurately implement clinical protocols. It should be emphasized that this pathway is the opinion of our group and may differ somewhat from the published guidelines. The pathway has been designated with the acronym of RACE, which reflects the four main components in patient management: ***R***ate control, ***A***nticoagulation therapy, ***C***ardioversion, and ***E***lectrophysiology/antiarrhythmic medication.

This pathway is an attempt to incorporate, in a user-friendly format, the key concepts of the initial diagnosis and management of these prevalent arrhythmias. This is followed by a comprehensive guideline for therapy using the RACE acronym.

INITIAL ASSESSMENT

All patients should undergo an initial assessment (**Figure 24.2**) on presentation to the emergency department, including a 12-lead ECG, history, and physical examination.

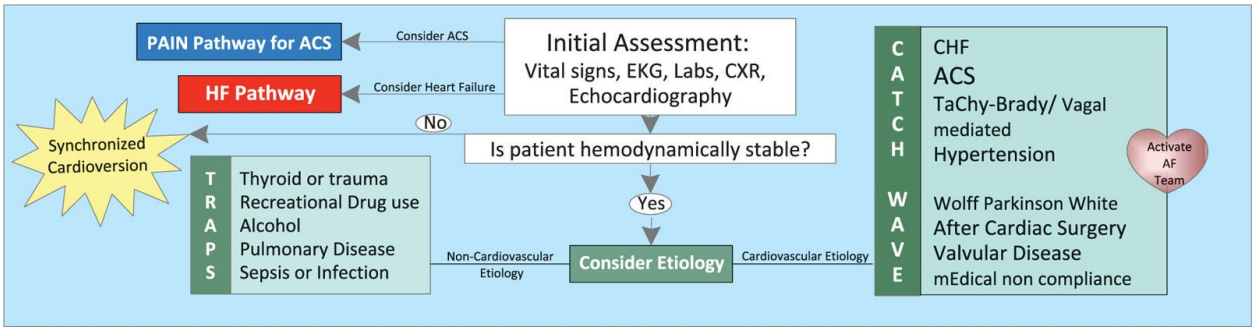


FIGURE 24.2 Initial assessment of patients with atrial fibrillation and atrial flutter. ACS, acute coronary syndrome; AF, atrial fibrillation; CHF, congestive heart failure; CXR, chest X-ray; HF, heart failure.

All patients should be immediately assessed for hemodynamic stability. If patients are hemodynamically unstable (low blood pressure, cold extremities, signs of heart failure, depressed mental status), emergency synchronized D/C cardioversion should be considered.

Patients should also be evaluated for acute coronary syndrome if they have suggestive symptoms, ECG changes, and/or elevated cardiac biomarkers. A comprehensive evaluation for acute heart failure is also essential, including an assessment of natriuretic peptide levels when appropriate. Prior studies have demonstrated a strong association between the heart failure syndrome and AF. Acute coronary syndrome and acute heart failure should be treated, respectively, per published guidelines and pathways.[9, 10]

Initial laboratory testing should include a comprehensive metabolic panel, complete blood count, magnesium level, thyroid function tests, and coagulation panel if a patient is on warfarin therapy. All patients should have a transthoracic echocardiogram for assessment of left and right ventricular function, valvular disease, and pericardial effusion.

Owing to recent advances in the management of AF, including complexities of medical and nonpharmacologic therapies, early involvement of an arrhythmia service (AF team) should be considered in all patients with AF/Afl.

We have developed a systematic approach to the pathophysiology of AF and Afl (**Figure 24.2**) using acronyms that can easily be remembered by physicians, nurses, and other health care personnel:

a. Non-cardiovascular etiology: **TRAPS**
- **T**—Thyroid disease
- **R**—Recreational drug use
- **A**—Alcohol
- **P**—Pulmonary disease
- **S**—Sepsis/infection

b. Cardiovascular etiology: **CATCH WAVE**
- **C**—Congestive heart failure
- **A**—Acute coronary syndrome/acute myocardial infarction (MI)
- **TC**—TaChy-brady syndrome/vagal mediated
- **H**—Hypertension
- **W**—Wolff–Parkinson–White syndrome
- **A**—After cardiac surgery
- **V**—Valvular heart disease
- **E**—mEdical noncompliance

RATE MANAGEMENT

In about 60% to 70% of patients with AF, a rapid ventricular rate is observed, and symptoms are usually present depending on the rapidity of the ventricular response, the length of time the arrhythmia is sustained, and the presence and type of underlying heart disease.[11] Acute ventricular rate control is the primary goal initially because patients' symptoms are chiefly governed by the rapid ventricular rate. In addition, a reduction in ventricular rate in AF results in a longer diastolic filling period and higher ventricular stroke volume. Acute ventricular rate control in AF can be achieved by pharmacotherapy, nonpharmacologic therapy, and early cardioversion to sinus rhythm. In addition, correction of precipitating factors often helps in controlling ventricular rates in addition to enhancing the chances for conversion to sinus rhythm.

We have defined the rate control goal in AF as a resting ventricular rate of less than 110 beats/min.

Atrioventricular (AV) node blocking agents including β-adrenergic blockers, non–dihydropyridine calcium channel blockers, and digoxin are usually effective in controlling ventricular rate in AF and Afl. Intravenous (IV) β-blocker and non–dihydropyridine calcium channel blockers are considered equally effective in rapidly controlling the ventricular rate. The addition of digoxin to the regimen is helpful, but digoxin as a single agent is generally less effective. Magnesium and amiodarone have also been used for acute ventricular rate control in AF. The agent of first choice is usually individualized depending on the clinical situation. β-Blockers are preferable in patients with myocardial ischemia, MI, and hyperthyroidism and in a postoperative state, but should be avoided in patients with bronchial asthma and chronic obstructive pulmonary disease, whereby non–dihydropyridine calcium channels blockers are preferred.β-blockers are preferred in AF during pregnancy. In addition, in AF with Wolff–Parkinson–White syndrome, β-Blockers, calcium channel blockers, and digoxin should be avoided, because these drugs are selective AV node blockers without slowing conduction through the accessory pathway, which can lead to increased transmission of impulses preferentially through the accessory pathway and precipitate ventricular fibrillation. The drug of choice for AF in pre-excitation syndrome is procainamide.

Figure 24.3 outlines our recommendations for rate control medications. It summarizes the IV loading and maintenance dose, as well as the oral dose for recommended medications.

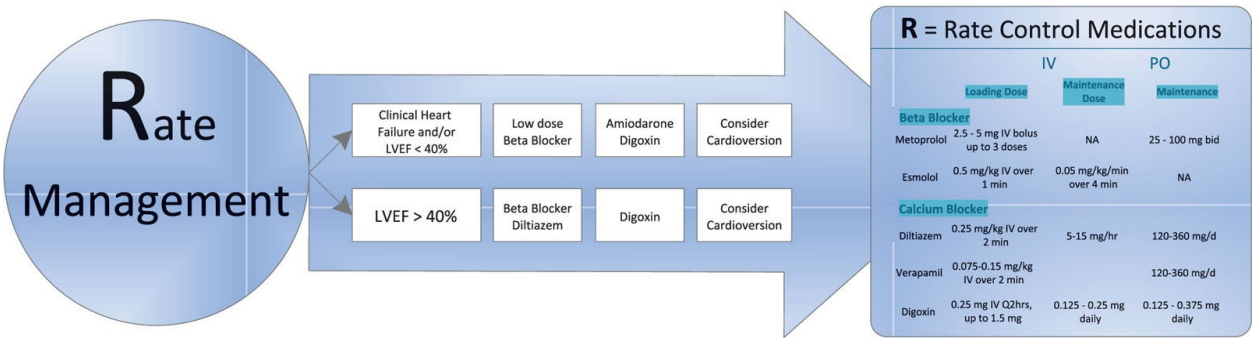

FIGURE 24.3 Rate management in patients with atrial fibrillation and atrial flutter. IV, intravenous; LVEF, left ventricular ejection fraction.

The first-line therapy to slow the ventricular rate in patients with AF and clinical heart failure and/or left ventricular ejection fraction (LVEF) <40% is a low-dose β-blocker.

The second-line therapy includes amiodarone or digoxin. Amiodarone can cause conversion to normal sinus rhythm in some patients and potentially precipitate a cardioembolic event in patients who are not adequately anticoagulated. If all these drugs fail to slow the ventricular rate, we suggest considering cardioversion.

For patients with LVEF >40%, we recommend using a β-blocker or diltiazem and as a second line to use digoxin.

If these agents fail to slow the ventricular rate, cardioversion should be considered.

ANTICOAGULATION

AF is thought to be responsible for approximately 15% to 25% of ischemic strokes.[12, 13] The pathophysiology of AF-associated stroke is complex, but it appears to arise as a result of the embolization of a thrombus formed within the dysfunctioning left atrium, especially the left atrial appendage (LAA). Clot formation is more likely to occur under the conditions of stasis accompanying impaired atrial contraction.

Stratification of thromboembolic risk is central to the current recommendation for anticoagulation of patients with AF.

The CHA_2DS_2-VASc stroke risk stratification score (**Table 23.1**), recommended for use by the 2014 AHA/ACC/HRS Guideline for the

Management of Atrial Fibrillation, is an expansion of the $CHADS_2$ score with three additional risk factors including female sex, age of 65 to 74 years, and history of vascular disease, such as prior MI, peripheral arterial disease, and aortic plaque.

The total score of the CHA_2DS_2-VASc is up to 9 points. On the basis of a strong level of evidence, the recommendation is to provide anticoagulation therapy for CHA_2DS_2-VASc scores of 2 or higher that indicates high risk for a thrombotic event. A CHA_2DS_2-VASc score of 1 indicates an intermediate risk of an event, and the clinician may consider offering antithrombotic therapy with either aspirin, an anticoagulant, or no therapy with continued monitoring with an implantable loop recorder for better understanding of the burden of AF. Assessing bleeding risk may assist with the decision process.

Several tools are available to assess the bleeding risk from anticoagulation for AF. The HAS-BLED score (**Table 23.2**) has been validated to predict clinically significant bleeding and has been demonstrated to outperform other scores.

Figure 24.4 outlines our summarized protocol for anticoagulation in the management of AF and Afl.

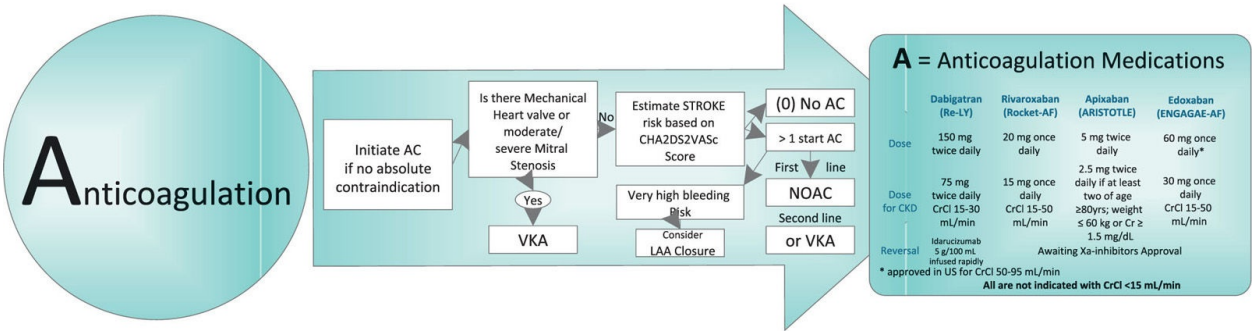

FIGURE 24.4 Anticoagulation in patients with atrial fibrillation and atrial flutter. AC, anticoagulant; LAA, left atrial appendage; NOAC, novel oral anticoagulation; VKA, vitamin K antagonist.

Our group decided to adopt the ESC definition of valvular AF as a mechanical heart valve or evidence of moderate or severe mitral stenosis. These patients will benefit from anticoagulation with only warfarin.

We recommend estimating the stroke risk based on the CHA_2DS_2-VASc scores and assessing bleeding risk based on the HAS-BLED score (**Table 23.2**).

Stroke risk of 0 does not require anticoagulation. If the stroke risk is above 1, we recommend assessing the bleeding risk for the purpose of mitigation of the

bleeding risk factors.

In patients with a very high risk of bleeding, in patients with bleeding on anticoagulation, and in patients who cannot tolerate long-term anticoagulation therapy, a LAA closure device can be considered.

Otherwise, we recommend anticoagulation and the first-line therapy should be one of the four available novel oral anticoagulation (NOAC) agents. Warfarin should be considered only as a second-line option.

Figure 24.4 outlines the dosing of the currently available NOAC agents.

CARDIOVERSION

The decision to electively cardiovert a patient to and maintain normal sinus rhythm are complex and requires careful consideration of patient-specific factors as well as shared decision making with the patient. Timing the duration of AF and Afl is sometimes difficult if the patient cannot pinpoint the starting time of the arrhythmia. It is well accepted that patients whose arrhythmia is less than 48 hours in duration can safely have a cardioversion performed, and those with arrhythmia over 48 hours may have developed atrial thrombus, which increases the risk of thromboembolic events post cardioversion.

Figure 24.5 outlines our recommendations for cardioversion in patients with AF or Afl. We recommend starting the evaluation of the patient by assessing the duration of AF and Afl.

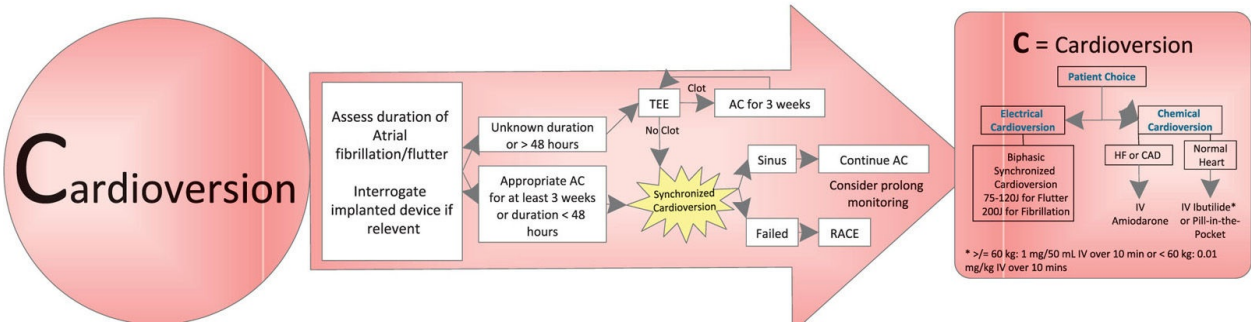

FIGURE 24.5 Cardioversion in patients with atrial fibrillation and atrial flutter. AC, anticoagulant; CAD, coronary artery disease; HF, heart failure; IV, intravenous; TEE, transesophageal echocardiogram.

This assessment can be quite easy if the patient has an implantable device—as the interrogation of the device will reveal the starting time of the arrhythmia.

For patients whose arrhythmia is *firmly established* to be less than 48 hours in duration, or if they have a *documented evidence* of appropriate anticoagulation for at least 3 weeks, a synchronized cardioversion can be safely performed.

When the onset of AF cannot be accurately determined or if AF is longer than 48 hours, anticoagulation should always be administered for at least 3 weeks before attempting cardioversion. Anticoagulation before cardioversion can be shortened if a transesophageal echocardiogram (TEE) is done and indicates the absence of thrombus in the left atrium and the LAA. The TEE-guided approach has been evaluated in the "Assessment of Cardioversion Utilizing Echocardiography (ACUTE) trial."[14, 15] With this approach, which we often employ, cardioversion is done immediately when the TEE suggests that there is no evidence of thrombus; anticoagulation is continued for at least 4 weeks or longer depending on the long-term cardioembolic risk.

The consideration to discontinue anticoagulation therapy after 4 weeks can be made when there is no recurrence of AF and there are no stroke risk factors.

Transthoracic electrical cardioversion is more successful than pharmacologic cardioversion, with an overall success rate of 75% to 93%, inversely related to the duration of AF, chest wall impedance, and left atrial size. The success rate for pharmacologic cardioversion in selected patients approaches 70% at best, and there is a risk of proarrhythmia. For this reason, we recommend electrical cardioversion.

Figure 24.5 outlines our recommended options for electrical or chemical cardioversion.

There are two conventional positions for the electrode placement: anterior-lateral and anterior-posterior. Several studies have shown that less energy is required and a higher success rate is achieved with electrodes in the anterior-posterior position. For this reason, we recommend the anterior-posterior location. The energy required for cardioversion of AF is often 200 joules. More energy is required in obese patients and for long-standing AF. The initial energy used depends in part on the waveform of the current delivered by the defibrillation. Biphasic devices have been shown to be more effective and require less energy than monophasic devices.

Although electrical cardioversion is the more widely used technique, chemical cardioversion using class III antiarrhythmic drugs such as ibutilide can certainly be used provided that the patient will be observed for at least 2 hours post cardioversion in a monitored setting. Dofetilide also has been shown to be effective in acute conversion of AF, typically after two doses with a documented

conversion rate up to 70%.[16, 17]

ELECTROPHYSIOLOGY MANAGEMENT

Over the past decades, various antiarrhythmic drugs and catheter-based procedures have been investigated for maintenance of sinus rhythm in patients with AF. Although the AFFIRM trial showed no significant difference in the outcome of patients using these medications, the long-term outcome of a population-based administrative databases from Quebec, Canada, from 1999 to 2007 in selected patients 66 years or older and followed up for more than 4 years showed rhythm control therapy to be superior in the long term, particularly as the study population got older.[18]

Figure 24.6 presents an abbreviated algorithm for selection of the most appropriate antiarrhythmic drug for maintaining sinus rhythm in selected categories of patients. The figure lists selected doses of our recommended class Ic and class III antiarrhythmic medications.

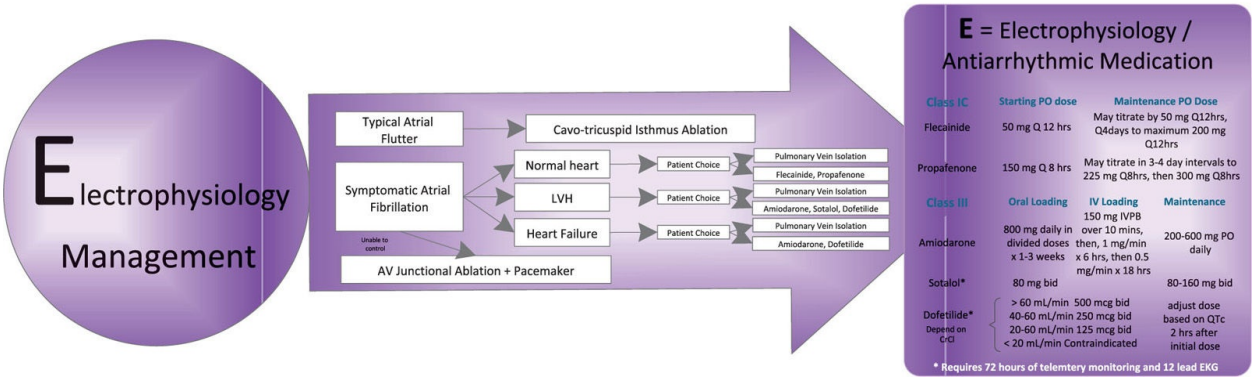

FIGURE 24.6 Electrophysiology management in patients with atrial fibrillation and atrial flutter. AV, atrioventricular; IV, intravenous; LVH, left ventricular hypertrophy.

That being said, several studies have shown that several class IA, IC, and III drugs, as well as class II drugs (β-blockers), are moderately effective in maintaining sinus rhythm; however, they are known to increase adverse events, including proarrhythmia, and some (eg, disopyramide, quinidine, and sotalol) may even increase mortality.[19]

Catheter ablation of AF has become an established therapeutic modality for the treatment of patients with symptomatic AF.

Pulmonary vein (PV) isolation using radiofrequency energy where a wide area or PV antral circumferential ablation strategy or the use of CRYO-ablation poses acute success rates documented in about 85% and long-term freedom from AF that is maintained at follow-up of at least 3 years with rates up to 80% in patients with paroxysmal Afl. Certainly, there are better outcomes when the procedure is performed by experienced operators.[20]

In rare cases when rate and rhythm control are unsuccessful despite maximally tolerated medical therapy and patients continue to be symptomatic because of the rapid Afl, treatment plans should include an electrophysiology (EP) consult to consider AV nodal junction ablation and permanent pacemaker implantation (ablate–pace technique).[21]

MANAGEMENT OF ATRIAL FLUTTER

The RACE pathway published in September 2005[1] was the first to include both AF and Afl in a single pathway. Because both arrhythmias will require anticoagulation and rate control medication, the initial assessment and management is similar. However, if the ECG is consistently Afl, we highly recommend consulting the EP team for consideration for Afl ablation, as shown in **Figure 24.6**.

EP studies have shown that Afl results from tachycardia using a reentry circuit. The reentry circuit occupies large areas of the atrium and is referred to as “macroreentrant.” The classic type of Afl (typical flutter) is dependent on the cavotricuspid isthmus. Catheter ablation of the cavotricuspid isthmus for isthmus-dependent flutter had been proved to be 95% to 100% successful,[22, 23] and is superior to antiarrhythmic therapy.[24]

Our recommendation is to consult the EP team for all patients with Afl for consideration of ablation. If medically treated, Afl resumes in the vast majority of patients within 6 months.[23]

Ventricular Arrhythmia

Ventricular arrhythmias (VAs) refer to a wide variety of tachyarrhythmias, which originate from the left or right ventricle. VA is a spectrum of arrhythmias ranging from premature ventricular contraction to ventricular tachycardia (VT) to ventricular fibrillation (VF). Various forms of VA are commonly seen in both the outpatient and inpatient clinical setting. However, it is prudent to review them while in the cardiac care unit (CCU), because patients with acute and life-threatening VAs will be treated here.

VA can be due to one of the following three mechanisms—Abnormal automaticity, triggered activity, or reentry.

a. **Abnormal automaticity:** Some of the cardiac tissue has the ability to automatically generate electrical impulse through spontaneous depolarization. Abnormal automaticity refers to the automatic firing of electrical impulse by cardiac tissue which, under normal conditions, does not demonstrate automaticity. Example: Right Ventricular Outflow Tachycardia.
b. **Triggered activity:** Triggered activity refers to an electrical impulse which is triggered by preceding impulse. Preceding impulse causes oscillations in the membrane potential of the abnormal cardiac tissue, which are called after-depolarizations. Once the after-depolarization crosses the threshold of depolarization, it creates abnormal electrical impulse. Example: Long QT Syndromes.
c. **Reentry:** This is the most common mechanism for VAs. Reentry refers to

propagation of impulse around a circuit that comprises two distinct electrical pathways with distinct electrical properties. As the circuit gets activated, it emits the electrical impulse at fixed cycle length. Example: Ischemic/scar-related VT.

BASIC DEFINITIONS

Table 25.1.describes some of the basic definitions related to VAs.

TABLE 25.1 Basic Definitions of Ventricular Arrythmia

Premature ventricular complexes (PVCs)	Ectopic beats originating from an abnormal automaticity focus. The depolarization of these beats is of ventricular origin and not conducted through the His–Purkinje system; they manifest as isolated wide QRS (>120 ms) complex beats on electrocardiogram (ECG).
Couplet	Two consecutive PVCs
Triplet	Three consecutive PVCs
Ventricular bigeminy	Occurrence of a PVC after every other normal/sinus beat
Ventricular trigeminy	Occurrence of a PVC every third beat
Nonsustained ventricular tachycardia (NSVT)	3 or more consecutive PVCs, at a rate of > 100 beats/min and spontaneously terminates within 30 s, without hemodynamic compromise
Ventricular tachycardia (VT)	Rapid (>100 beats/min), wide QRS complexes (>120 ms) of ventricular origin
Sustained ventricular tachycardia	VT that is greater than 30 s and/or is accompanied by hemodynamic instability and/or symptoms
Monomorphic ventricular tachycardia	VT in which all beats have the same morphology manifesting as uniform widened QRS complexes on ECG. Monomorphic VT originates from a single automaticity focus or reentry circuit within the ventricles
Polymorphic ventricular tachycardia	VT with widened QRS complexes that vary in amplitude and duration on ECG. Polymorphic VT originate from multiple ventricular foci firing together, leading to irregular ventricular depolarizations

Torsades de pointes	Type of polymorphic VT with widened QRS complexes that change in amplitude, giving the appearance of a “twisting pattern.” This is usually associated with long QT interval
Ventricular fibrillation	A rapid (typically > 300 beats/min) and irregular rhythm of chaotic electrical activity of ventricular origin, essentially leading to no meaningful cardiac output, and is a rapidly fatal rhythm

PREMATURE VENTRICULAR COMPLEXES

Premature ventricular complexes (PVCs) are extremely common in the population, and up to 40% of people without cardiac disease may have them. [1] PVCs originate from abnormal automaticity foci in the ventricles, which can be due to hypoxia, electrolyte abnormalities, or cardiac pathology. Common areas of these foci include the right ventricular outflow tract (RVOT), left ventricular outflow tract (LVOT), papillary muscle, or diseased cardiac tissue after a myocardial infarction (MI) or fibrosis. They manifest as isolated widened QRS complexes (>120 ms). Several studies have shown the presence of PVCs to be associated with increased risk of cardiovascular mortality in patients with structural heart disease. 2,3 **Figure 25.1** shows PVCs in a bigeminy pattern.

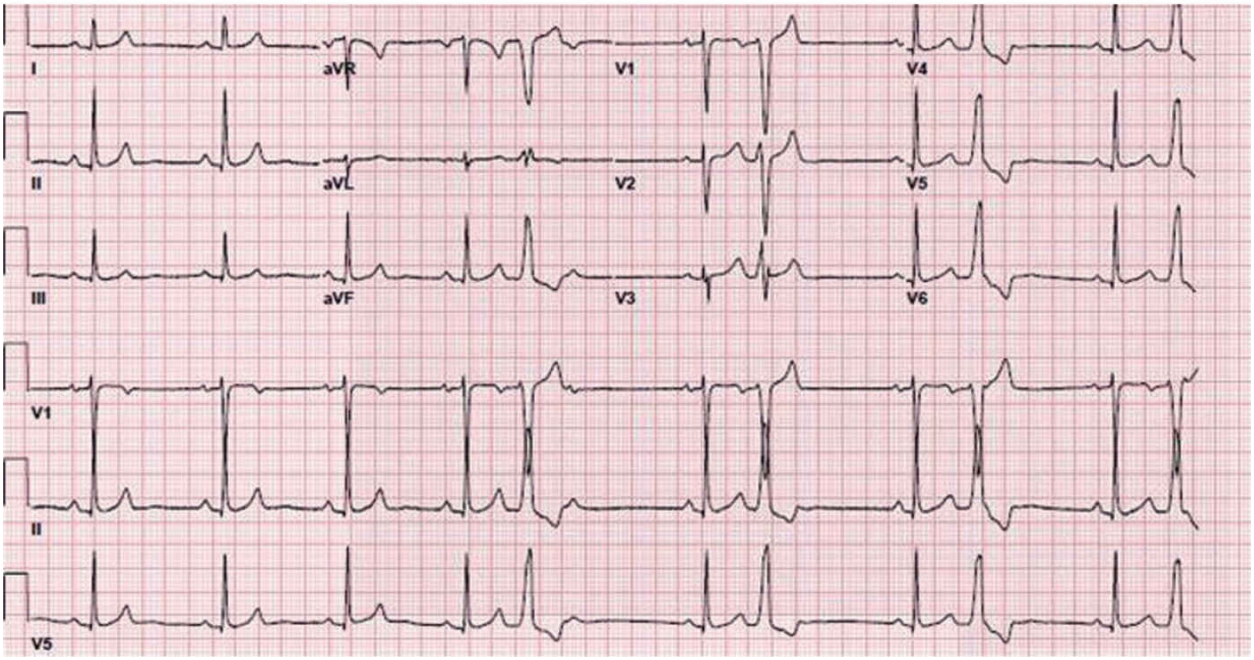

FIGURE 25.1 Normal sinus rhythm followed by ventricular bigeminy. This pattern involves the presence of a premature ventricular complexes (PVC) after every normal sinus beat. aVF; augmented vector foot; aVL; augmented vector left; aVR, augmented vector right.

In the vast majority of patients, PVCs do not produce symptoms, but they can manifest as palpitations and, rarely, lightheadedness or near syncope. Diagnosis of PVCs in the outpatient setting can be made by ambulatory Holter monitor or event monitor, specifically to quantify the burden of PVCs. Whether to treat the PVCs or not depends on the presence of structural heart disease, burden of PVCs, and presence of symptoms. Treatment options for symptomatic patients includes rectifying correctable causes or triggers such as ischemia, alcohol, illicit drugs, or caffeine and also includes workup to check electrolyte levels and thyroid stimulating hormone. For patients with structural heart disease, β - blockers may help reduce the frequency of PVCs. Catheter ablation should be considered for patients with high PVC burden (> 10%) that is associated with significant symptoms unresponsive to antiarrhythmic medications and/or left ventricular (LV) dysfunction. [4] PVCs originating from outflow tracts are relatively easily amenable to catheter ablation.

NONSUSTAINED VENTRICULAR TACHYCARDIA

Like PVCs, nonsustained ventricular tachycardia (NSVT) can be seen in a wide range of medical conditions as well as in healthy individuals. NSVT is mostly diagnosed on telemetry, Holter monitors, or event monitors. Typically, NSVT is not associated with hemodynamic compromise. However, it may produce lightheadedness, palpitations, or chest pain when it lasts for more than a few seconds. β-Blockers are recommended for symptomatic NSVT. In some cases, amiodarone can be used to suppress the NSVT in symptomatic patients.

Clinical relevance and prognostic value of NSVT remain the subject of debate in different clinical settings. Studies have shown that patients with significant coronary artery disease, left ventricular ejection fraction (LVEF) < 40%, and NSVT are at increased risk for sudden cardiac death (SCD), if sustained VT can be induced by electrophysiology study. These patients should have an implantable cardioverter defibrillator (ICD) placement (MUSTT trial).[5] However, such an association is absent for the first 48 hours post-MI. In hypertrophic cardiomyopathy patients, NSVT predicts elevated risk of SCD. Placement of defibrillator for primary prevention is justified in these patients.[6]

VENTRICULAR TACHYCARDIA

Sustained VT is characterized by wide complex tachycardia with a rate > 100 beats/min, lasting for more than 30 seconds, or any VT accompanied with hemodynamic compromise. Sustained VT has multiple etiologies-ischemic VT being the most common. Sustained VT can also be seen in patients with structurally normal heart. Refer to **Table 25.2** for details of types and etiologies of VT.

TABLE 25.2 Types and Etiologies of Ventricular Tachycardia (VT)

Structurally normal heart • Focal VT • Fascicular VT
VT due to structural heart disease • Ischemic VT • Dilated cardiomyopathy
Inherited channelopathies or genetic causes • Long QT syndrome • Brugada syndrome • Catecholaminergic polymorphic ventricular tachycardia • Hypertrophic cardiomyopathy • Arrhythmogenic right ventricular cardiomyopathy (ARVC)
Systemic disease or infiltrative disorders • Sarcoidosis (cardiac sarcoidosis) • Rheumatoid arthritis • Systemic lupus erythematous • Hemochromatosis • Amyloidosis • Myocarditis
Electrolyte abnormalities • Hypokalemia • Hypomagnesemia • Hypocalcemia
Congenital heart disease • Tetralogy of Fallot • Mitral valve prolapse
Drugs/medication induced • IV inotropes • Digitalis • Cocaine • Methamphetamine • Drugs that prolong the QT interval (class IA and class III antiarrhythmics, methadone, etc.)
Other • Commotio cordis

In patients with ischemic heart disease, VT and VF are often the result of scarring and fibrosis secondary to MI. Common nonischemic etiologies include dilated cardiomyopathy, hypertrophic cardiomyopathy, and arrhythmogenic right ventricular cardiomyopathy (ARVC). Infiltrative disorders such as myocarditis, sarcoidosis, and amyloidosis can also cause VT. Finally, electrolyte abnormalities such as hypokalemia and hypomagnesemia can also precipitate VT.

Along with VF, sustained VT is a cause of sudden cardiac arrest and commonly also of syncope and chest pain in predisposed patients. Occasionally, if sustained VT is slow in rate, patients can be asymptomatic or may only have lightheadedness or dizziness.

One of the most challenging and clinically relevant issues while diagnosing VT from ECG is to distinguish it from supraventricular tachycardia (SVT) with aberrant conduction (**Table 25.3**). Both rhythms have wide QRS complexes (> 120 ms) with rates greater than 100 beats/min. In the emergent setting, recognizing the difference between the two is paramount. When doubt exists, it is safest to assume any wide complex tachycardia is VT, especially in patients with known cardiovascular disease. Presence of underlying structural heart disease is the strongest predictor of VT.[7, 8] Previous baseline 12-lead ECG obtained during sinus rhythm may also reveal the etiology of the tachycardia. Fusion or capture beats and atrioventricular (AV) dissociation (**Figure 25.2**) provide the strongest electrocardiographic evidence for differentiating VT from SVT with aberrancy, and are diagnostic of VT. However, in their absence, other clues from the electrocardiogram (ECG) may be required to help with this differentiation. Apart from the aforementioned features, several algorithms have been created for distinguishing VT from SVT with aberrancy, the most notable being Brugada criteria. In any young patient with irregular wide complex tachycardia with rate > 200 beats/min, atrial fibrillation caused by conduction over an accessory pathway should be suspected.

TABLE 25.3 Differentiating VT from SVT with Aberrancy

1. History of structural heart disease or coronary artery disease
2. QRS complexes of > 160 ms in absence of any class IC antiarrhythmic
3. True AV dissociation
4. Presence of capture or fusion beats
5. Extreme axis deviation (QRS positive in aVR and negative in I and aVF)
6. Presence of negative or positive concordance (all precordial leads are negative or

positive)

7. Presence of these signs:
   - **a.** Rsr′ (left R wave taller than right R wave) pattern or notched downslope of R wave in V1
   - **b.** Notching near the nadir of S wave (i.e., Josephson sign)
   - **c.** R wave > 30 ms in V1 or V2
   - **d.** QRS onset to nadir of S in V1 > 60 ms (i.e. Brugada sign)

AV, atrioventricular; aVF, augmented vector foot; aVR, augmented vector right; SVT, supraventricular tachycardia; VT, ventricular tachycardia.

FIGURE 25.2 Sustained ventricular tachycardia (VT) with atrioventricular (AV) dissociation. This figure shows AV dissociation in a sustained VT, wherein the relationship between the P waves and the QRS complexes is completely lost. aVF; augmented vector foot; aVL; augmented vector left; aVR, augmented vector right.

MANAGEMENT OF VENTRICULAR TACHYCARDIA

Pulseless Sustained Ventricular Tachycardia

In any patient with pulseless sustained VT/VF (VT with cardiac arrest), cardiopulmonary resuscitation (CPR) should be initiated immediately. The patient should be treated per Acute Cardiac Life Support (ACLS) protocols. If return of spontaneous circulation is achieved, the patient should be started on chronic VT therapies along with post–cardiac arrest treatment. A detailed discussion of ACLS protocols and post–cardiac arrest treatment is beyond the scope of this chapter.

Sustained Monomorphic Ventricular Tachycardia with Pulse

Patients with hemodynamically compromised, unstable VT requires emergent cardioversion or defibrillation. If the patient is stable, he or she can be given antiarrhythmics while being carefully monitored in the critical care unit. Once the acute episode is resolved, workup should be initiated to identify the etiology, along with chronic medical and device therapies (**Table 25.4**). Current guidelines of the American College of Cardiology (ACC)/American Heart Association (AHA) recommend ICD therapy in patients who are survivors of cardiac arrest or who have had hemodynamically unstable VT for secondary prevention.[9]

TABLE 25.4 Acute and Chronic Management of Sustained VT with Pulse

SUSTAINED VT WITH PULSE	
Monomorphic	***Polymorphic***
Unstable: Emergent/urgent cardioversion	**Acute:** Emergent/urgent defibrillation
• Supplemental O_2 • 12-Lead ECG • Establish IV access • Initial labs—(electrolyte level, cardiac biomarkers, urine toxicology, magnesium level)	
Stable: Consider one of the following **antiarrhythmic medications**: • **Intravenous lidocaine** (1–1.5 mg/kg [typically 75–100 mg] at a rate of 25–50 mg/min; lower doses of 0.5–0.75 mg/kg can be repeated every 5–10 min as needed) • **Intravenous procainamide** (20–50 mg/min until arrhythmia terminates or a maximum dose of 17 mg/kg is administered) • **Intravenous amiodarone** (150 mg IV over 10 min, followed by 1 mg/min for the next 6 h; bolus can be repeated if VT recurs)	• If in setting of **myocardial ischemia**: consider IV nitroglycerin and urgent revascularization • **Short QT interval**: can use IV β-blocker or IV amiodarone (150 mg IV over 10 min, followed by 1 mg/min for the next 6 h; bolus can be repeated if VT recurs) • **Long QT interval**: IV isoproterenol can be used to increase the HR in patients with bradycardia • **Torsades de Pointes**: IV magnesium should be given even if the magnesium level is normal
Chronic therapies • β-Blockers • ICD implantation • Antiarrhythmic mediation • Radiofrequency catheter ablation • Surgical therapies—sympathetic denervation	

ECG, electrocardiogram; HR, heart tare; ICD, implantable cardioverter defibrillator; VT, ventricular tachycardia.

Sustained monomorphic VT (SMVT) (**Figure 25.3)** is commonly seen with

acute myocardial ischemia, chronic ischemic heart disease with LV scar formation as well as in the structurally normal heart. In patients with chronic ischemic heart disease, myocardial cells around the border of the scar act as a substrate for a reentrant circuit, causing monomorphic VT. Idiopathic focal VT is usually a monomorphic VT arising from areas of abnormal automaticity.

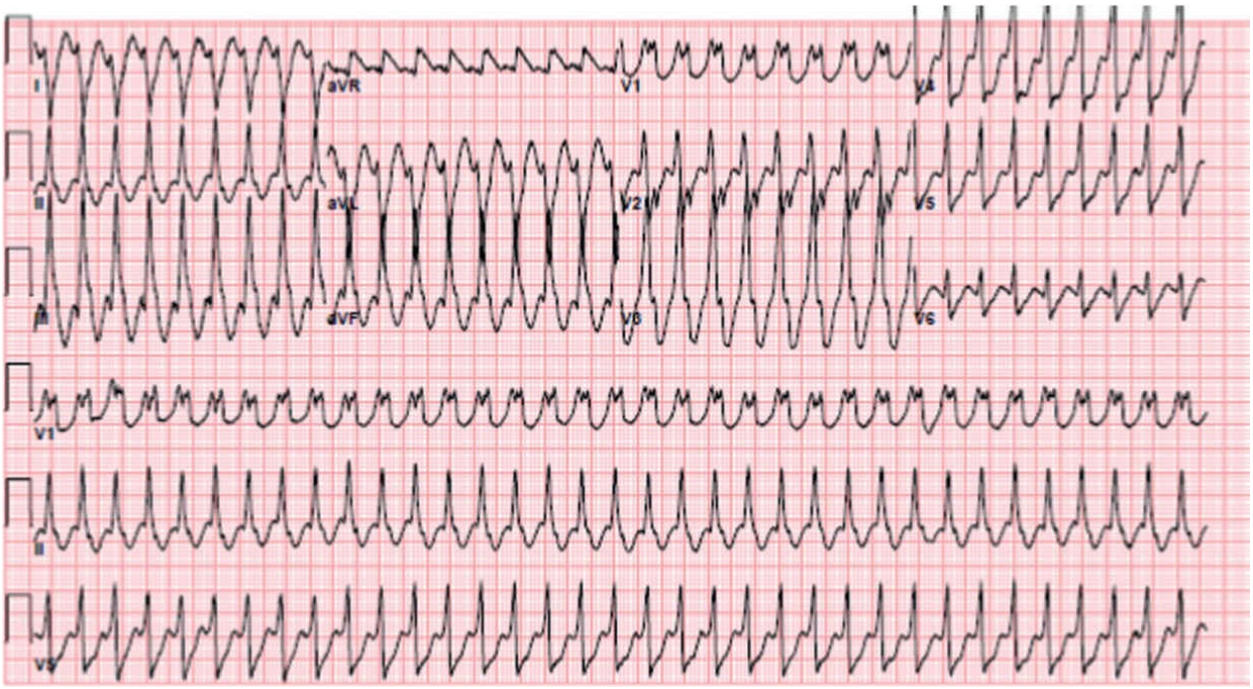

FIGURE 25.3 Sustained monomorphic ventricular tachycardia (SMVT). In SMVT, all beats have the same morphology manifesting as uniform widened QRS complexes on electrocardiogram. aVF; augmented vector foot; aVL; augmented vector left; aVR, augmented vector right.

All patients with sustained monomorphic VT should have basic workup to assess etiology. Features of instability include chest pain, dyspnea, hemodynamic instability, and altered mental status. Stable patients can be treated with any of three antiarrhythmic medications—lidocaine, amiodarone, or procainamide. Intravenous procainamide is not easily available in the United States. Lidocaine is usually more effective in VT associated with myocardial ischemia or infarction. Amiodarone acts slowly and is the most effective as well as most commonly used out of the three medications. Although IV administration of these medications can be stopped once the acute episode is over, infusion should be continued if there is recurrent SMVT. Intravenous amiodarone can be followed by oral amiodarone to prevent recurrent VT. Other concurrent managements include treatment of the reversible cause—electrolyte imbalance correction or urgent revascularization if myocardial ischemia is

present.

Once the acute episode is over, long-term medical therapy should be started, which commonly includes β -blocker with or without antiarrhythmic medication. ICD placement should be considered for secondary prevention. The European Heart Rhythm Association/Heart Rhythm Society (EHRA/HRS) recommends radiofrequency catheter ablation for patients with structural heart disease in the following situations: 1. recurrent VT that is not responding to antiarrhythmic drugs; 2. VT leading to recurrent ICD shocks with no response to or side effects with antiarrhythmic therapy; 3. incessant VT or VT storm not attributable to a reversible cause; 4. a patient who is not a candidate for ICD or refusing ICD.[10]

Surgical therapies for VT can be considered in patients who are undergoing cardiac surgery for another cause (coronary bypass graft placement/valve replacement) and have identifiable substrates such as ventricular aneurysms or large myocardial scars. Surgical approaches that have proven effective include LV aneurysmectomy, encircling endocardial ventriculotomy and subendocardial resection. In some patients with recurrent VT who have failed to respond to antiarrhythmic drugs and catheter ablation, bilateral surgical sympathectomy has been shown to be helpful.

Sustained Polymorphic Ventricular Tachycardia with a Pulse

Polymorphic VTs are classified on the basis of their QT interval. Polymorphic VT with normal QT intervals is most commonly caused by myocardial ischemia after acute MI, severe heart failure, or cardiogenic shock. When feasible, urgent myocardial revascularization should be undertaken. These patients have high mortality, especially when VT is associated with heart failure and cardiogenic shock. Antiarrhythmic drugs have limited success in improving their outcome.

Torsades de pointes (TdP) (**Figure 25.4**) is a specific type of polymorphic VT (which has characteristic ECG morphology in which QRS complexes appear to “twist” around the isoelectric line). When in sinus rhythm, an ECG classically shows prolonged QT interval. This can be congenital or acquired. Congenital long QT syndrome is caused by multiple genetic variants. Acquired long QT intervals are secondary to acute myocardial ischemia or drug administration. Medications known to contribute to QT prolongation include several antiarrhythmic drugs (Class III antiarrhythmics), antibiotics (specifically fluoroquinolones and macrolides), antipsychotics, and antihistamines.

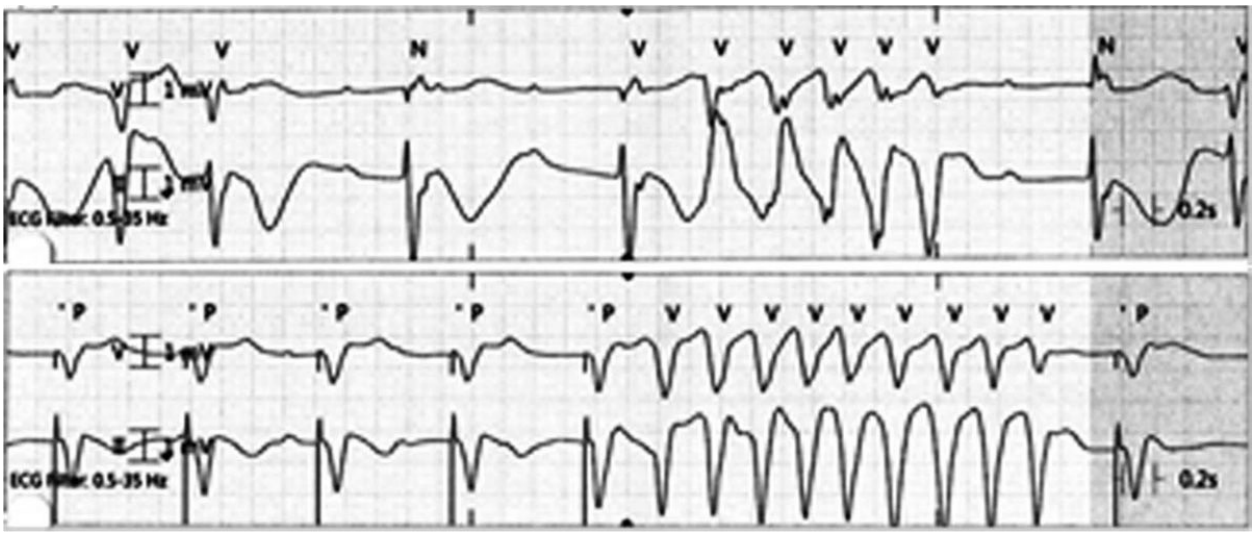

FIGURE 25.4 Torsades de pointes. Both rhythm strips showing electrocardiogram with baseline rhythm having prolonged QT interval and a short burst of polymorphic ventricular tachycardia, that is torsades de pointes. Upper panel: sinus bradycardia with prolonged QT interval. Lower panel: V-paced rhythm with prolonged QT interval.

There are other types of polymorphic VT without definitive association with QT interval. Bidirectional VT is a rhythm characterized by two distinct wide complex QRS (> 120 ms) morphologies (rate > 100 beats/min) that alternate every beat. Although bidirectional tachycardia is a rare occurrence in general, it is pathognomonic for digoxin toxicity. Catecholaminergic polymorphic ventricular tachycardia (CPVT), also known as familial polymorphic ventricular tachycardia (FPVT), is a congenital disorder caused by mutations in ryanodine receptors or other calcium channel binding proteins in the sarcoplasmic reticulum. It is a rare condition that manifests within the first or second decade of life, presenting as dizziness, syncope, or even sudden death, after exercise or emotional stress. Brugada Syndrome is a rare syndrome that is seen most commonly in South-East Asians. Resting ECGs show right-bundle branch block (RBBB) pattern with ST-elevations in the right precordial leads, specifically in V1 and V2, and have the potential to degenerate into polymorphic VT and even VF.

Most polymorphic VTs are unstable with hemodynamic compromise and require emergent or urgent defibrillation. In the patient with polymorphic VT and normal QT interval, the likely etiology is myocardial ischemia. β-Blockers and IV amiodarone can be used (bolus followed by infusion) to prevent recurrence of the arrhythmia. Urgent coronary angiography and revascularization is necessary to relieve the ischemia.

In the patient with congenital long QT syndrome, β -blockers may be used to reduce the frequency of PVCs and shorten the QT interval. ICD therapy is indicated if patients have recurrent syncope despite β-blocker therapy. Isoproterenol is used in patients with polymorphic VT triggered by sinus pauses or bradycardia. For patients with TdP, IV magnesium is first-line therapy (even in patients with normal serum magnesium) for both termination and prevention of recurrence of this rhythm. If the patient does not respond to intravenous magnesium, temporary intravenous pacing at 100 beats/min may be reasonable to prevent recurrence.

VENTRICULAR FIBRILLATION

VF is a rapid (typically > 300 beats/min) and irregular rhythm of chaotic electrical activity of ventricular origin. VF causes SCD because there is no cardiac output during this rhythm. Typically, this rhythm is seen during the acute phase of MI. VF is further divided into primary VF, which occurs less than 48 hours after a MI, and nonprimary VF, which does not occur in the setting of MI (but typically in the setting of heart failure or recurrent ischemia). Predictors of primary VF include ST-elevation MI (STEMI), early repolarization on baseline ECG during an acute coronary syndrome, hypokalemia, hypotension, large infarcts, male sex, and history of smoking. If not treated immediately, VF is almost universally lethal.

Treatment of VF involves defibrillation and pharmacotherapy. Defibrillation at an initial shock of 120 to 200 joules for biphasic defibrillators and 360 joules for monophasic defibrillators is currently recommended by ACLS guidelines. Pharmacotherapy involves epinephrine, which is to be administered as 1mg IV of 1:10,000 every 3 to 5 minutes. An initial bolus of 300 mg of IV amiodarone diluted in 20 to 30 mL of normal saline, followed by 150 mg IV boluses has been shown to increase the efficacy of electrical defibrillation in out-of-hospital cardiac arrest. Prior to the most recent guidelines regarding ACLS by the AHA, vasopressin was used, but is currently not recommended.[11] Lidocaine has been shown to have no evidence of efficacy in the management of VF. Chronic therapy for VF is similar to sustained VT, which includes ICD implantation for secondary prevention and β -blockers.

VENTRICULAR TACHYCARDIA—SPECIFIC VTS

VENTRICULAR TACHYCARDIA IN THE STRUCTURALLY NORMAL HEART

About 10% of patients with VT do not have any evidence of structural heart disease.[12] In general, these VTs present as monomorphic VT. Although idiopathic VT can originate from any ventricular site, the most frequent sites are RVOT, LVOT and Left ventricular fascicles.

Focal Ventricular Tachycardia

RVOT VT is seen in greater proportion in females compared to males, whereas the distribution of LVOT VT is more equal with respect to gender. They are both seen early in life, sometime between the third and fifth decades. The most likely mechanisms for these rhythms include triggered activity (catecholamine-mediated after-depolarizations). Symptoms include palpitations, dizziness, and, on occasion, syncope. On presentation, these rhythms commonly present as nonsustained repetitive monomorphic VT or paroxysmal exercise-induced VT. Frequent NSVT and high PVC burden can lead to ventricular dysfunction (tachycardia-induced cardiomyopathy) in these patients. On ECG, RVOT VT has a characteristic left bundle branch block morphology with inferior axis, where LVOT VT presents with RBBB morphology with inferior axis.

Idiopathic VTs are associated with good long-term prognosis. The decision to treat depends on the frequency and severity of symptoms, and presence of ventricular dysfunction. Acute termination can be achieved with adenosine and verapamil. RVOT and LVOT VTs respond well to β-blockers, calcium channel blockers, and antiarrhythmic drugs as well. As these patients have no structural heart disease, all antiarrhythmic drugs can be used. However, catheter ablation is preferred management option because it offers a permanent safe cure and has a high success rate, exceeding 90%.

Fascicular Ventricular Tachycardia

Fascicular VT originates from the fascicles in the left ventricle. Although commonly seen in the second to fourth decades of life, frequently patients may recall episodes of palpitations or dizziness at an earlier age. Up to 70% of these patients are males. This rhythm may be precipitated by emotional stress or exercise. Fascicular tachycardias are related to reentry in the His–Purkinje

system, most commonly in the left posterior fascicle. At times, the site of origin is a false tendon or a fibromuscular band that extends from the posteroinferior left ventricle wall to the basal septum, which has reportedly been observed on echocardiography.[13] On 12-lead ECG, fascicular VTs have a RBBB-like morphology and relatively short QRS interval (120 ms to 140 ms). Depending on the site of exit in the left ventricle, they are associated with left axis deviation (more commonly) or right axis deviation. Fascicular VT has good long-term prognosis and can be treated medically with β -blockers and calcium channel blockers. They are particularly sensitive to verapamil. Fascicular VT can be confused for SVT because of ECG characteristics and sensitivity to verapamil. Catheter ablation has high success rates (90–95%) and is preferred compared to lifelong medical therapy.

VENTRICULAR TACHYCARDIA IN THE STRUCTURALLY ABNORMAL HEART

Ventricular Tachycardia in Ischemic Heart Disease

This refers to VT that develops in the setting of both acute and chronic ischemic heart disease. Life-threatening VAs, including VT and VF, are infrequent but possible sequelae of acute STEMIs and acute non-ST-elevation MIs (NSTEMI), with an overall lower incidence in NSTEMIs compared to STEMIs. Life-threatening arrhythmias such as symptomatic VT and VF can be the first presentation of acute MI. These are primarily treated by coronary revascularization.

Patients with chronic ischemic heart disease usually have myocardial scarring and present with monomorphic VT. This involves a reentrant circuit involving damaged slow conducting myocardium and increased automaticity in the border zone of myocardial scars. On ECG, VT from old MIs are typically monomorphic, whereas VT in the acute MI presents as polymorphic. Patients who develop VT or VF in the acute MI phase, specifically in the first 24 to 48 hours, do not have an increased risk of sudden death and do not require an implantable cardioverter defibrillator (ICD) for secondary prevention.

For those who develop recurrent VT or VF, and are thus at risk for SCD, the primary treatment is ICD therapy. β-Blockers have anti-ischemic and bradycardic properties and have been shown to reduce SCD, if continued at least 90 days post-MI.[14] Antiarrhythmic medications such as sotalol and amiodarone may be used for recurrent VT and VF despite defibrillator implantation. Catheter

ablation has been shown to be highly successful for management of these patients and involves mapping and ablation of areas of slow conduction.

ICDs are indicated for primary and secondary prevention of sudden death in patients with chronic ischemic heart disease. Class IA indications for primary prevention include 1. patients with LVEF < 35% caused by prior MI who are at least 40 days post-MI and are in New York Heart Association (NYHA) Functional Class II or III, 2. patients with LVEF < 30% who are 40 days post-MI and are in NYHA Functional Class I. Class IA recommendation for ICD placement in the patient with ischemic cardiomyopathy for secondary prevention include those who are survivors of cardiac arrest caused by VT/VF.

Ventricular Tachycardia in Dilated Cardiomyopathy

This refers to VT that occurs in the setting of dilated cardiomyopathy (DCM). DCM is the most common cause of heart failure and is among the most common diagnosis that requires hospitalization in North America. The current prevalence of DCM in the United States is roughly 4.7 million, and the 5-year mortality rate in patients with heart failure caused by DCM is 50%.[15]

VT in the patient with dilated cardiomyopathy has been proposed by several different mechanisms: (1) arrhythmogenic substrates may result from myocardial fibrosis, leading to an irritable focus and (2) high catecholamine levels or stretching of myocardial fibers induced by increased LV end-diastolic volume. Acute management of VT in DCM is similar to that of ischemic cardiomyopathy. In addition, β-blockers show similar benefits as they do in ischemic cardiomyopathy. Current guidelines recommend ICD implantation for primary prevention in patients with new diagnosis of nonischemic dilated cardiomyopathy (NIDCM)with NYHA class II–III symptoms and EF <30%; or with at least 3 months of medical therapy in a patient with LVEF <35%.[16] Catheter ablation has been shown to have limited success in patients with VT and NIDCM, but it is particularly successful in a small proportion of these patients when VT is related to bundle branch reentry.

VENTRICULAR TACHYCARDIA RESULTING FROM INHERITED CHANNELOPATHIES OR CONGENITAL CAUSES

This section will focus on several different genetic and congenital causes of VT and their managements. Several of these causes of VT owe their arrhythmogenicity to channelopathies and receptor protein defects.

Long QT Syndrome

Long QT syndrome is a congenital disorder, which is characterized by a prolonged QT interval (greater than 450 ms in adult males and 470 ms in adult females) on baseline ECG. Several different mutations have been identified in patients with genetic long QT syndrome involving several different subunits of potassium and sodium channel proteins. Syncope provoked by being startled, exercise, or swimming in light of previous family history of SCD and an ECG showing prolonged QT may help make this diagnosis. As the QT interval may vary throughout the day, ambulatory ECG monitoring may provide some information to help confirm the diagnosis of long QT syndrome.

As discussed earlier, long QT syndrome can lead to a specific type of VT known as TdP, which is a polymorphic VT with a characteristic twisting pattern around an isoelectric point. TdP in these patients may develop from an adrenergic response precipitated by stress, electrolyte abnormality, or drug administration. Acute management to break TdP involves intravenous administration of magnesium, regardless of serum magnesium levels. β - Blockers and ICD therapy should be used for patients who are survivors of SCD and be considered for patients with a family history of SCD.

Brugada Syndrome

Brugada Syndrome is a rare autosomal dominant disorder that is seen most commonly in the Southeast-Asian male. Mutations in cardiac sodium channels are typically responsible for this condition. Resting ECG shows a right-bundle branch–like pattern with ST-elevations in the right precordial leads. Procainamide has been used as a diagnostic challenge test because it is able to provoke patients who do not have the baseline ECG findings. With Brugada pattern ECGs, ICD therapy is treatment of choice in patients with a history of syncope and aborted sudden death to prevent future SCD. Chronic therapy involving medications such as quinidine and cilostazol have been shown to suppress VAs in these patients, but currently should be used in conjunction with ICD therapy.

Catecholaminergic Polymorphic Ventricular Tachycardia

CP VT is a rare condition that manifests within the first or second decade of life, presenting as dizziness, syncope, or even sudden death, after exercise or emotional stress. Cardiac ryanodine receptor gene and calsequestrin 2 gene

mutations induce calcium release, leading to delayed after-depolarizations and triggered activity, which can lead to polymorphic ventricular tachycardia and VF; there are no characteristic baseline ECG findings. Chronic prevention recommendations include avoiding competitive sports and strenuous exercising. All adult patients without any documented VA history should be on a β -blocker. Survivors of cardiac arrest should be on β -blockers and have consideration of an ICD. In the patient who continues to have VAs despite being on a β -blocker and having an ICD, flecainide can be used for further suppression.

Hypertrophic Cardiomyopathy (HCM)

Hypertrophic Cardiomyopathy (HCM) is a relatively common genetic disorder (1 in 500) caused by several mutations involving sarcomere genes, with a multitude of clinical manifestations and hemodynamic abnormalities (LV outflow obstruction, diastolic dysfunction, myocardial ischemia, and mitral regurgitation) that are related to profound hypertrophy and myopathic processes. Signs and symptoms are variable: Some patients are asymptomatic; some may experience dyspnea, palpitations or syncope; and some may experience advanced heart failure symptoms. Current Class I recommendations for treatment of symptoms such as angina or dyspnea include β-blockers and verapamil in patients with obstructive (referring to LV outflow obstruction) or nonobstructive HCM. Phenylephrine can be used for acute hypotension in patients with obstructive HCM who do not respond to fluid administration. Current class I recommendation for patients with severe treatment-refractory symptoms and LVOT obstruction is septal reduction either surgically (myomectomy) or percutaneously (alcohol septal ablation).

This condition may predispose to developing VAs and to SCD in young persons. Patients with a high risk of SCD include those with a previous history of VF, sustained VT or other SCD events, family history of SCD events, unexplained syncope, documented NSVT on Holter monitoring, and maximal LV wall thickness greater than or equal to 30 mm. These patients should be considered for ICD implantation.[2] There is no consensus on the role of electrophysiology testing in risk stratification of asymptomatic HCM patients who do not have any of the aforementioned criteria.

Arrhythmogenic Right Ventricular Cardiomyopathy

ARVC occurs in roughly 1 in 5000 patients and is characterized pathologically

by morphologic alterations caused by fibrofatty replacement of the right ventricle. ARVC is known as a cause of VAs developing after strenuous exercise, and 80% of cases are diagnosed before the age of 40. There are no specific findings on ECG, but electrocardiograms may reveal T-wave inversions in leads V1 to V3 in the presence of complete or incomplete RBBB. In addition, epsilon waves (characterized by small amplitude waves after the QRS complexes) have been seen in a large number of ECGs in patients with ARVC. With respect to pharmacologic treatment, β-blockers are reasonable recommendations, which should be added to ICD therapy if the patient has a history of frequent PVCs, NSVT, or sustained VT or VF. Patients with recurrent events should be treated with antiarrhythmic therapy and/or catheter ablation. Radiofrequency ablation in these patients can be attempted with limited success because of multiple arrhythmogenic foci.

Cardiac Sarcoidosis

Cardiac Sarcoidosis is being increasingly recognized as a cause of VTs in young patients. The involvement of cardiac muscle has been noted in 10 to 30% of patients with systemic sarcoidosis. A small proportion of these patients develop AV block and/or VT. Diagnosis is confirmed by the presence of myocardial granulomas in biopsy-proven systemic sarcoidosis. Patients with cardiac sarcoidosis and VT should get ICD. Prophylactic ICDs are indicated for patients with systemic sarcoidosis and large myocardial scar. Therapeutic options for management of recurrent VT in patients with cardiac sarcoidosis include antiarrhythmic drugs and, if need be, catheter ablation. Related to complex arrhythmia substrates, both endocardial and epicardial catheter ablation are often needed and are associated with limited success.

Other Congenital Heart Disorders (Tetralogy of Fallot and Mitral Valve Prolapse)

Tetralogy of Fallot (TOF) is a congenital heart defect classically involving four anatomic abnormalities of the heart (pulmonary stenosis, overriding aorta, ventricular septal defect, and right ventricular hypertrophy.) The prevalence of TOF in the United States is 4 to 5 in 10,000 live births. Pathophysiologically, the severity of symptoms largely depends on the degree of the RVOT obstruction. TOF itself is not responsible for VT; however, repair of the RVOT obstruction may involve scarring and patches that may provide an ideal substrate for reentry. Patients with a QRS longer than 180ms are at higher risk of developing

monomorphic VT. Because of the rarity of TOF, there is a lack of strong data for specific drug treatment in VAs in patients with this condition. ICD implantation may be useful in patients with a history of sustained VT or VF. Medical therapy or catheter ablation should be considered for these patients with recurrent VT.[17]

Mitral valve prolapse (MVP) is a valvular disease affecting 2% to 3% of the general population. Proteoglycan accumulation is responsible for leaflet thickening, leading to valvular abnormality. Patients with MVP have a variety of other cardiac complications like atrial fibrillation, congestive heart failure, endocarditis, and, rarely, VAs and sudden cardiac death. The logical explanation for VT in this patient population would be LV dysfunction seen with severe mitral regurgitation. However, multiple sudden cardiac deaths have been reported in MVP patients with mild MR and normal LV function. Etiology in these cases is believed to be caused by VA. VT should be suspected in all patients with MVP who present with presyncope or syncope.

MISCELLANEOUS CAUSES OF VT

Drug-Induced VT

Several drugs may lead to life-threatening VAs. In particular, polymorphic VT and TdP may result from medications that may cause prolongation of the QT interval, leading to acquired long QT syndromes. Antiarrhythmics, macrolide and fluoroquinolone antibiotics, antiprotozoals, antipsychotics, opiates, promotility agents, antihistamines, and toxins such as arsenic are recognized to prolong QT intervals in patients and should be used judiciously in patients with preexisting long QT intervals. Apart from intrinsic properties of the aforementioned medications, electrolyte abnormalities such as hypokalemia and hypomagnesemia should be recognized as potential side effects or from drug–drug interactions.

Commotio Cordis

Translated directly from Latin, meaning “agitation of the heart,” commotio cordis refers to VAs caused by chest trauma and has been recognized as a cause of SCD in young athletes. Young males are most affected, and this phenomenon has been reported in sports with physical contact (baseball, hockey, football). There is a 10 - to 30-millisecond window of the cardiac cycle (specifically in the ascending portion of the T wave), in which the heart is particularly vulnerable to mechanical trauma. When applied at the right time, even a small amount of

energy can disrupt the normal sinus rhythm into VF. This should be suspected when an athlete collapses following chest trauma even when relatively mild. It is the timing of the trauma with respect to the cardiac cycle rather than force that is important for precipitation of this arrhythmia. Treatment includes immediate initiation of CPR. Availability of automatic external defibrillators on playgrounds will improve survival from commotio cordis.

Patient and Family Information for:VENTRICULAR ARRHYTHMIAS

WHAT IS A VENTRICULAR ARRHYTHMIA?

The heart is comprised of four chambers (two upper chambers called the left and right atria and two lower chambers called the left and right ventricles), and a coordinated sequence of electrical activation of these chambers (the atria pump first, followed by filling and pumping of the ventricles) is what allows the heart to effectively pump blood. A normal electrical sequence, also known as normal sinus rhythm, helps to generate adequate blood pressure in the arteries to deliver blood to the rest of the body and the brain. When this electrical sequence is interrupted, an arrhythmia is said to occur. Ventricular arrhythmias (VA) are disturbances of the rhythm of the heart when they originate in the lower chambers—the ventricles.

TYPES OF VENTRICULAR ARRHYTHMIAS

VA can be classified into the following categories:

1. Isolated Premature Ventricular Complexes (PVCs): These are single abnormal extra beats that originate in the ventricles.
2. Ventricular Tachycardia (VT): Refers to a longer sequence of abnormal ventricular beats, which if persistent, may be harmful to patients. VT is defined as more than 3 consecutive PVC. VT can be *nonsustained* if the patient's blood pressure remains stable, and the episode of VT is relatively short in duration (<30 seconds) or *sustained* if the patient is hemodynamically unstable and/or the episode lasts >30 seconds. VTs are

typically identified on electrocardiogram (ECG) as having a rate of more than 100 bpm.

3. Ventricular Fibrillation (VF): Ventricular fibrillation happens when the ventricles quiver but do not have an orchestrated contraction, resulting in essentially no meaningful pumping activity. This leads to no circulation of blood within the body and typically leads to death if not treated promptly.

SYMPTOMS

1. Isolated PVCs and nonsustained VT (NSVT) may cause palpitations, and/or dizziness; however, some patients do not feel anything at all.
2. Sustained VT lasts for more than 30 seconds, and many patients may lose consciousness and collapse.
3. VF will lead to collapse of the patient, loss of consciousness, and death if not treated promptly.

CAUSES OF VENTRICULAR ARRHYTHMIA

VAs may occur for a variety of reasons such as structural or inherited, or even on account of other physiologic abnormalities of the body.

1. Structural heart disease:
   a. Coronary Artery Disease (CAD): Many VAs occur in the setting of blocked coronary arteries in the heart after an acute heart attack. When a heart attack occurs, scarring and dead heart tissue cause electrical disruption. This disruption develops by several different mechanisms (explained in the above chapter). VA in the setting of heart attacks may even result in sudden cardiac death.
   b. Cardiomyopathies: This is a general term to describe various diseases of the heart (which may or may not be caused by blockage of the heart vessels such as in CAD). Cardiomyopathy can lead to weakness and/or stiffness of the heart muscle. Diseases that are not caused by CAD include viral infections, thickening of heart tissues, and dilatation of the chambers of the heart.
   c. Infiltrative heart disease: There are some other medical conditions that cause inflammation and scarring of the heart and that can lead to electrical disturbances and cause VAs.
2. VA without structural heart disease: There are some congenital conditions that affect the proteins that mediate the transport of ions (sodium, potassium, and calcium) in heart cells. Improper functioning of these channels causes disruption of electrical activity and increases the chances of VA.
3. Other reversible factors: Most commonly, abnormal levels of ions such as potassium or magnesium in the blood can cause VAs. Lack of oxygen, if

severe, has been known to irritate heart muscles and cause arrhythmias. Some medications, if not taken judiciously or combined with other medications, may affect different ions in the blood and lead to predisposition to VAs.

TREATMENT OPTIONS

Treatment of VA is divided into two parts. The first is to acutely treat and terminate the arrhythmia. The second is to prevent further arrhythmias from happening. Three different modalities of treatment currently exist today.

ANTIARRHYTHMIC MEDICATIONS

Antiarrhythmic medications are used to acutely treat rhythm disturbances, but may also be used to help maintain normal heart rhythms. β-blockers can slow down the heart rate and suppress the abnormal ventricular complexes. β-blockers are often used in the setting of a heart attack to help prevent VAs from happening. Traditional antiarrhythmic medications such as Amiodarone can also be used in the setting of VT—both to terminate the VT and to maintain a normal sinus rhythm. It is important to note that many antiarrhythmic medications are associated with the development of new and more severe arrhythmias, so care must be taken when given these medications to patients. Amiodarone is known to cause several side effects involving the liver, lungs, thyroid, and eyes when used chronically.

CATHETER ABLATION OF VENTRICULAR TACHYCARDIA

Patients can sometimes be taken into the electrophysiology lab and have abnormal rhythm pathways essentially destroyed. This is a rather invasive but safe procedure. During catheter ablation, abnormal electrical foci within the heart are identified by electrical stimulation. Heat energy is then delivered by a catheter to ablate/burn abnormal electrical pathways. This procedure can even be used in patients who experience a high enough burden of PVCs.

Depending on the type of disease, ablation may be extremely successful, with reported success rates of up to 95% in preventing recurrence of VAs.

Although they happen infrequently, some rare complications might occur with these procedures that include clot formation at the burn site and/or a collection of blood in the sac that surrounds the heart.

PACING AND ELECTRIC SHOCK

Devices known as implantable cardioverter defibrillators (ICDs) have been shown to reduce the death rate in patients who have experienced VT/VF or in those who are survivors of sudden cardiac death. ICDs can detect VAs and deliver two kinds of therapy that help maintain normal sinus rhythm: antitachycardia pacing (ATP) and electric shock. When a patient has VT, ATP can overdrive the pacing of the heart and slow the heart rate down. When a patient has a sustained VT or experiences VF, ICDs can deliver a shock and terminate the rhythm. This shock is similar to the therapy that is delivered by external defibrillators carried by paramedics and hospitals.

ICDs are placed in patients who have weak hearts after heart attacks, who have previously suffered cardiac arrest, or who are known to have high risks of sudden cardiac death.

The Approach to the Patient with Syncope

Syncope is a syndrome consisting of a relatively short period of temporary and self-limited loss of consciousness caused by transient diminution of blood flow to the brain.[1, 2] The term derives from the Greek word *synkoptein*, which means "to cut short,"[3] and is used to classify a common clinical problem. The incidence of self-reported syncope was 6.2 per 1000 person-years in the Framingham study, with a cumulative incidence of 3% to 6% over 10 years.[4, 5] In selected patient populations, the lifetime prevalence of syncope could reach almost 50%. In the United States, 1 to 2 million patients are evaluated for syncope annually, making up 3% to 5% of emergency department visits, and 1% to 6% of urgent hospital admissions.[6]

Several guidelines have been published for the diagnostic approach to patients with syncope; however, they do not apply to every clinical situation encountered.[7, 8] The European Society of Cardiology[9] and the American College of Cardiology[10] have published detailed documents specifying a classification of the principal causes of syncope (**Table 26.1**). However, given the vast differential diagnosis, the varied therapies for patients presenting with syncope and the lack of consensus guidelines, a structured approach to the management of these patients was needed. To address this issue, we developed a standardized pathway which is comprehensive, yet simple, and provides guidelines for the

management of all patients presenting with syncope[11] (**Figure 26.1**).

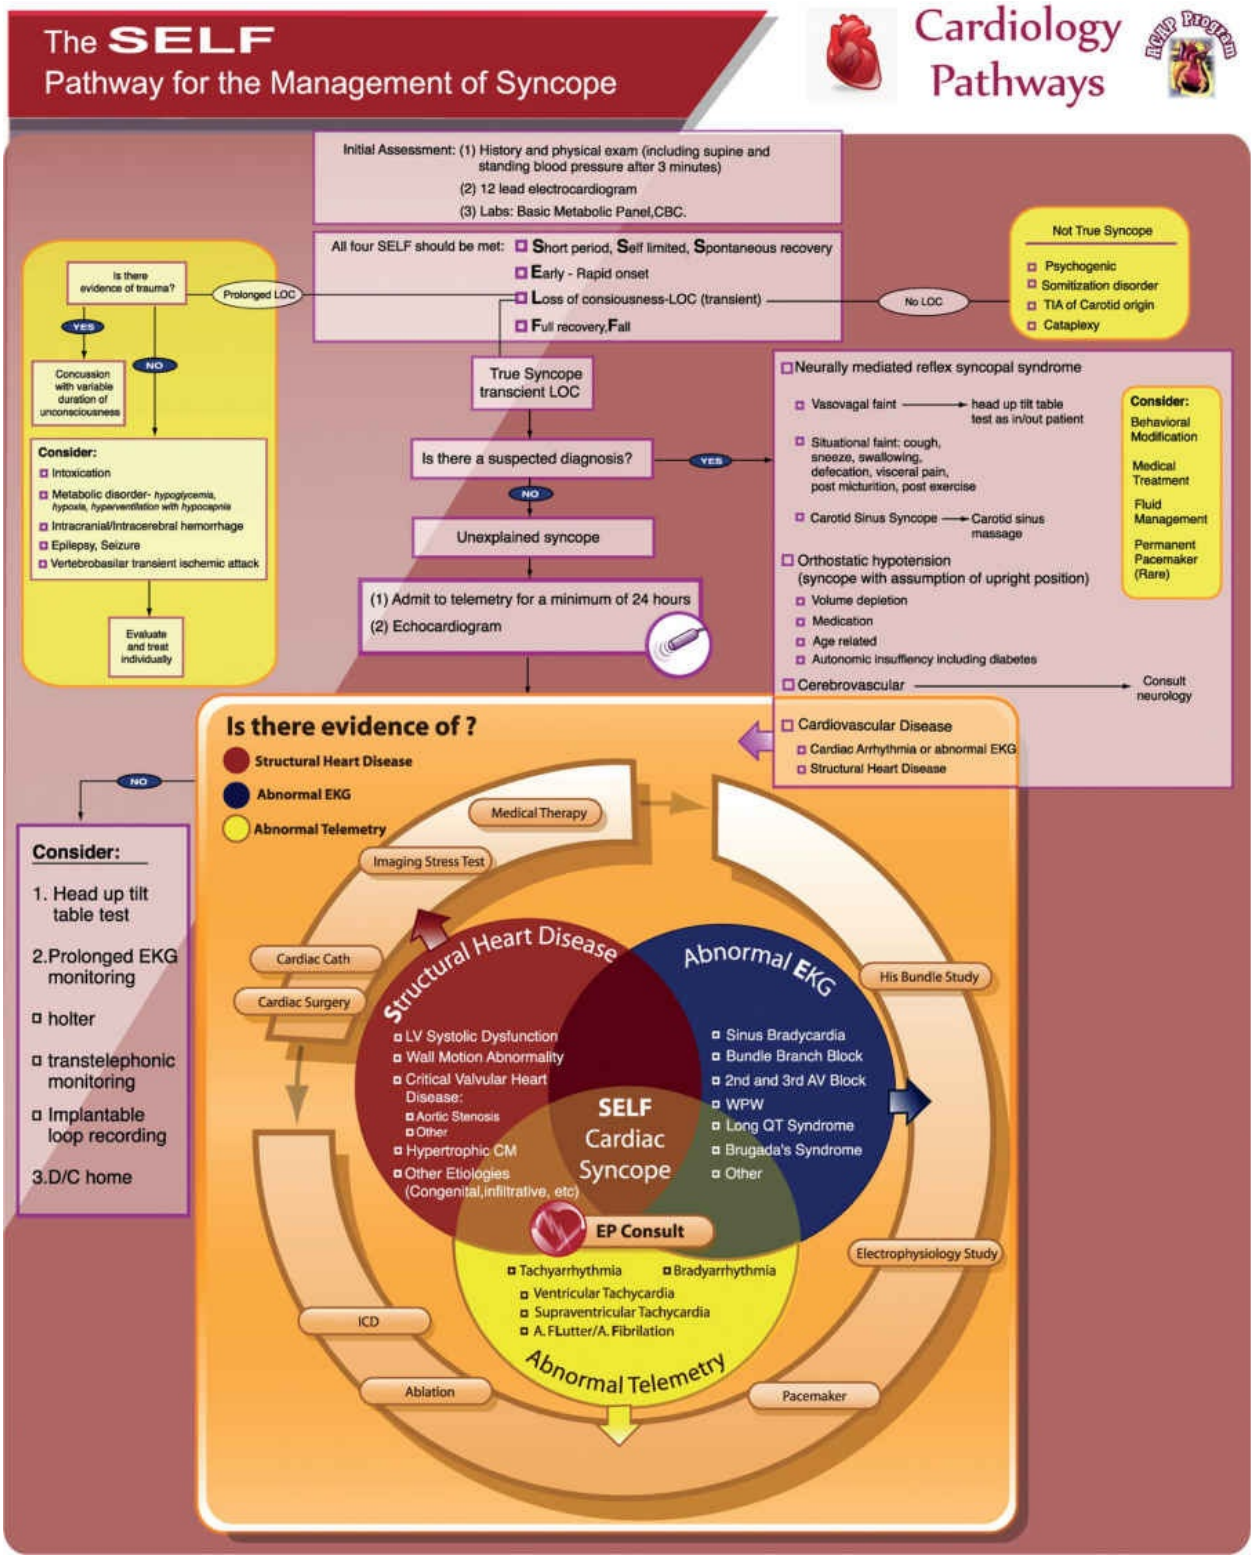

FIGURE 26.1 The SELF pathway for the management of syncope. CBC, complete blood count; ECG, electrocardiogram; EP, electrophysiologic; ICD. implantable cardioverter defibrillator; TIA, transient ischemic attack; WPW, Wolff–Parkinson–White.

TABLE 26.1 Classification of the Principle Causes of Syncope (Adapted from the European Society of Cardiology guidelines[9])

Reflex (neurally mediated) syncope

- Vasovagal:
  - Mediated by emotional distress: fear, pain, instrumentation, blood phobia
  - Mediated by orthostatic stress
- Situational:
  - Cough, sneeze
  - Gastrointestinal stimulation (swallow, defecation, visceral pain)
  - Micturition (post micturition)
  - Post exercise
  - Postprandial
- Carotid sinus syncope

Syncope due to orthostatic hypotension

- Primary autonomic failure:
  - Pure autonomic failure, Parkinson disease with autonomic failure, dementia
- Secondary autonomic failure:
  - Diabetes, amyloidosis, uremia, spinal cord injuries
- Drug-induced orthostatic hypotension:
  - Alcohol, vasodilators, diuretics, phenothiazine, antidepressants
- Volume depletion:
  - Hemorrhage, diarrhea, vomiting

Cardiac syncope (cardiovascular)

- Arrhythmia as primary cause:
  - Bradycardia:
    - Sinus node dysfunction (including bradycardia/tachycardia syndrome)
    - AV conduction system disease
    - Implanted device malfunction
  - Tachycardia:
    - Supraventricular
    - Ventricular (idiopathic, secondary to structural heart disease or to channelopathies)
  - Drug-induced bradycardia and tachyarrhythmias
- Structural disease:
    - Cardiac: cardiac valvular disease, acute myocardial infarction/ischemia
    - Hypertrophic cardiomyopathy, cardiac masses (atrial myxoma, tumors)
    - Pericardial disease/tamponade, congenital anomalies of coronary arteries, prosthetic valve dysfunction
- Others: pulmonary embolus, acute aortic dissection, pulmonary hypertension

AV, atrioventricular.

INITIAL ASSESSMENT OF A PATIENT WITH SYNCOPE

The initial assessment of a patient with syncope includes a meticulous and comprehensive medical history; incorporating eyewitness accounts can help determine the cause of syncope (**Table 26.2**).[7] Important questions to be asked in assessing patients with syncope are listed in **Table 26.3**. Orthostatic hypotension and autonomic dysfunction can be identified by measuring blood pressure and pulse rate in the upper and lower extremities in the supine and upright positions.

A 12-lead electrocardiogram (ECG) and basic laboratory tests, including a basic metabolic panel and complete blood count, should be performed in all patients with syncope.

TABLE 26.2 Initial Assessment of a Patient with Syncope

For every patient presenting with syncope:
- Detailed history
- Comprehensive physical examination
- Standard 12-lead ECG
- Basic labs (including basic metabolic panel, complete blood count)

For *all admitted patients (when appropriate):*
- Echocardiogram
- In-hospital 24-h telemetry monitoring (out-of-hospital telemetry may be applicable where available)
- Neurologic evaluation

ECG, electrocardiogram.

TABLE 26.3 Important Questions That Can Be Asked in Assessing Patients with Syncope

Questions about situations before syncope
- Position (supine, sitting, or standing)
- Activity (rest, change in posture, during or after exercise, during or immediately after urination, defecation, cough, or swallowing)
- Predisposing factors (crowded or warm places, prolonged standing, postprandial period) and precipitating events (fear, intense pain, neck movements)

Questions about onset of syncope
- Nausea, vomiting, abdominal discomfort, feeling of cold, sweating, pain in neck or shoulders, blurred vision, dizziness
- Trauma

Questions for eyewitness
- Way of falling (slumping forward, backward, or kneeling over), skin color (pallor, cyanosis, flushing), duration of loss of consciousness, breathing pattern (snoring), movements (seizure-like) and their duration, onset of movement in relation to fall, tongue biting

Questions after the episode
- Nausea, vomiting, sweating, feeling of cold, confusion, muscle aches, skin color, injury, chest pain, palpitations, urinary or fecal incontinence

Questions about past family and medical history
- Family history of sudden death, congenital arrhythmogenic heart disease or fainting
- Previous cardiac disease (coronary artery disease, heart failure)
- Neurologic history (epilepsy, narcolepsy)
- Metabolic disorders (diabetes, hypo or hyperthyroidism)
- Medication (antihypertensive, antianginal, antiarrhythmic, diuretics, and QT prolonging agents)
- In instance of recurrent syncope, information on recurrences such as the time from the first syncopal episode and on the number of spells

DEFINITION OF TRUE SYNCOPE

We use the acronym **SELF-1** which reflects the four criteria that should be met for an event to be considered true syncope. These criteria include

S—***S***hort period, self-limited, spontaneous recovery
E—***E***arly-rapid onset
L—***L***oss of consciousness—transient
F—***F***ull recovery—fall
Patients who did not lose consciousness are defined as “not true syncope.”

CLASSIFICATION OF SYNCOPE WHEN THERE IS A CERTAIN OR SUSPECTED DIAGNOSIS

These are certain disorders causing true syncope with a transient loss of consciousness:

1. *Reflex syncope:* Reflex syncope is a neurally mediated reflex syndrome[12] in the absence of structural heart disease. It refers to a reflex that, when triggered, gives rise to vasodilatation and bradycardia. These triggers include fear, pain, instrumentation, blood phobias, prolonged standing, crowded warm places, nausea, vomiting, and abdominal pain.
2. *Orthostatic hypotension syncope:* In orthostatic hypotension syncope, syncope occurs with assumption of an upright position. It can occur after starting of medications that can lead to hypotension, or can be due to an autonomic neuropathy.[13] Volume depletion is an important cause of orthostatic hypotension.
3. *Cardiovascular disease:* Structural heart disease can cause syncope when circulatory demands outweigh the impaired ability of the heart to increase its output. Cardiac arrhythmia can cause a decrease in cardiac output, which usually occurs irrespective of circulatory demands.

RISK STRATIFICATION FOR ADMISSION

One of the main dilemmas that face emergency department physicians is whether

to admit patients to the hospital or to refer them for an outpatient evaluation. Many risk assessment scores have been developed. These include the San Francisco Syncope Rule (SFSR),[14] the *Osservatorio Epidemiologico della Sincopenel Lazio* (OESIL),[15] and the Evaluation of Guidelines in Syncope Study (EGSYS).[16] In all of these risk scores, there is a consensus to admit patients with abnormal ECG, hypotension, heart failure, and anemia. In our standardized SELF pathway,[11] we use the **SELF-2** criteria to evaluate the need for admission. These criteria include

S—***S***tructural heart disease
E—abnormal ***E*CG**
L—atrial f***L***utter
F—atrial ***F***ibrillation

Admitted patients should be monitored for a minimum of 24 hours, which could potentially reveal bradyarrhythmias or tachyarrhythmias. The management of bradyarrhythmias may include an electrophysiologic testing with or without subsequent pacemaker implantation. Tachyarrhythmias include ventricular tachycardia, supraventricular tachycardia, atrial fibrillation, and atrial flutter. The treatment for these patients may include radiofrequency ablation or a device therapy with a pacemaker or an implantable cardioverter defibrillator (ICD). We recommend that all patients with a diagnosis of cardiac syncope be evaluated by an electrophysiologist during their hospitalization.

MANAGEMENT OF CARDIAC SYNCOPE

The major goal of the evaluation of syncope in patients with heart disease is to identify a potentially life-threatening diagnosis, particularly arrhythmias. Workup and management of these patients can include medical therapy, stress testing with cardiac imaging, cardiac catheterization, and possible revascularization with a percutaneous coronary intervention or cardiac surgery.

DIAGNOSTIC TOOLS THAT AID IN THE MANAGEMENT OF CARDIAC SYNCOPE

Electrocardiogram

Electrocardiography is essential in the workup of patients with unexplained syncope; however, it may only reveal a direct cause in 5% of patients. Abnormal

ECGs include the following findings: sinus bradycardia resulting from sinus node dysfunction or atrioventricular (AV) block resulting from AV node or His-Purkinje system dysfunction, pre-excitation patterns, a long/short QT-interval, Brugada syndrome, and characteristic ECG features of arrhythmogenic right ventricular dysplasia. Patients with unexplained bradycardia (heart rate of < 50 beats/min) should be evaluated for potential medical causes, specifically hypovolemia, hypoxia, acidosis, hypoglycemia, and hypothermia. Mild hyperkalemia when combined with a low *glomerular filtration rate* can also potentiate cardiac syncope in the elderly.[17] Hypothyroidism should also be considered in this age group.

Marked bradycardia can be the result of many medications such as β-blockers, calcium channel blockers, and digoxin, particularly in the presence of renal disease; this should be assessed and managed promptly. Lyme disease can be an unusual cause of heart block and needs to be considered in a patient from an endemic area. Finally, heart block can be a manifestation of myocardial infarction (MI), and patients with acute anterior wall MI and Mobitz type-II second-degree AV block, have a class IIa indication for a temporary transvenous pacing. This is in contrast to patients with inferior wall MI, where heart block can be a manifestation of the Bezold–Jarisch reflex (*this is a cardiovascular decompressor reflex involving a marked increase in vagal efferent discharge to the heart, elicited by stimulation of chemoreceptors, primarily in the left ventricle*). It causes a slowing of the heart beat and dilatation of the peripheral blood vessels with resultant lowering of the blood pressure. In patients with inferior wall MI, the heart block usually has a narrow escape rhythm and it usually resolves within a few days.

Echocardiography

Echocardiography should be performed in all patients with true syncope because it can identify patients with critical aortic stenosis, aortic dissection, severe pulmonary hypertension, acute pulmonary embolism, left atrial myxoma, and pericardial tamponade—situations that can lead to obstruction of flow in the heart and cause syncope.[18] These patients tend to be seriously ill and may require a lengthy intensive care stay. Echocardiography is considered the gold standard diagnostic tool for the finding of hypertrophic cardiomyopathy, segmental wall motion abnormalities suggestive of ischemic heart disease, and left ventricular systolic dysfunction.

Holter Monitoring

Holter monitoring enables correlation of symptoms with episodes of bradycardia; diagnostic clues are obtained in 50% to 70% of patients with bradycardia suspected on clinical grounds. However, events can be missed if symptoms do not occur in the 24- to 48-hour monitoring period. Holter monitoring can reveal sinus pauses, sinus arrest, second- or third-degree AV block, or severe sinus bradycardia with symptoms. Nocturnal asymptomatic bradycardia and pauses are not uncommon in the normal heart and are probably nondiagnostic. First-degree AV block or Mobitz type I AV block may be noted while patients are asleep owing to a high vagal tone. A long-monitored strip should be obtained because a 2:1 AV block is unlikely to persist. The other forms of AV block (Mobitz I or II) should then become apparent. Monitoring while the patient performs some form of exertion (eg, arm exercise, standing, and walking) may also help demonstrate the level of block. A block at the level of the AV node should improve with the adrenergic stimulation, but a block below the AV node in the His-Purkinje system may worsen as AV nodal conduction improves and increases the frequency of inputs to the His-Purkinje system.

Cardiac Event Monitoring

Cardiac event monitors, particularly those with auto-triggering capability, are widely used in the diagnosis of symptomatic and asymptomatic bradycardia and can be worn for up to 30 days. These devices can detect sinus pauses, sinus arrest, second- or third-degree AV block, or severe sinus bradycardia with symptoms[19]; however, their diagnostic yield for syncope and presyncope is only 6% to 25%.[20, 21]

Exercise Testing

A subnormal increase in heart rate after exercise (*chronotropic incompetence*) can be useful in diagnosing sick sinus syndrome. However, sensitivity and specificity are unclear and the results obtained may not be reproducible.[22] Exercise-induced AV block, even if asymptomatic, can be significant and suggests disease of the His-Purkinje system. Identifying symptoms due to sinus bradycardia can be difficult; nonetheless, exercise testing can be useful to help determine sinus node dysfunction as the cause of symptoms.

Electrophysiologic Testing

Electrophysiology testing is recommended when symptoms cannot be correlated clearly with a syncopal event and when significant bradyarrhythmias are suspected but cannot be diagnosed by noninvasive modalities. Sinus node dysfunction (*diagnosed as sinus node recovery time more than 1600 to 2000 milliseconds and/or corrected sinus node recovery time over 525 milliseconds*) serve only as an adjunct to clinical and noninvasive parameters because these tests are based on assumptions that limit their validity and clinical utility. There is little utility for electrophysiology testing in already-documented second- and third-degree AV block. Testing can be useful in patients with AV block and no clear symptom association; in patients with symptoms of bradycardia in whom AV block is suspected but not documented; and when the site of AV block cannot be determined reliably by surface tracings. His-ventricle interval of over *100 milliseconds* in a patient with bradycardia, even in the absence of symptoms, is a high-risk finding. Asymptomatic patients with Mobitz II AV block may benefit from this test to localize the site of block and to guide therapy. Overall, the role of electrophysiologic testing for bradycardia is limited, owing to low sensitivity and specificity. Positive findings may not be the reason for patient symptoms.[23]

MANAGEMENT OF PATIENTS WITH UNEXPLAINED SYNCOPE BUT WITH NO EVIDENCE OF CARDIAC ETIOLOGY

In the absence of underlying heart disease, syncope is not associated with excess mortality. Our recommendation for these patients is for early discharge, with consideration of head-up tilt-table testing and prolonged ECG monitoring (including Holter monitoring, trans-telephonic monitoring, and implantable loop recording).

OUTPATIENT DIAGNOSTIC TOOLS

Tilt-Table Testing

Tilt-table testing is used to evaluate the adequacy of the autonomic system, especially when there is suspicion of neurocardiogenic syncope.[24] The test can be performed either using head-upright tilting, which causes dependent venous pooling and thereby provokes the autonomic response, or by using adenosine to

facilitate the induction of vasovagal syncope. However, this test is limited by its poor sensitivity and the lack of uniformity.

Implantable Loop Monitor

Implantable loop recorders (ILRs) are subcutaneous monitoring devices that are typically implanted in the left parasternal or pectoral region and used for the detection of cardiac arrhythmias (**Figure 26.2**). The monitor has a loop memory and a battery life of 3 to 4 years. The current versions store an ECG that includes tracings recorded up to 40 minutes before and 2 minutes after activation by the patient and up to 7 hours of abnormal rhythm. If the patient activates the device when his consciousness returns, the probability of demonstrating a correlation between the ECG signals and the syncope is high. Krahn et al.[25] were among the first to describe a high diagnostic yield of the ILR in 16 patients with recurrent syncope. Extensive investigations including electrophysiology studies, treadmill testing, 48-hour ambulatory monitoring, and tilt-table testing failed to obtain a definite diagnosis in these patients. In 94% of the cases, recurrent syncope had occurred after implantation of the device revealing an arrhythmogenic cause in 60%. Consequently, in 40% of these patients, no arrhythmias were detected. In all patients with an arrhythmogenic cause, successful therapy was implemented. The Place of Reveal in the Care Pathway and Treatment of Patients with Unexplained Recurrent Syncope (*PICTURE*) registry,[26] a prospective, multicenter, observational study that followed up 570 patients with recurrent unexplained presyncope or syncope who received an ILR, showed that these patients were evaluated on average by three different specialists and underwent a median of 13 nondiagnostic tests (ranges between 9 and 20). Within the first year, syncope recurred in a third of the patients; the ILR provided a diagnosis in 78% of the patients, most commonly a cardiac etiology. In addition, the remote capability of these loops has revolutionized management for patients with syncope, as the patient is monitored continuously 24 hours a day, 7 days a week, and any abnormality is automatically transmitted through the Internet to the caring physician who then can take an action for management (**Figure 26.3**).

FIGURE 26.2 Example of commercially available implantable loop recorder; Reveal (Medtronic), Biomonitor II (Biotronik).

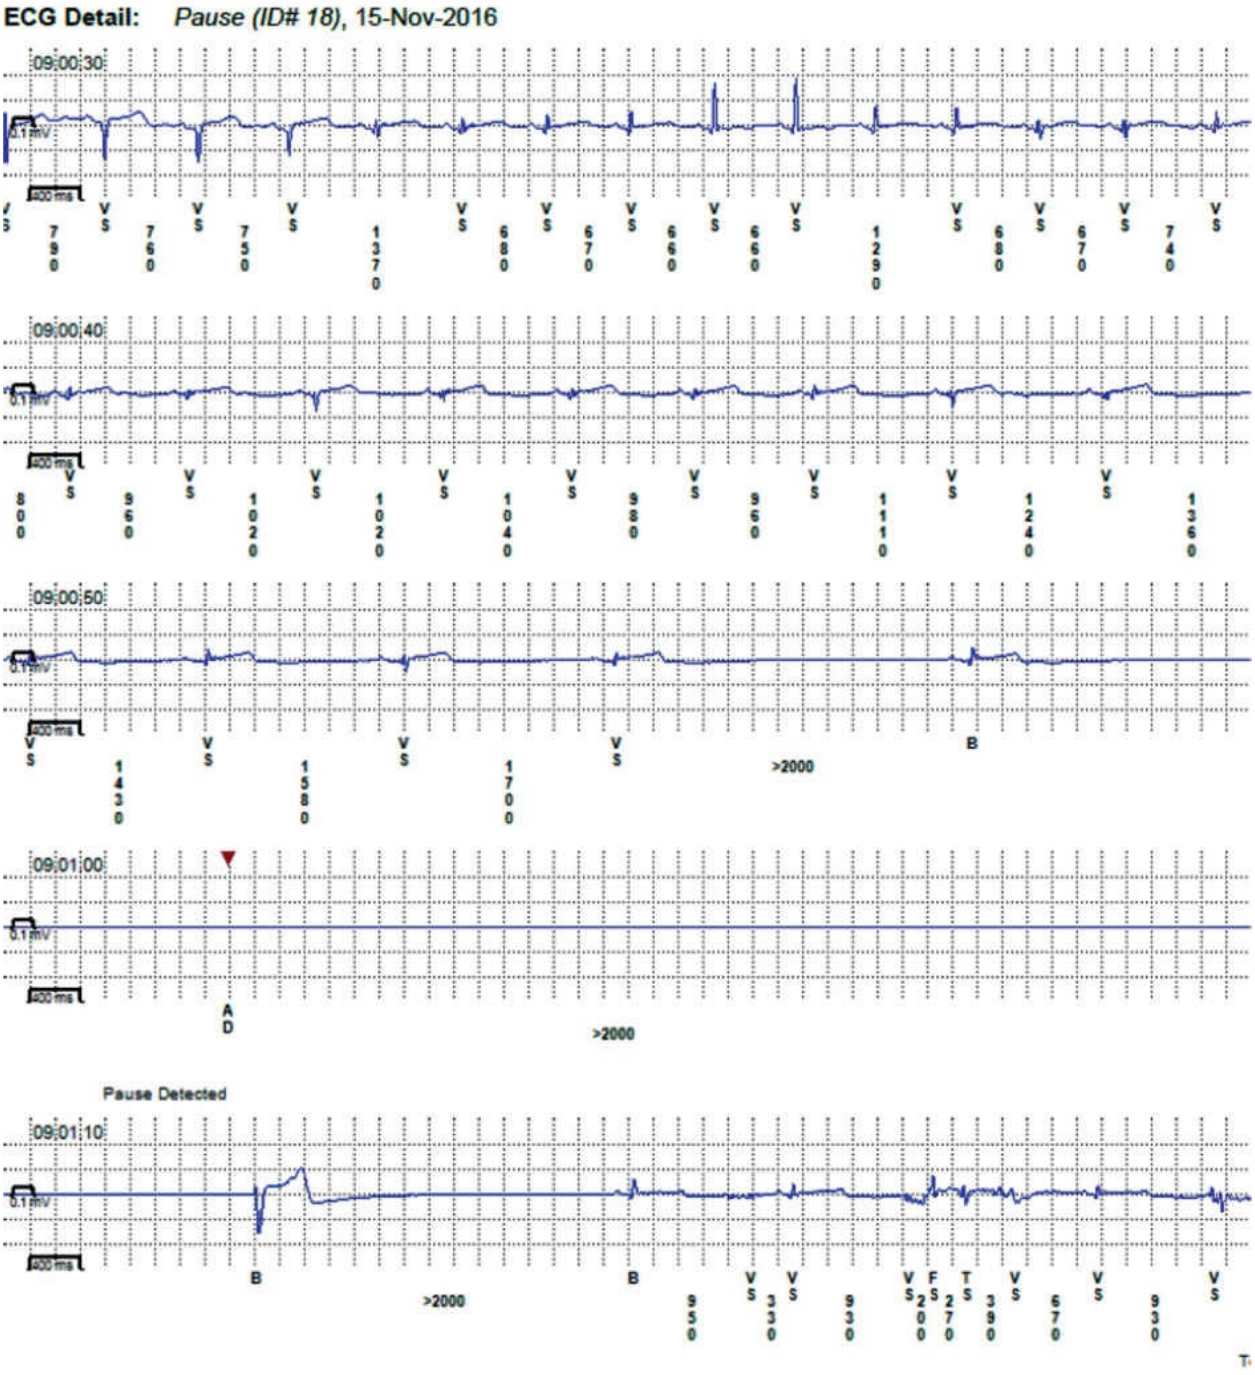

FIGURE 26.3 A long pause in a young patient who was mistakenly diagnosed with seizure for a long time. A long sinus pause of 12 seconds is seen and was transmitted by the implanted loop recorder.

Figure 26.3 demonstrates a long pause in a young patient who was mistakenly diagnosed as having seizure for a long time. A long sinus pause of 12 seconds is seen and was transmitted by the ILR.

Clinical validation of the SELF pathway from a database of 3100 patients who

were followed up longitudinally at our institution showed that this novel pathway is comprehensive, yet simple and provides effective risk stratification for patients presenting to the hospital with unexplained syncope and even with patients who could be missed by the standard risk stratification scores.[27] Also, implementing this pathway predicts the short- and long-term outcomes for those patients.[28]

CONCLUSION

In summary, having a standardized protocol for the management of patients with unexplained syncope should begin with a thorough medical history and a detailed physical examination including basic laboratory testing. High-risk patients (meeting SELF-2 criteria) should be admitted for at least 24-hour monitoring and echocardiography evaluation. Low-risk patients do not require hospital admission and they can be evaluated as outpatients with tilt-table testing or with a prolonged monitoring including ILR.

Patient and Family Information for: THE APPROACH TO THE PATIENT WITH SYNCOPE

Syncope (sin-co-pee) is a medical term used to describe a temporary loss of consciousness that is caused by a sudden lack of blood flow to the brain. Syncope is commonly called fainting or “passing out.” If an individual is about to faint, he or she will feel dizzy, lightheaded, or nauseated and his field of vision may “white out” or “black out.” The skin may be cold and clammy. After fainting, an individual may be unconscious for a short time, but will eventually return to his baseline. Syncope can occur in otherwise healthy people and affects all age groups, but it is more common among the elderly. It can occur in many situations, such as standing up fast, working or playing hard especially in hot weather, breathing too fast (called hyperventilating), being upset, during long standing, during coughing, urinating, or all other situations that get in the way of the flow of oxygen to the brain.

There are several types of syncope. Vasovagal syncope usually has an easily identifiable triggering event such as emotional stress, trauma, pain, the sight of blood, or prolonged standing. Carotid sinus syncope is a medical term used for a situation in which there is pressure on the carotid artery in the neck and this may occur after turning the head, while shaving, or even when wearing a tight collar. Situational syncope is the term used when syncope occurs with urination, defecation, coughing, or as a result of gastrointestinal stimulation. Syncope is not usually a primary sign of a neurologic disorder, but it may indicate an increased risk for some neurologic disorders such as Parkinson disease, diabetic neuropathy, and other types of neuropathy. Certain medicines can cause fainting, including diuretics, calcium channel blockers, angiotensin-converting enzyme inhibitors, nitrates, antipsychotic medications, antihistamines, levodopa, and

narcotics. Alcohol, cocaine, and marijuana can also cause fainting.

INITIAL EVALUATION OF A PATIENT WITH SYNCOPE

A doctor would like to know what exactly happened when the person fainted and all the details about how he or she felt. Symptoms vary from patient to patient; however, the most common symptoms are light headedness, dizziness, and nausea. Some people will feel very hot and clammy, sweaty, and will complain of visual and hearing disturbances. Information about current medications and preexisting medical conditions such as diabetes, heart disease, or psychiatric illness can help pinpoint the cause of syncope. There are certain tests and procedures that might be ordered to help guide management. These tests might lead the physician to a definitive diagnosis and would guide treatment.

PHYSICAL EXAMINATION AND LABORATORY TESTING

The doctor will compare the heart rate and blood pressure while the patient is lying down with the heart rate and blood pressure in a standing position. The doctor will listen to the heart beats for abnormal sounds that can be present in conditions such as narrowing of the aortic valve. The doctor will listen for *bruit* in the sides of the neck to rule out narrowing of the neck arteries (called carotid arteries). The doctor may firmly massage the carotid artery while the heart rate is closely monitored with an ECG. The heart's response to this maneuver can give clues to the cause of the syncope.

Laboratory tests may identify low red blood cell count (*anemia)* or other abnormalities including thyroid abnormalities and electrolyte imbalances (sodium, potassium, glucose, and magnesium).

ADDITIONAL DIAGNOSTIC TESTS

ELECTROCARDIOGRAM

An ECG will be performed on arrival. Sticky pads will be placed on the chest, arms, and legs, and will be connected to a recording device with long, thin cables. This is not a painful procedure and there is no risk involved. The ECG

provides a picture of the electrical activity throughout the heart muscle. A normal ECG does not necessarily mean that syncope is not caused by a heart rhythm problem. Heart rhythm problems are often brief, intermittent, and may not be present at the moment when the ECG is performed.

TILT-TABLE TESTING

Tilt-table testing is a noninvasive test performed to diagnose recurrent or unexplained light headedness or fainting spells. The test can define whether a patient has a condition called vasovagal syncope, in which there is malfunction of nerves that causes the heart to slow down and the blood pressure to drop with a change in position. The test takes about an hour to complete, and in preparation for it the patient would be asked not to eat or drink for 5 hours before the test including holding the medications. The patient will be asked to lie down on a special flat table. A nurse will insert an intravenous line in a vein in the arm. ECG electrodes will be attached to the chest to monitor the heart rate and the rhythm during the procedure. A blood pressure cuff will be placed on the arm. Safety straps will secure the patient to the table. After obtaining the blood pressure and ECG while lying on the table, the table will be tilted to a 60-degree angle. The patient will be standing on a footboard at the bottom of the table. The blood pressure and ECG will be monitored as the patient remains tilted up for 20 to 30 minutes. The patient will be instructed to tell the nurse if any symptoms, such as feeling sweaty, nauseous, lightheaded, or cold and clammy, are experienced. If the blood pressure starts to fall, the patient will be returned to the flat position. A doctor will be in the room during the entire procedure. If no symptoms are experienced, the table will be lowered to the flat position and the test will be terminated. On occasion, a short-acting medication may be given intravenously to assist in the test. The patient may need to rest for several minutes after the test before going home. A nurse will stay with the patient until the conditions for discharge are met.

ELECTROPHYSIOLOGY STUDY

An electrophysiology study is an invasive procedure performed in the hospital setting. Sedative medications are given before the procedure, but the patient may stay awake during the procedure. The physician uses a local anesthetic to numb a small area over the blood vessels (veins), usually in the groin, and then threads small catheters (thin electrical wires) through the blood vessels into the heart

using X-ray (fluoroscopic) guidance. Once in the heart, precise measurements of the heart's electrical function can be obtained. This procedure typically lasts 60 to 90 minutes.

IMPLANTABLE LOOP RECORDER

With ILR, the heart rate and rhythm can be monitored for a long time. The device has a memory and a battery that can last between 3 and 4 years. The ILR is implanted under the skin, usually in the upper left chest area. It stores events automatically according to programmed criteria, or it can be activated by the patient. The ILR may be useful if symptoms are sporadic and an arrhythmia is suspected, and other forms of testing were negative or inconclusive.

THERAPIES

PERMANENT PACEMAKER

A pacemaker is a small device, the size of a silver dollar, which is implanted under the skin just below the collarbone. The device is connected to wires threaded into the heart muscle, where they emit impulses that help regulate the heartbeat. Pacemakers are occasionally recommended if the syncope is caused by a very slow heartbeat, carotid sinus hypersensitivity, or by heart block. A pacemaker battery typically lasts 8 to 12 years and would require replacement after that time period with a simple procedure.

IMPLANTABLE CARDIOVERTER DEFIBRILLATOR

Certain dangerous conditions arise when irregular heartbeats originate from the lower chamber of the heart (ventricles), particularly in patients with a very weak heart. These patients may benefit from an ICD. Similar to a pacemaker, the ICD is typically implanted under the skin just below the collarbone. The device is connected to wires threaded into the heart muscle. However, in addition to its pacemaker capability, the ICD has the ability to detect fatal arrhythmias and deliver a high-energy electrical shock to the heart, which in turn will terminate the arrhythmia and return the heart to normal rhythm.

Basic Approach to Pacemaker and ICD Interrogation

INTRODUCTION

Cardiovascular implantable electronic device (CIED) is a term that encompasses pacemakers (PPM) for bradyarrhythmia treatment, implantable cardioverter defibrillators (ICD) for tachyarrhythmia management, and cardiac resynchronization therapy (CRT) devices for systolic dysfunction with conduction delays.[1] Cardiac arrhythmias have an estimated prevalence of 14.4 million patients in the United States, and they account for approximately 40,700 deaths annually.[2] As the indications for device placement continue to expand, these devices have evolved from a treatment of last resort to a first-line therapy to an increasing number of patients.[3] Approximately 1.6 million patients in the United States and Europe receive a PPM or ICD each year. Therefore, it is imperative that all physicians understand the operational basics of these devices and be able to retrieve and manage essential data when needed particularly in the critical care hospital setting.

A summary of the most updated pacing and defibrillator indications are seen in **Figures 27.1 and 27.2**.

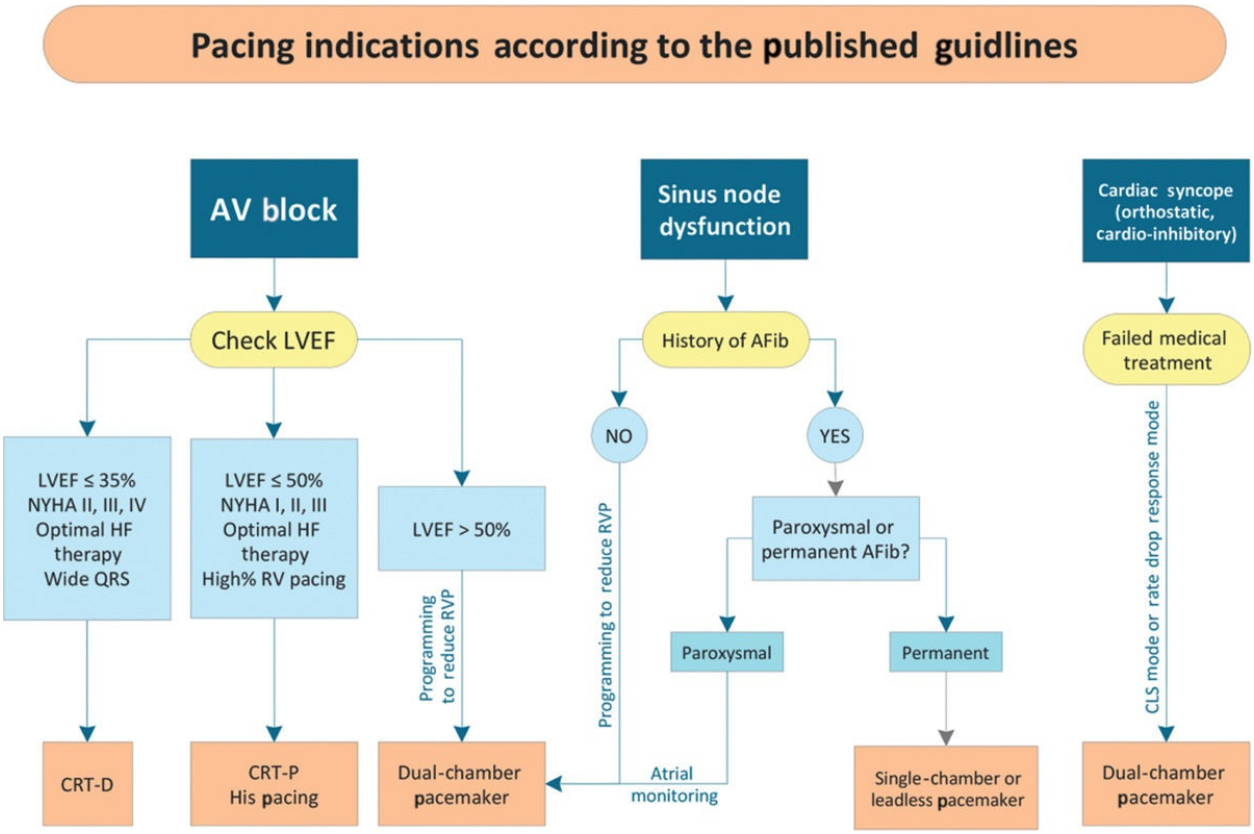

FIGURE 27.1 Class I pacing indications according to the published guidelines. AFib: atrial fibrillation; CLS: closed-loop system; HF: heart failure; LVEF: left ventricular ejection fraction; NYHA: New York Heart Association Class; RVP: right ventricular pacing.

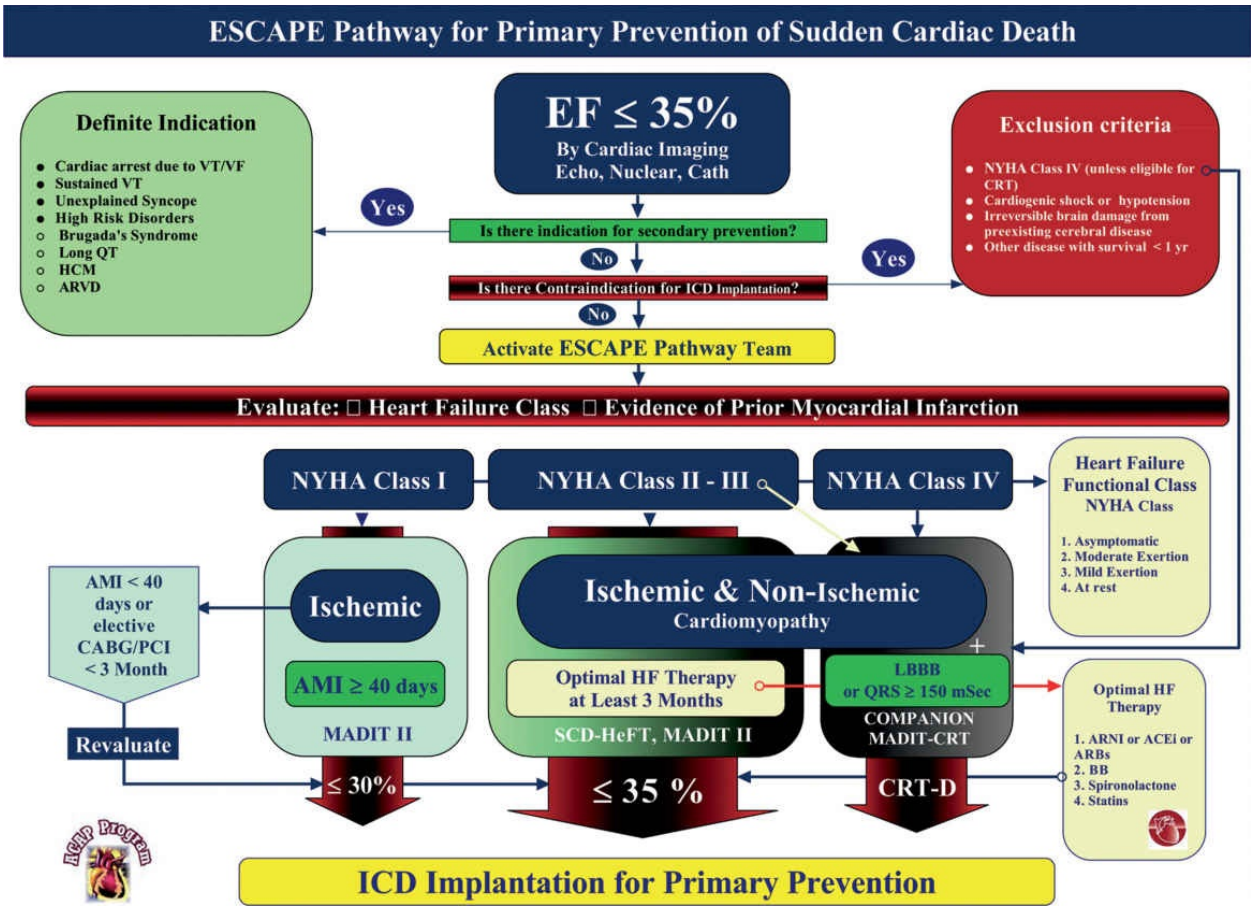

FIGURE 27.2 The ESCAPE pathway for prevention of sudden cardiac death.

EVALUATION OF CIED ON ADMISSION AND REASON FOR CONSULTATION

When called for a device evaluation consultation, it is imperative to identify the reason for the consult. This may include the evaluation for device functionality such as appropriate pacing and sensing, particularly if there is any question of device malfunction, or to identify arrhythmias like atrial fibrillation or ventricular tachycardia, or to rule out device-delivered therapy like antitachycardia therapy or firing. Device interrogation could also be appropriate after surgery, especially if device parameters were changed or cautery was used close to the device site.

IDENTIFICATION OF THE DEVICE MAKER

The first step is to identify the manufacturer of the device and the type of the device in order to utilize the proper programmer for the interrogation. Most patients carry a device identification card with them (**Figure 27.3**). If the card is not available, searching the patients' electronic medical records or manufacturers' patient registries can be of help. **Table 27.1** has the phone numbers for major device companies.

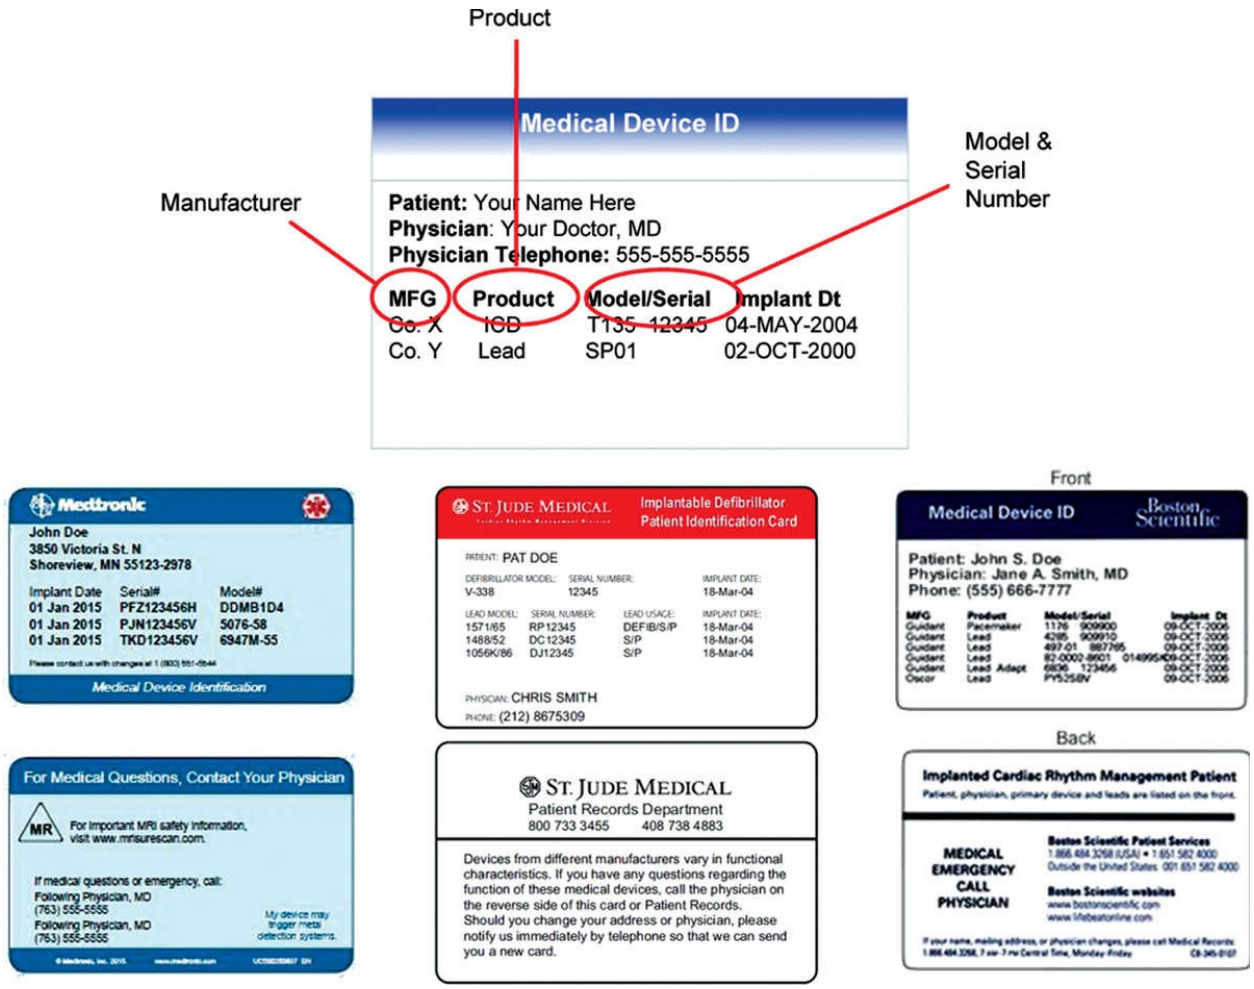

FIGURE 27.3 Patient identification cards examples from different manufacturers.

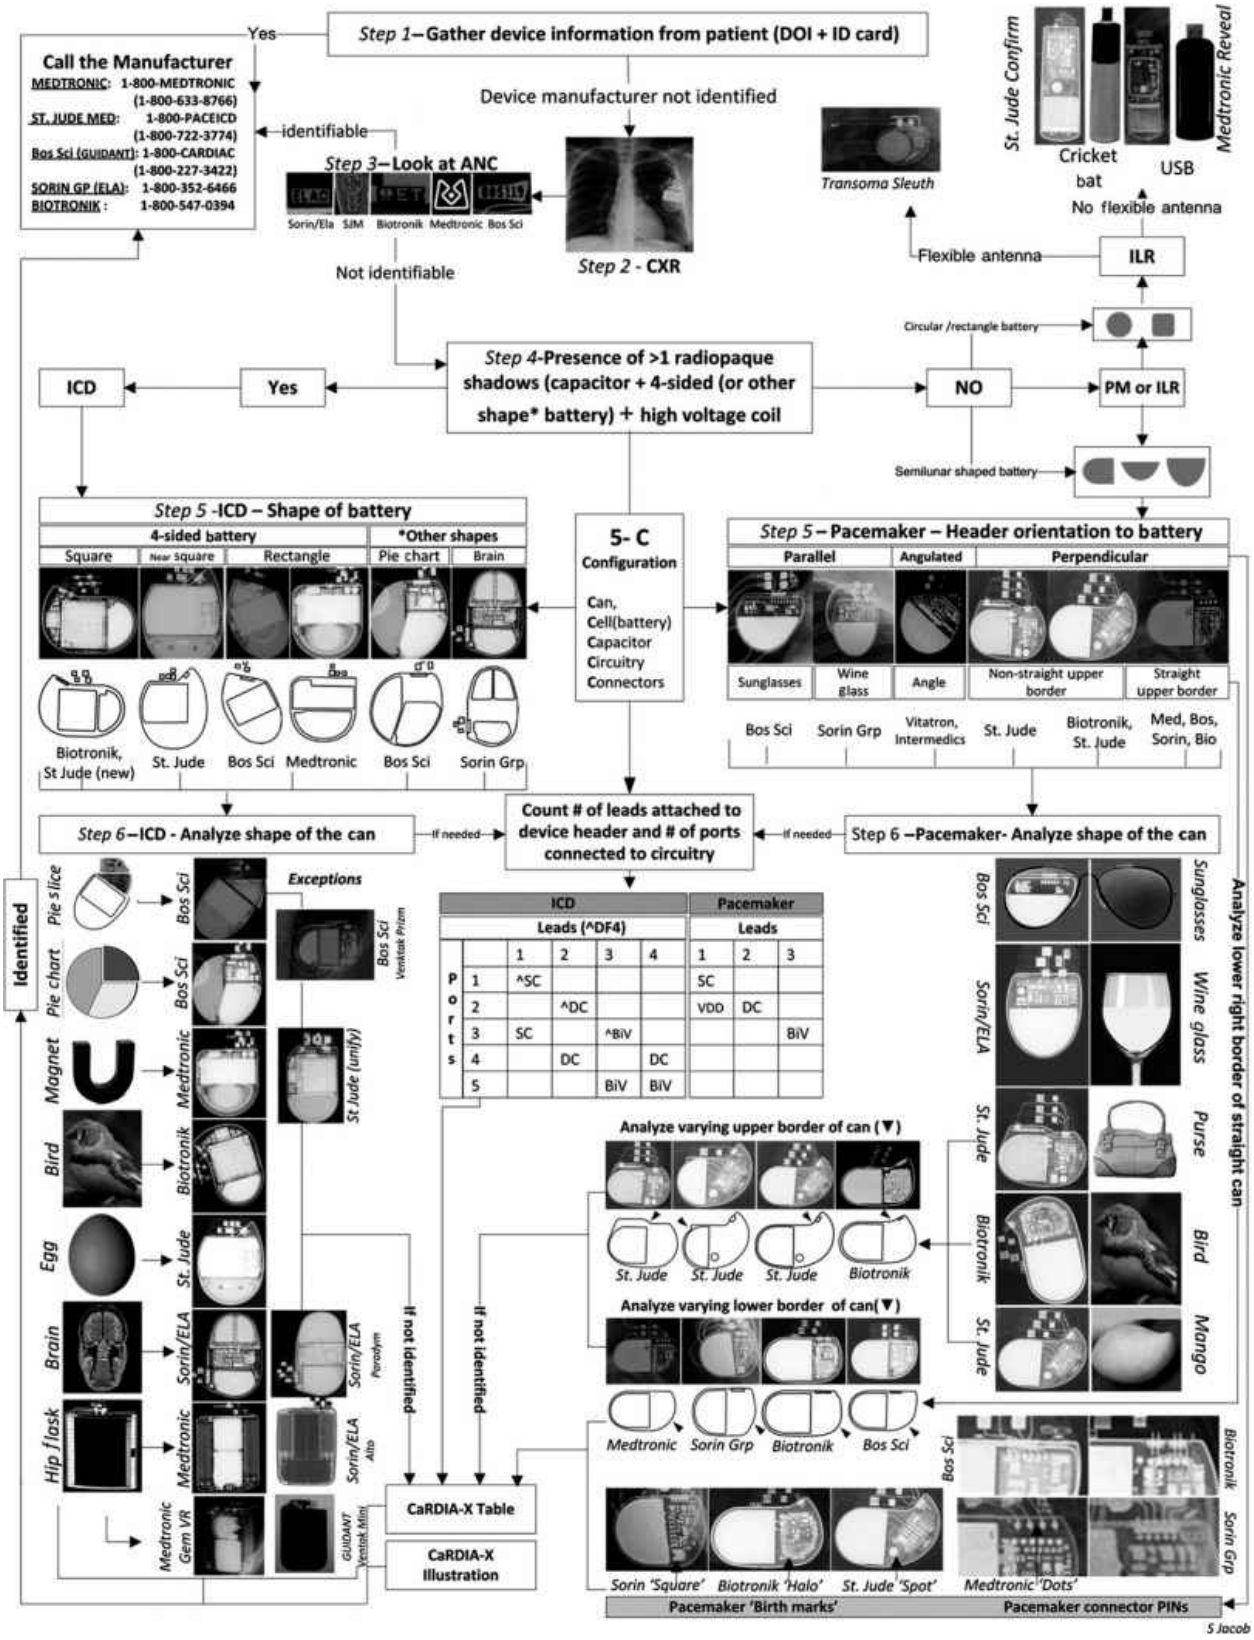
TABLE 27.1 Contact Number for Major Device Companies

Company	Contact Number
Biotronik	(800) 547-0394
Boston Scientific (Cameron, CPI, Guidant)	(800) CARDIAC
Medtronic (Vitatron)	(800) MEDTRONic
Sorin (ELA)	(877) 663-7674
St. Jude Medical (Pacesetter, Telectronics, Ventritex)	(800) SHOCKVF

In those instances where none of the above are available, or if the patient is

incoherent or intubated, one can identify the device from the CaRDIA-X algorithm (**Figure 27.4**) published by Jacob et al.[4] or the CRMD Finder app (**Figure 27.5**), which is based on the same source. This guide is unique as it utilizes a stepwise algorithm including device-specific radiopaque alphanumeric codes (ANC), device type (ICD, pacemaker, or ILR), the shape of the device, and the battery as well as the device leads. Currently in the United States, five major device manufacturers can be identified: Medtronic, St. Jude Medical, Boston Scientific, Biotronik, and Sorin.



Step 1– Gather device information from patient (DOI + ID card)

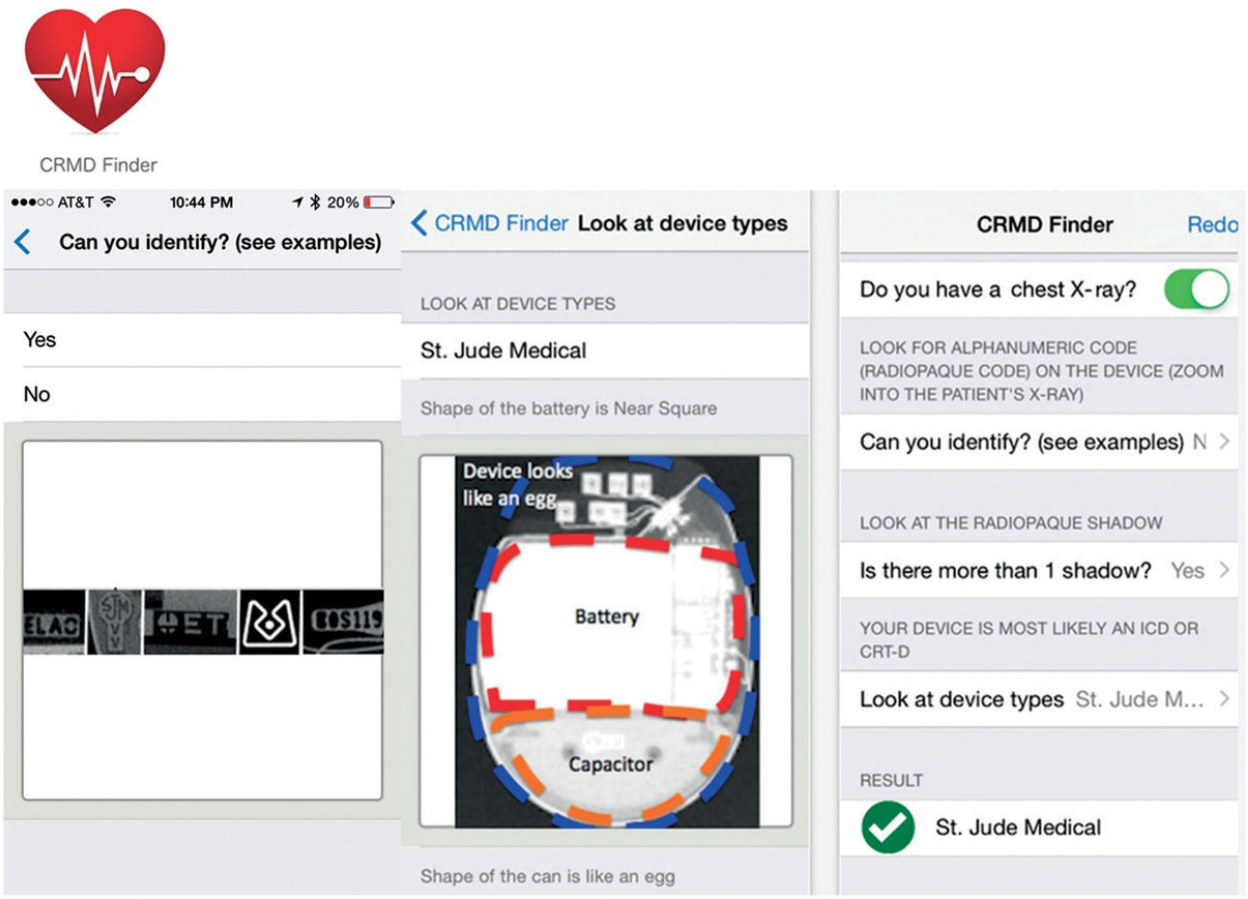

FIGURE 27.5 CRMD Finder app.

Once the device maker is identified, one should examine the x-ray for the following:

1. Identify device type: ILR, pacemaker, or ICD
2. If ILR, identify either Medtronic Linq, Transoma, or Biotronik (BioMonitor–II)
3. Identify if the device is a single, dual-chamber, or biventricular one
4. Epicardial leads or arrays
5. Recognize any further potential malfunctions like lead fractures, conductor externalization (Riata leads), dislodgment, twiddler syndrome, or any abandoned leads

After identifying the device manufacturer, the next step is to use the appropriate programmer and link it to the device by placing the wand at the device site. **Figure 27.6** illustrates the programmers of the five major device companies in the United States.

FIGURE 27.6 The programmers of the 5 major device manufacturers: Medtronic, St. Jude Medical, Boston Scientific, Biotronik, and Sorin.

ANALYZING THE PATIENTS' RHYTHM

1. Obtain presenting rhythm strip:
   - **a.** After the summary screen has been displayed, press the "25 mm" button on the programmer to print a presenting rhythm strip.
   - **b.** Press the "0 mm" button to stop printing.

c. This step will identify if the patient is (atrial, ventricular, or biventricular) paced.

2. Obtain underlying rhythm strip:

a. In this step, one must go to the Temporary Pacing Parameters screen. The Temporary Parameters screen allows you to change any and all pacing parameters in a temporary setting—without affecting any permanent settings.

b. Suggested Settings to view intrinsic rhythm: Mode: DDI; Rate: 30 bpm (if tolerated by patient); AV Delay: 300 ms (400 ms, if allowed); "DDI will allow backup ventricular pacing if needed, and allow you to see heart block by separating Atrial and Ventricular pacing function—and AV Delays greater than 300 ms. You must assess patient's ability to tolerate lower rate change prior to running test."

c. Run paper (press the 25-mm button) to document underlying rhythm. Press the "0 mm" button to stop printing.

INTERROGATION AND REPORTING

After placing the wand over the device, interrogation will either automatically begin or need to be initiated by pressing the interrogate button, depending on the programmer. At the end of the chapter, the appendix depicts examples from the initial page of each programmer with description of their most important functions.

BATTERY LIFE

Most device manufacturer will have a battery management screen that displays a battery "gauge," voltage graph, voltage, and/or estimated longevity (**Figure 27.7**). There are few abbreviations that one needs to be familiar with when evaluating a battery status; ***>ERI*** (elective replacement indicator), ***RRT*** (recommended replacement time), ***EOS*** (end of service), and ***EOL*** (end of life). The general rule of thumb is that ***ERI*** is about three months before reaching *EOL*.

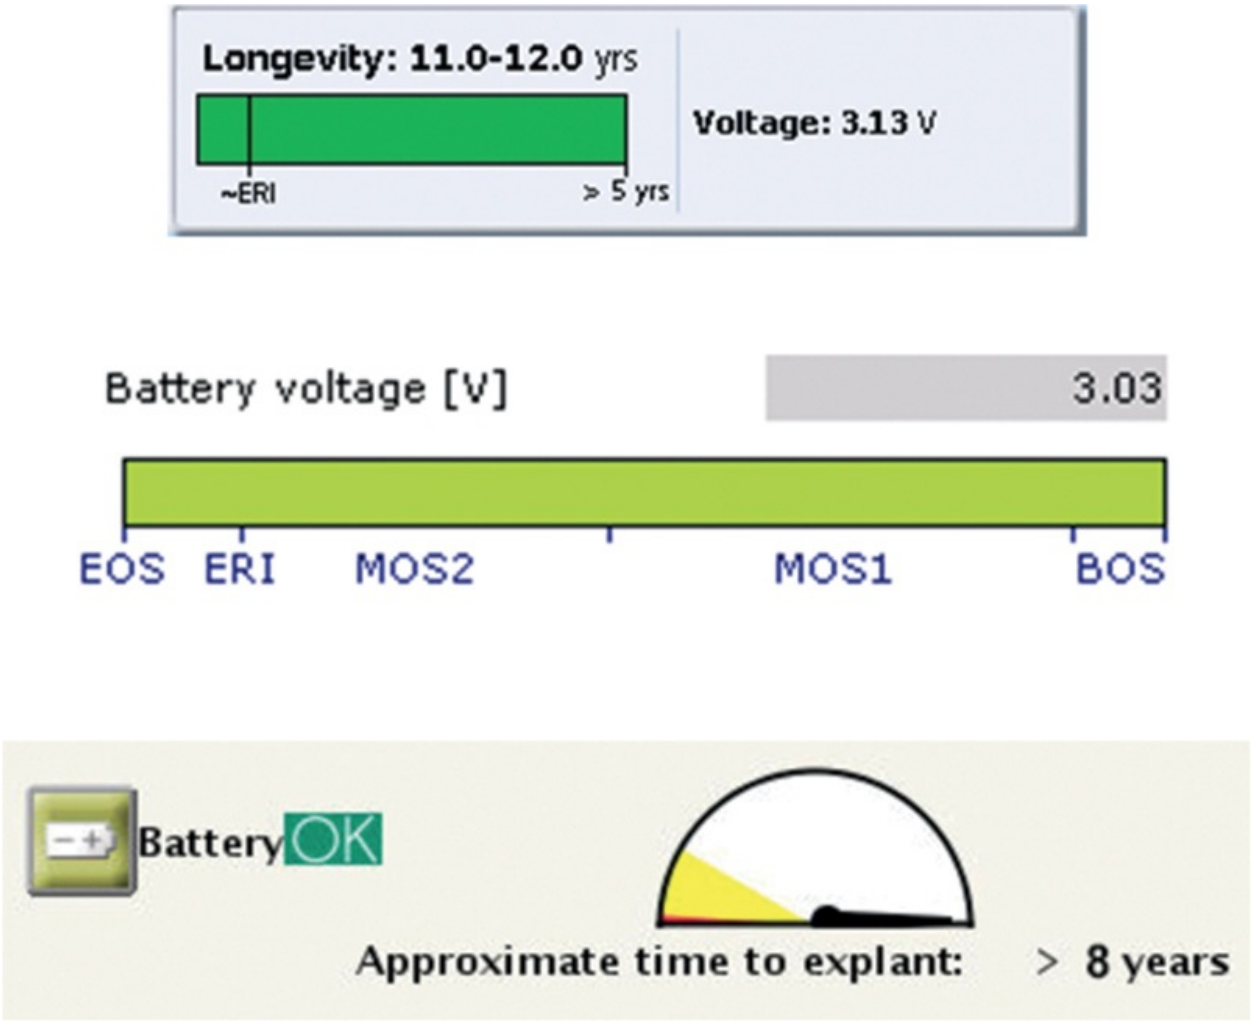

FIGURE 27.7 Examples of battery status, graphs, and gauges.

What to Do When ERI is Reached?

In Brady Devices (Pacemakers)

- Use all the available data, voltage, battery impedance, longevity predictors.
- Manufacturers can give accurate predictions with access to telemetry data.
- Look at follow-up intervals as ERI approaches; consider use of remote monitoring and consider changes at ERI (VVI).
- Have access to technical data; be aware of safety margins and errors in prediction.

In Tachy Devices (Defibrillators)

- Use remote monitoring to manage battery Middle of Life 2 (MOL2) → ERI period.
- Ensure patient is familiar with alarms/vibrations indicating ERI.
- Check advisories for changes in ERI point of some devices.
- Longer charge time usually indicates battery depletion; a charge time in excess of 20 seconds is abnormal.

SENSING TESTING

The ability of a pacemaker lead to sense an intrinsic electrical signal of the chamber that it is placed in is measured in millivolts (mV). The programmed sensitivity setting indicates the minimum intracardiac signal that will be sensed (seen) by the pacemaker to initiate the pacemaker response (inhibited or triggered). It is important to evaluate the trend of sensing of the chamber overtime rather than the actual sensed value of the (P) or (R) waves (**Figure 27.8**). There are certain conditions that can affect the sensing of a lead, such as dislodgment, chronic fibrosis at the lead tip, metabolic changes, and myocardial infarction.

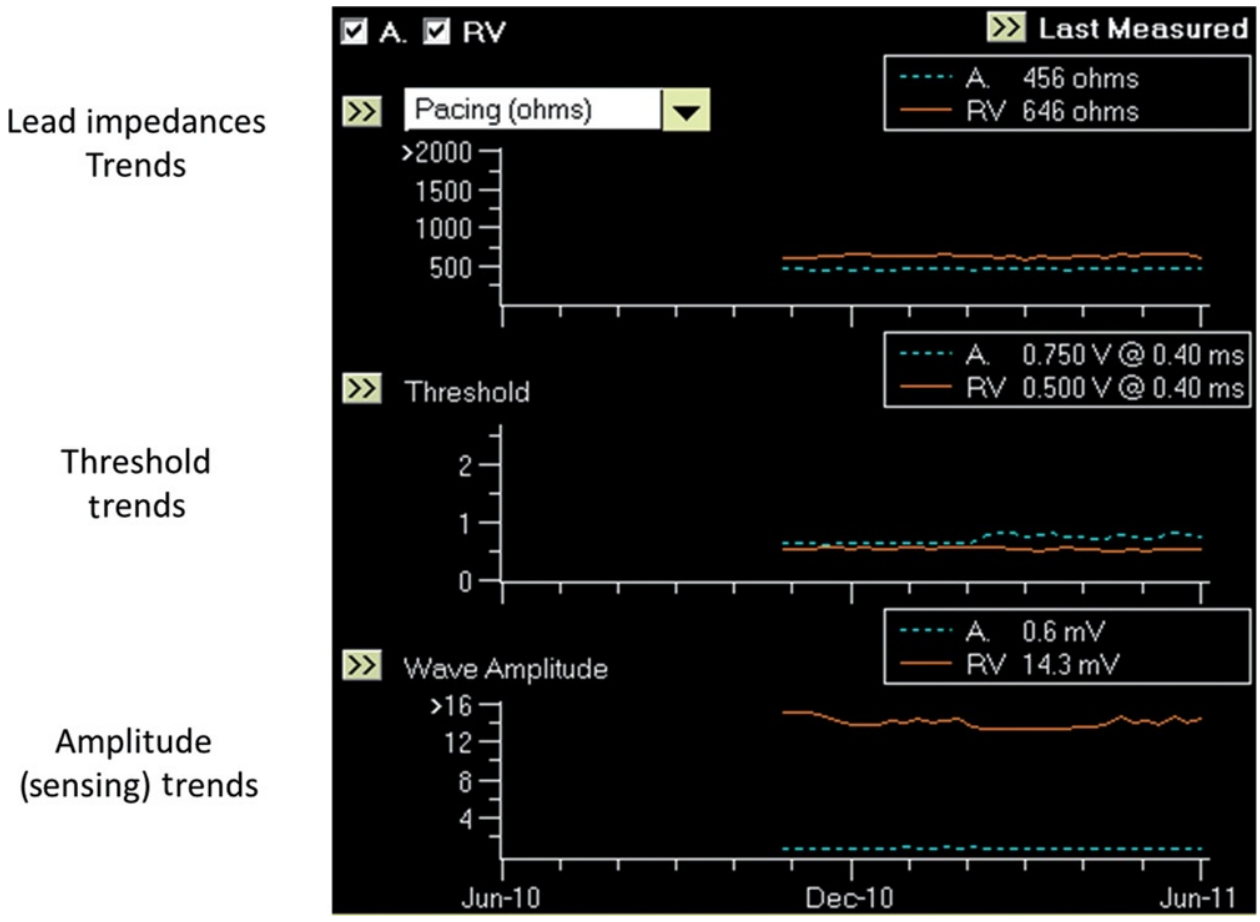

FIGURE 27.8 Example of a Medtronic device sensing, thresholds, and lead impedance trends.

We Recommend

- To evaluate the sensing of a chamber, adjust the Brady parameters if necessary to maintain proper device performance. (For pacemakers, the sensed P and R waves should be at least twice the sensitivity setting.)
- Suggested settings: Mode: DDI; Rate: 30 bpm; AV Delay: 300 ms (400 ms if allowed)

"DDI will allow backup ventricular pacing if needed, and allow you to see heart block by separating Atrial and Ventricular pacing function—and AV Delays greater than 300 ms. DDI is not available on some older pacemakers. Use DDD or VVI on these devices as appropriate."

It is very important to test the sensing of the device to avoid potential problems that could result from undersensing or oversensing.

- **Undersensing** occurs when the pacemaker fails to sense native cardiac

activity, which results in asynchronous pacing. This could be due to increased stimulation threshold at electrode site (exit block), poor lead contact, new bundle branch block, or programming problems.

- **Oversensing** occurs when electrical signal are inappropriately recognized as native cardiac activity and pacing is inhibited. These inappropriate signals may be large P or T waves, skeletal muscle activity, or lead contact problems.

LEAD IMPEDANCE TESTING

Lead impedance describes the sum of all resistance to current flow. It is a function of the characteristics of the conductor (wire), the electrode (tip), and the myocardium; thus, checking the lead impedances gives us information about the lead integrity. Normal lead impedance ranges from *300 to 1000* ohms (some leads have higher impedances by design). Similar to sensing amplitude, the steadiness of lead impedances overtime is more important than the number obtained (**Figure 27.8**). Lead impedance values can change as a result of lead fractures or insulation breakage.

- *Low-impedance* conditions, mainly insulation break exposing the lead wire to body fluids, which have low resistance, allows current to drain through the insulation break to the path of least resistance, leading to potential loss of capture and more rapid battery depletion.
- *High-impedance* conditions, mainly due to fractured conductor, are a result of not enough current flow from the device battery to the tissues. Other reason for high impedance is the lead not having properly seated in the pacemaker header.

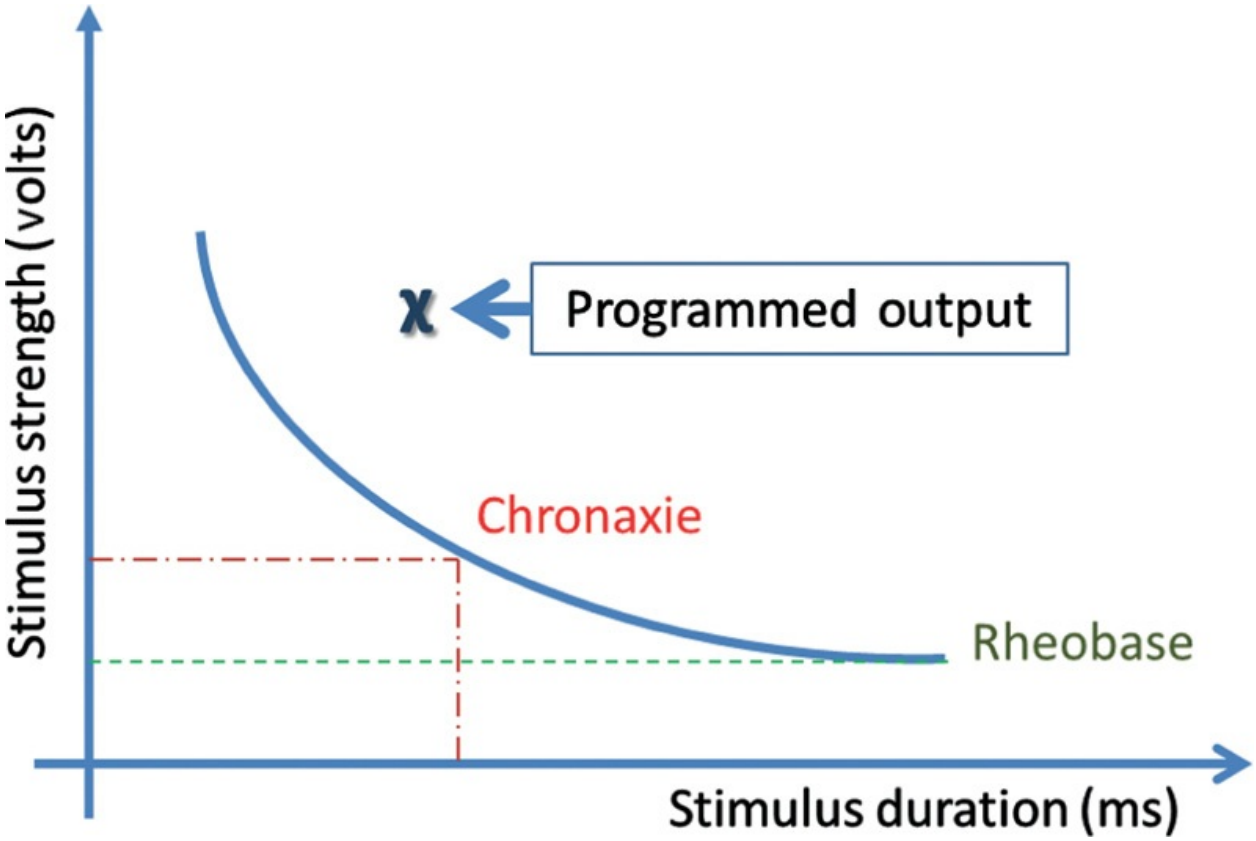
All devices perform automatic lead impedances in the course of the initial device interrogation. However, ICDs require you to test the pacing leads separately from the shocking lead impedance. Should you need to test impedance manually, look for the appropriate tabs on the Impedance screen to select which leads you are testing (ie, RA, RV, LV, and shocking lead impedance).

THRESHOLD (CAPTURE) TESTING

Capture threshold is the minimum electrical stimulus needed to consistently capture the myocardium. There are few factors that affect pacing thresholds. First, lead maturation as a result of the fibrotic capsule that develops around the tip of the lead can cause a slight rise in the threshold. Second, the newer leads

that are steroid eluted reduce the inflammatory process and allow the leads to maintain low chronic thresholds.

Myocardial capture is a function of amplitude, which is the strength of the impulse expressed in volts as it must be large enough to depolarize the heart and the pulse width, which is the duration of the current flow expressed in milliseconds. This is done using the strength–duration curve,[5] which illustrates the relationship of amplitude and pulse width as seen in **Figure 27.9**; any combination of pulse width and voltage on or above the curve will result in capture.



- The rheobase is the least voltage needed to depolarize the heart at infinite pulse duration.
- The chronaxie is the shortest pulse duration required to depolarize the heart at a voltage twice the rheobase.
- (X) is the programmed output equal 2x chronaxie.

FIGURE 27.9 The strength–duration curve.

By accurately determining capture thresholds, we can assure adequate safety

margins, keeping in mind that thresholds may differ in acute or chronic pacing systems and could slightly fluctuate on a daily basis.

The ultimate goal in performing capture threshold testing is to ensure patient safety and appropriate device performance as well as extend the service life of the battery if possible. A common output value is ≤2.5 V, but we should always maintain an adequate safety margin.

- To perform threshold testing, find the appropriate tab and adjust Brady parameters if necessary to maintain proper device performance.
  - Perform test using Voltage Testing criteria (fixed Pulse Width). Starting voltage should be approximately three-fourths of the programmed Amplitude setting.
